PART 3

Behavioral Time Discounting

INTRODUCTION TO PART 3

Decisions that have a time dimension are central to many economic problems facing firms, governments, and individuals, although our focus will primarily be on individual decisions. Examples of individual decisions that are considered in Part 3 include the amount and type of savings; timing of retirement; investment in liquid versus illiquid assets; purchase of an annual, or pay-as-you-go health club membership. There is a long history of economic thought devoted to analyzing the complex issues associated with temporal choices. The classical economists focused squarely on the psychological foundations of such decisions (Frederick et al., 2002; Loewenstein, 2007, Ch. 3).

The basic idea in most modern theories of time preference is the following. Delaying a reward can increase its size, e.g., due to the accrual of interest payments. However, delayed outcomes are less valuable to impatient individuals. This trade-off determines the optimal temporal choice of individuals. The basic unit of analysis is preferences over sets of outcome–time pairs, or sequences of consumption levels. The subset of models that are separable in time and outcome and allow for impatience is sometimes called *discounted utility* (DU) models.

Chapter 9 considers a special member of the class of DU models, the *exponential discounted utility* (EDU) model. The EDU model owes its origin entirely to a technical question: it is the unique member of the DU class that gives rise to *time consistent preferences*. However, the psychological foundations of the EDU model are fairly weak. A single parameter, the *discount rate*, captures all relevant psychological considerations. It is no surprise that a very large literature on the anomalies of the EDU model has sprung up. This would not have surprised its inventor (Samuelson, 1937), who argued that there was no presumption that individuals maximized a functional of the form proposed by EDU. Furthermore, he also cautioned against using it for welfare analysis. But his caveats were either forgotten or ignored.

Among the anomalies of the EDU model that we consider, are the following. The most serious is the rejection of constant discounting (*common difference effect*). In a famous example of the common difference effect that violates constant discounting, Richard Thaler proposed the following example. Most people would prefer one apple today to two apples tomorrow, but they prefer two apples in 51 days to one apple in 50 days. Clearly, if the discount rate were constant across any interval of fixed size, as in the EDU model, we would not observe this preference reversal.

Observed discount rates increase as a future reward is brought forward towards the present. Experiments on animals and humans show that discount rates are hyperbolically declining when plotted against time (Ainslie, 1975, 1992). This has led to the development of the *hyperbolic discounting utility model*. Losses are more salient than gains, in the sense that they are discounted less (*the sign effect*), greater magnitudes are discounted less than smaller ones (*the magnitude effect*), discounting over an interval depends on how that interval is subdivided (*subadditive discounting*), choices may appear to be cyclical (*apparent intransitivity of preferences*), and choices may depend on the *spread and shape of the consumption sequence* for two consumption sequences that have the same exponentially discounted utility.

Chapter 10 considers alternative explanations of the anomalies of the EDU model, and exposit a range of behavioral models of time discounting that have emerged to explain these anomalies. We explain the *magnitude effect* and the *sign effect* by putting appropriate restrictions on the

utility function. We also introduce the class of *simple increasing elasticity* utility functions that are able to operationalize these restrictions.

The explanation of the *common difference effect* has been a major endeavor in behavioral time discounting. *Hyperbolic discounting* is the leading explanation. Individuals who use hyperbolic discounting are more impatient over shorter horizons, giving rise to present-biased preferences. We consider the *general hyperbolic discounting function*, as well as the *quasi-hyperbolic* or (β, δ) form, that is popular in applied work. *Subadditivity*, the finding that splitting a time interval into subintervals reduces the extent of discounting is our second explanation of the common difference effect. We also consider the *Read–Scholten discount function*, which is one of the most flexible discount functions available. Finally, we consider the role of uncertainty and the interaction of risk preferences and time preferences in explaining the common difference effect.

In any choice between outcome–time pairs, there are two *attributes*, *outcome* and *time*. We consider three different attribute-based models. These are *the model of vague time preferences*, *the model of similarity relations*, and *the trade-off model of intertemporal choice*. These models typically prescribe a hierarchical choice among outcome–time pairs, based on primary, secondary, or tertiary criteria. However, the choices may be quite sensitive to the order in which the criteria are applied. These models will need further developments, but they can potentially explain phenomena such as the common difference effect, and apparent intransitivity of preferences.

The final model that we consider is a general theory of time discounting, the *reference time theory*, RT. RT combines generalized hyperbolic discounting with subadditive discounting. It also introduces a reference time in addition to a reference outcome level. RT can explain all the main anomalies of the EDU model and can incorporate recent developments in time discounting such as uncertainty and attribute models. Preferences in RT are complete and transitive, yet it is able to explain apparent intransitivity of preferences by shifts in the reference point for time.

While Chapter 10 highlights the present bias of humans, Chapter 11 considers applications of present-biased preferences, with particular emphasis on models of quasi-hyperbolic discounting. In the presence of self-control problems, it becomes critical to specify one's degree of awareness about future self-control problems. The convenient device of humans as *multiple selves* postulates any individual as a succession of multiple selves, one for each time period. All selves exhibit hyperbolic discounting (i.e., relatively greater impatience at shorter horizons), but may not be fully aware of their future self-control problems. The current self may then wish to take some costly actions that can mitigate the self-control problems of future selves. For instance, tying one's resources in illiquid assets to reduce the chances that future selves will splurge on consumption.

We begin by considering applications in *behavioral macroeconomics*. In particular, we consider a model of life-cycle consumption with hyperbolic discounting and limited awareness of future self-control problems. We derive a *behavioral Euler equation*. This framework can address several puzzles in the neoclassical model. These include the following. Why does consumption track income so closely? Why do individuals undersave for retirement? Why is there a sharp drop in consumption at retirement? Why do individuals hold illiquid assets and credit card debt simultaneously? Why have national savings rates been declining? Why is marginal propensity to consume asset-specific? Why is high consumption variability not associated with high consumption growth? We also clarify the relation between intertemporal substitution and risk.

Retirement is another important decision that falls in the domain of present-biased preferences. The present bias of future selves might induce them to retire too early relative to the preference of the current self, who is more patient at longer horizons. One solution is for the current self to withhold savings for the future selves that can potentially reduce the benefits of early retirement. However, should this not work, then the current self might be resigned to save too much

in order to counteract the early retirement decision of future selves. Employment legislation such as a mandatory retirement age may be an important commitment device that solves the problem of the current selves.

Chapter 11 also presents several other applications. We consider features of temporal reward and cost profiles that lead, in the presence of limited awareness, to *procrastination*, or *preproportionation*. Market competition between present-biased agents may reduce procrastination for low costs of procrastination, but give rise to multiple equilibria for intermediate costs. Current selves may, through harmful addictions such as smoking, create a negative externality for their own future selves. Sales taxes on cigarettes may then lead to an improvement in the welfare of individuals by reducing the stock of harmful habits. This is a variant of the standard *Pigouvian taxes* argument.

Consider *investment goods* that have a current cost and a future benefit such as gym memberships. Current selves may be willing to pay high gym membership fees in return for a lower price/visit in the future if they underestimate their future self-control problems. Indeed, in this case, it is optimal for the firm to charge a unit price below marginal costs. In the opposite case of *leisure goods*, there are current benefits, but future costs (e.g., credit card borrowing). We show that in this case, the opposite result holds, i.e., price exceeds marginal costs. In each of these cases, the variation in the price serves as a commitment device to reduce future self-control problems. We close the chapter with a range of applications of hyperbolic discounting that illustrate the rich domain of problems to which it can be applied.

CHAPTER 9

The Evidence on Temporal Human Choice

9.1 Introduction

In this chapter, we discuss the *discounted utility model* (DU) with particular emphasis on its most popular variant in economics, the *exponential discounted utility model* (EDU). Our main aim is to outline the basics of EDU and consider the empirical evidence on the model.

In Section 9.2 we discuss the DU model, due to Samuelson (1937), and define the concepts of *discount function*, *discount rate*, and *discount factor* in discrete and in continuous time. The DU model is often too general for making precise predictions. For instance, choices under the DU model could be *time inconsistent*, i.e., decision makers may wish to alter previously made plans. In the class of DU models, the EDU model uniquely gives *time consistent choices* (Strotz, 1956). EDU is the dominant model of time discounting in economics and it has proved extremely useful for many purposes. However, its psychological foundations are fairly limited. In fact, a single parameter, the *discount rate*, encapsulates all psychological considerations. Samuelson (1937, p. 156) himself realized that it is completely arbitrary to assume that individuals behave in accordance with the EDU model and he also expressed reservations about its use for welfare comparisons (p. 161): “In conclusion, any connection between utility as discussed here and any welfare concept is disavowed.” Despite Samuelson’s own reservations, the EDU model is still the dominant model used in welfare comparisons in economics.

Section 9.3 discusses the EDU model and outlines its properties. These properties include *time-invariant instantaneous utility function*, *consumption independence*, *independence of discounting from consumption*, *constant discounting*, *stationarity of preferences*, and *time consistency*. Section 9.3.2 shows that EDU is the unique functional form that gives rise to time consistent choices in the class of DU models (Strotz, 1956). Section 9.3.3 gives a brief note on the assumption of constant marginal utility in eliciting the discount rate under EDU. Section 9.3.4 briefly outlines the axiomatic foundations of EDU (Fishburn and Rubinstein, 1982).

Section 9.4 discusses the *anomalies* of EDU. Think of an anomaly as violating an axiom or an implication of EDU.¹ The anomalies of the EDU model pose a serious challenge to its continued use. Under EDU, the discount rate between two consecutive time periods (assuming discrete

¹ We begin Section 9.4 with a small note on the distinction between *refutations* (rejection of the axioms of EDU) and *anomalies* (rejection of the auxiliary assumptions of EDU). But in line with the practice in this literature, we use the term anomaly for both.

time), remains the same, irrespective of the location of these periods. This derives from the *stationarity axiom* of EDU (Fishburn and Rubinstein, 1982). However, this assumption is routinely violated. A violation of the stationarity axiom is known as the *common difference effect*. Consider the following well-known example.

Example 9.1 (*Thaler's (1981) apples example*): It is reasonable to assume that a person will prefer one apple today to two apples tomorrow. The same person will, however, in all likelihood, prefer two apples in 51 days to one apple in 50 days.

Such a pattern of preference reversals is not consistent with the assumption of stationarity in EDU. Stationarity implies that the discount rate is constant. By contrast, the evidence shows that when the time delay before a future reward is received is short, the per-period discount rate is high and the decision maker appears very impatient. However, when the time delay is long, the per-period discount rate is low and the decision maker appears more patient. This can explain the puzzle in Example 9.1. In particular, not only is the discount rate declining with delay, evidence has been given to show that it declines in a hyperbolic manner (Ainslie, 1975, 1992); this holds for humans and close primate relatives such as chimps. In this case, the decision maker is said to be using *hyperbolic discounting*. This is a leading explanation for *present-biased preferences* that is able to explain a wide range of important phenomena.

Other anomalies of EDU that we consider in Section 9.4, include the following. (i) *Sign effect*: Losses are discounted less as compared to gains; thus, losses are temporally more salient than gains (Thaler, 1981). (ii) *Magnitude effect*: Outcomes of greater magnitudes are discounted less than smaller ones. Thus, elicited discount rates for larger outcomes are lower (Thaler, 1981). (iii) *Subadditive discounting*: Discounting over an interval depends on how that interval is sub divided (Read, 2001). Sub dividing an interval reduces salience. (iv) *Intransitivity of preferences or cyclical preferences*: Time preferences often appear intransitive (Roelofsma and Read, 2000), although controlling for reference point, context, or frame, such intransitivities may be reduced (Gintis, 2009). (v) *Shapes of consumption profile*: Under EDU, if two consumption profiles have identical discounted utility, then their shape is irrelevant. However, keeping discounted utility fixed, individuals may have a preference for rising consumption profiles (Loewenstein and Sicherman, 1991), and individuals may violate *consumption independence*² (Loewenstein and Prelec, 1992; Mayer and Russell, 2005).

9.2 The discounted utility model

Suppose that time $t \in \Gamma = \{0, 1, 2, \dots, T\}$, where $0 < T \leq \infty$. Denote by $c_t \in C \subset R$, the real-valued consumption of an individual at time t ; c_t could be a scalar, or a vector that denotes a bundle of consumption goods. Let $\mathbf{c}_0 = (c_0, c_1, \dots, c_T)$ denote the *temporal consumption profile* of the individual at time $t = 0$. Denote by $C \subset R^{T+1}$, the set of all bounded consumption profiles. One popular utility representation of preferences over C is the *discounted utility model* (DU). It requires the existence of a utility function $U : C \rightarrow \mathbb{R}$ such that,

$$U(\mathbf{c}_0) = \sum_{j=0}^T D(j)u(c_j); \mathbf{c}_0 \in C. \quad (9.1)$$

² Under EDU, if one compares two consumption profiles and if at any time t , the outcomes in both profiles are identical then one may ignore the outcome at t in a comparison of the two profiles (consumption independence).

In DU models, $u : C \rightarrow \mathbb{R}$ is typically a time-invariant, bounded, instantaneous utility function (sometimes referred to as *felicity*). $D(t)$ is known as the *discount function* at time t . The continuous time analogue of (9.1) over the time interval $[0, T]$ can be found by letting each time period be divided into n equal intervals and letting $n \rightarrow \infty$. In this case,

$$U(c_0) = \int_{t=0}^T D(t)u(c_t) dt; c_0 \in C. \quad (9.2)$$

We assume that $D : [0, T] \rightarrow (0, 1]$.

The discount function, D , is often assumed to be decreasing in order to reflect *impatience*, i.e., individuals prefer to receive the same reward earlier rather than later. Hence, $D(\tau') > D(\tau)$ for $\tau' < \tau$. When D is differentiable, then, in the continuous case, impatience is captured by the condition $D'(t) < 0$.³ Further, it is also standard practice to normalize $D(0) = 1$.

Definition 9.1 (*Discount Rate*): The discount rate or the “pure rate of time preference” is defined as the rate at which the discount function declines over time. In discrete time, the discount rate at time t , $\theta(t)$, is given by

$$\theta(t) = - \left[\frac{D(t) - D(t-1)}{D(t)} \right]; t \in \Gamma. \quad (9.3)$$

Dividing each time period into n equal intervals and letting $n \rightarrow \infty$, the discount rate in continuous time is given by

$$\theta(t) = - \frac{D'(t)}{D(t)}; t \in [0, T]. \quad (9.4)$$

The multiplication by -1 ensures that $\theta(t) > 0$, thus, its magnitude reflects how fast the discount function falls; $\theta(t)$ has no units. A higher discount rate implies a greater impatience to consume in the current period.⁴

9.3 The exponential discounted utility model (EDU)

A special case of the DU model is the *exponential discounted utility* model (EDU). In the discrete case, the discount function under EDU takes the form

$$D(t) = \frac{1}{(1 + \theta)^t} = \delta^t, \text{ where } \delta = \frac{1}{1 + \theta}, t \in \Gamma, \theta \in \mathbb{R}, \quad (9.5)$$

where θ is the discount rate over a single time period (in many cases, we refer to it as the annual discount rate) and δ is known as the *discount factor*. $\theta > 0$ captures the common assumption of impatience in the EDU model. Letting each time period be divided into n equal intervals, the continuous analogue of (9.5) can be found using $\lim_{n \rightarrow \infty} \left(1 + \frac{\theta}{n}\right)^{nt}$, which gives⁵

³ In the special case of $D'(t) = 0$ the individual gives equal weight to the instantaneous utility at each date, i.e., there is no impatience.

⁴ The *discount factor* is defined as $\phi(t) = \left[\frac{D(t)}{D(t-1)} \right]$, where $t \in \Gamma$.

⁵ Here we use the well-known formula $e = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{n}\right)^n$.

$$D(t) = e^{-\theta t}. \quad (9.6)$$

Under EDU, using (9.1), (9.5), the intertemporal utility of the consumer when time is discrete, is given by

$$U(c_0) = \sum_{t=0}^T \delta^t u(c_t), \text{ where } \delta = \frac{1}{1+\theta}, c_0 \in C. \quad (9.7)$$

Using (9.2), (9.6), the continuous time analogue of (9.7) is

$$U(c_0) = \int_{t=0}^T e^{-\theta t} u(c_t) dt. \quad (9.8)$$

Our choice between the discrete and the continuous case will be based largely on pedagogical grounds, and on the norm in a particular literature in order to ease transition from the book to the relevant papers.

The EDU model allows one to compare distinct consumption profiles. So, for instance, under EDU, the discrete consumption profile $c^a = (c_0^a, c_1^a, \dots, c_T^a)$ is preferred to the consumption profile $c^b = (c_0^b, c_1^b, \dots, c_T^b)$, if and only if, $U(c^a) \geq U(c^b)$, or

$$\sum_{t=0}^T \delta^t u(c_t^a) \geq \sum_{t=0}^T \delta^t u(c_t^b). \quad (9.9)$$

If the individual is asked to choose a consumption profile from some set $A \subset C$, then it is assumed that he chooses the consumption profile $c^* \in A$ that satisfies the condition $U(c^*) \geq U(c')$ for all $c' \in A$.

9.3.1 *Some salient properties of the EDU model*

We now highlight some salient properties of the EDU model and introduce some of the terminology used in the debates on the EDU model.

1. *Stationarity of the felicity:* The instantaneous utility, u , is time invariant.
2. *Consumption independence:* Using (9.7), the marginal rate of substitution between two consecutive time periods t and $t+1$ is $\frac{-u'(c_t)}{\delta u'(c_{t+1})}$, which is independent of any other time periods.
3. *Utility independence:* The numerical values associated with distinct consumption profiles determine which is preferred (e.g., see (9.9)). Provided that the numerical value is identical, there is no preference associated with particular shapes of the consumption profiles, for instance, increasing, or decreasing.
4. *Independence of discounting from consumption:* The same discount function applies to an individual's consumption of any two distinct goods (say, oranges and apples). Furthermore, EDU does not specify how and why the discount function could depend on individual-specific traits or behaviors.
5. *Constant discounting:* The discount rate between any two consecutive periods is θ , irrespective of the time-location of the periods. This is known as the assumption of constant discounting.
6. *Diminishing marginal utility and positivity of the discount factor:* For most practical purposes, it is assumed that the felicity, u , is concave (diminishing marginal utility), and the

discount rate is strictly positive, i.e., $\theta > 0$ (this reflects impatience). Diminishing marginal utility creates an incentive to postpone consumption; however, a positive discount rate pushes in the direction of current consumption. This is the basic trade-off in EDU that determines the choice between current and future consumption.

7. *Stationarity and the common difference effect*: Suppose that we begin with a consumption profile $c^a = (c_0^a, c_1^a, \dots, c_T^a)$. Perturb this profile by altering the individual's consumption by x and $-y$ at, respectively, time periods 0 and $t > 0$. This gives us a new consumption profile $c^b = (c_0^a + x, \dots, c_{t-1}^a, c_t^a - y, c_{t+1}^a, \dots, c_T^a)$. Using (9.9), profile c^b is at least as good as profile c^a if and only if

$$u(c_0^a + x) + \delta^t u(c_t^a - y) \geq u(c_0^a) + \delta^t u(c_t^a),$$

or,

$$u(c_0^a + x) - u(c_0^a) \geq \delta^t [u(c_t^a) - u(c_t^a - y)]. \quad (9.10)$$

Hence, the preference for a consumption adjustment at two dates depends only on the time difference t that separates them. It is completely independent of the shape of the remaining consumption profile; this is the implication of *stationarity*. Violation of this effect is also known as the *common difference effect*.⁶

9.3.2 Time consistency of consumption plans under EDU

A consumption profile constructed at time t is said to be *time consistent* if it continues to be optimal when reconsidered at any later time $t+k$, $k > 0$. We now derive the sufficient conditions for a time consistent plan under DU, due to Strotz (1956). Suppose that the interest rate is zero, and an individual has the endowment, y_0 . The individual maximizes (9.2) at time $t = 0$,

$$\int_{t=0}^T D(t) u(c_t) dt, \quad (9.11)$$

where $D(t)$ is a, as yet unspecified, discount function that only depends on time and u is a time-invariant, increasing, concave, utility function. The intertemporal budget constraint of the individual specifies that the present discounted value of lifetime consumption is no greater than the initial endowment, y_0 . Recalling that the interest rate is zero, we can write this constraint as

$$\int_{t=0}^T c_t dt \leq y_0. \quad (9.12)$$

The relevant Lagrangian is given by

$$\int_{t=0}^T D(t) u(c_t) dt + \mu \left(y_0 - \int_{t=0}^T c_t dt \right), \quad (9.13)$$

where μ is the Lagrangian multiplier. Maximizing the Lagrangian, pointwise, with respect to consumption at time t , c_t , the first order condition is

⁶ There is some confusion in the terminology in the literature. Some authors refer to stationarity and the common difference effect as the same things. However, it is the lack of stationarity that we will, in keeping with the standard usage, refer to as the common difference effect.

$$D(t)u_c(c_t) - \mu = 0; \quad 0 \leq t \leq T, \quad (9.14)$$

where u_c is the marginal utility of consumption. Differentiating both sides of (9.14) with respect to time, t , we get

$$D_t(t)u_c(c_t) + D(t)u_{ct}(c_t) = 0, \quad (9.15)$$

where D_t is the time derivative of the discount function, and u_{ct} is the time derivative of marginal utility. From (9.15), we get that

$$\frac{D_t(t)}{D(t)} = -\frac{u_{ct}(c_t)}{u_c(c_t)}, \quad 0 \leq t \leq T. \quad (9.16)$$

Using (9.12), (9.16), one can generate the optimal consumption profile, conditional on any initial endowment.

The optimal plan, so far, was generated from the perspective of period 0. Now suppose that we allow the individual to reoptimize at some future date $\tau > 0$. For any $t > \tau$, the analogue of condition (9.16) is given by

$$\frac{D_t(t - \tau)}{D(t - \tau)} = -\frac{u_{ct}(c_t)}{u_c(c_t)}, \quad \tau \leq t \leq T. \quad (9.17)$$

If the optimal plan for time t made at two different times, 0 and $\tau > 0$, $\tau \leq t \leq T$, is identical, then such a plan is said to be *time consistent*. What restrictions on the discount function do we need to ensure time consistency of plans? The optimal plan constructed from the perspective of the initial time period is time consistent (using (9.16), (9.17)), if and only if

$$\frac{D_t(t - 0)}{D(t - 0)} = \frac{D_t(t - \tau)}{D(t - \tau)}, \quad 0 \leq \tau \leq t \leq T. \quad (9.18)$$

Since (9.18) is an “if and only if” condition, it is also the unique condition for time consistency.

$$(9.18) \Leftrightarrow \frac{d \ln D(t)}{dt} = \text{constant}. \quad (9.19)$$

The *unique* solution to (9.19) is the exponential discount function, i.e.,

$$D(t) = e^{-\theta t}; \theta \in \mathbb{R}. \quad (9.20)$$

It can be readily checked that solution (9.20) satisfies (9.19). Furthermore, it is the unique functional form that does so. No restrictions are placed on the sign of θ . Thus the decision maker may be impatient ($\theta > 0$), or patient ($\theta < 0$). Since EDU uses (9.20), optimal consumption profiles under EDU are time consistent.

9.3.3 A note on eliciting time preferences under EDU

In testing the EDU model, one often needs to elicit the time preference of individuals. The discussion in this section is motivated by Fisher (1930). Suppose that we have a dated consumption

profile $\{c_t\}_{t=0}^T$. The instantaneous utility at time t is given by $u(c_t)$. Suppose that the individual is given an extra amount of money, m , expressed in units of consumption, at time t . Then, using a first order Taylor series approximation around c_t , we get

$$u(c_t + m) \cong u(c_t) + u'(c_t)m. \quad (9.21)$$

Suppose that the individual is indifferent between receiving an additional amount of money m at time t and receiving an additional amount $z_0(m, t)$ now, i.e.

$$(c_0 + z_0(m, t), c_1, \dots, c_t, \dots, c_T) \sim (c_0, c_1, \dots, c_t + m, \dots, c_T). \quad (9.22)$$

Denote by $\tilde{x}$, the estimated value of some variable, x . In experimental practice, the estimate of the EDU discount function in (9.5), denoted by $\tilde{D}(t)$, is given by

$$\tilde{D}(t) = \tilde{\delta}^t = \frac{z_0(m, t)}{m}. \quad (9.23)$$

Under what conditions is $\tilde{\delta}^t$ a valid estimate of δ^t ? Using the stationarity property of EDU (see above), the preference relation stated in (9.22) can be written as

$$u(c_0 + z_0(m, t)) + \delta^t u(c_t) = u(c_0) + \delta^t u(c_t + m), \quad (9.24)$$

or,

$$u(c_0 + z_0(m, t)) - u(c_0) = \delta^t [u(c_t + m) - u(c_t)]. \quad (9.25)$$

Using (9.21), and the first order Taylor series approximations of the terms $u(c_0 + z_0(m, t))$ and $u(c_t + m)$, we can rewrite (9.25) as

$$u'(c_0)z_0(m, t) = \delta^t u'(c_t)m,$$

or,

$$\delta^t \frac{u'(c_t)}{u'(c_0)} = \frac{z_0(m, t)}{m} \equiv \tilde{\delta}^t. \quad (9.26)$$

From (9.26), $\tilde{\delta}^t = \delta^t$, if only if

$$u'(c_t) = u'(c_0). \quad (9.27)$$

Equation (9.27) will hold only if the base level of consumption c_0 is comparable to c_t . If an individual expects his circumstances to alter significantly over this time, then the marginal utilities at dates 0 and t are not comparable, so $\tilde{\delta}^t$ is unlikely to be a good estimate of δ^t .⁷ A second, implicit, assumption is that the individual uses the money m at date t for consumption purposes only. So issues of intertemporal substitution are ignored.

⁷ These issues are exploited by Noor (2007).

9.3.4 Axiomatic foundations of EDU

In order to place the refutations of EDU in context, we first outline the axiomatic derivation of the EDU model (Fishburn and Rubinstein, 1982). Suppose that at time zero, $Z \subset \mathbb{R}$ is the set of possible outcomes, and $\bar{\Gamma} \subset \mathbb{R}_+$ is the set of corresponding times at which these outcomes are realized.

Elements of the outcome set Z are denoted by z or z_j , $j = 1, 2, 3, \dots$, and elements of the set $\bar{\Gamma}$ are denoted by t or t_j , $j = 1, 2, 3, \dots$. Denote by (z, t) an *outcome–time pair* such that the individual is *guaranteed* to receive the outcome z at time t .⁸ Let $\succsim$ denote the binary preference relation “at least as good as,” on the Cartesian product $Z \times \bar{\Gamma}$. Also, let $\succ, \sim$ denote, respectively, the binary relations “strictly preferred to” and “indifferent to.” Consider the following five axioms, A1–A5, in Fishburn and Rubinstein (1982); we term these as the *axioms of rationality for time discounting*.

Definition 9.2 (*Axioms of rationality for time discounting*): Let $z_m, z_n \in Z$, and $t_p, t_q \in \bar{\Gamma}$. Let $\succsim$ denote a binary preference relation on $Z \times \bar{\Gamma}$.

- A1. *Ordering*: $\succsim$ is reflexive, complete, and transitive.
- A2. *Monotonicity*: If $z_m > z_n$, then $(z_m, t) \succ (z_n, t)$ for any $t \in \bar{\Gamma}$, i.e., larger rewards are preferred if the time horizon is kept fixed.
- A3. *Impatience*: Let $t_q < t_p$, and $z > 0$, $z \in Z$. Then, $(z, t_q) \succ (z, t_p)$, i.e., the same outcome is preferred at an earlier date. If $z_j = 0$, then $(z_j, t_q) \sim (z_j, t_p)$, i.e., there is no time preference for zero rewards.
- A4. *Continuity*: Fix some outcome–time pair $(z_j, t_j) \in Z \times \bar{\Gamma}$. Then, $\{(z, t) : (z, t) \succsim (z_j, t_j)\}$ is a closed set. Similarly, $\{(z, t) : (z_j, t_j) \succsim (z, t)\}$ is also a closed set.
- A5. *Stationarity*: If $(z_m, t_q) \sim (z_n, t_p)$, then $(z_m, t_q + t) \sim (z_n, t_p + t)$, for any $t \in \bar{\Gamma}$, i.e., indifference between two outcomes depends only on the length of the time difference between the two.

Axioms A1–A4 are standard in economics and are typically used to show the existence of a well-defined utility function (Varian, 1992, p. 97). Axiom A5 is non-standard and crucial to producing the additive separability under EDU. Fishburn and Rubinstein (1982, p. 681) write: “However, we know of no persuasive argument for stationarity as a psychologically viable assumption.”⁹ The EDU preference representation is given next.

Proposition 9.1 (Fishburn and Rubinstein, 1982, p. 682): If A1–A5 hold, then for any $\delta \in (0, 1)$, there exists a continuous, increasing, real-valued function, u , defined on the domain Z such that:

- (i) For all $(z_m, t_q), (z_n, t_p)$ in $Z \times \bar{\Gamma}$, $(z_m, t_q) \succsim (z_n, t_p)$ if and only if

$$\delta^{t_q} u(z_m) \geq \delta^{t_p} u(z_n).$$

- (ii) The outcome–time pair $(0, t)$ is treated as $\delta^t u(0) = 0$.
- (iii) Given $\delta, u(\cdot)$ is unique up to multiplication by a positive constant.

⁸ While Fishburn and Rubinstein (1982) provide an axiomatization in terms of outcome–time space, Koopmans (1960) and Koopmans et al. (1964) provide an axiomatization in terms of time preferences over consumption streams.

⁹ Fishburn and Rubinstein (1982) consider other axioms in response to this problem such as “Thomsen separability.” However, it is not clear if these have significantly better grounding in psychological evidence.

9.4 Anomalies of the EDU model

Strictly speaking, a *refutation* or *rejection* of the EDU model arises if the evidence contradicts any of the axioms of EDU. However, in applications, the EDU model is typically used in conjunction with auxiliary assumptions in order to derive testable predictions. It might not be clear if the evidence rejects one of the axioms of EDU, or a set of auxiliary assumptions, or both. In this case, one may refer to *anomalies* or *puzzles* of the EDU model.

Ultimately, it is a form of defensive methodology to term rejections of the EDU model as puzzles or anomalies, subject to at least two caveats. (i) The rejections are replicated sufficiently under stringently controlled conditions, and (ii) all reasonable confounding factors have been ruled out. Likewise it is an exaggeration to term anomalies and puzzles as rejections. What may seem like a rejection at one point may be revealed to be a quirk of experimental design, or there could be other factors that are at variance with the assumptions of the relevant theory. For instance, subjects in experiments who choose between outcome–time pairs may be *uncertain* that the experimenter will honor a promise of a future reward. One may then be led to a more general theory that takes such concerns into account. We do consider these extensions in Part I and Section 10.3.3 below. The literature has used the terms such as refutations, violations, anomalies, and puzzles interchangeably. In the behavioral time discounting literature, the preferred catch-all term is *anomaly*, a practice we follow below, although this is hardly satisfactory. However, we shall also flag up instances where the evidence clearly refutes EDU.

In this section, we make the standard assumption that subjects do not integrate current temporal plans (say, the temporal choices offered in experiments) with existing temporal plans. This is an auxiliary assumption that is not an element of the axiomatic structure of EDU. Hence, refutations of EDU by the evidence may arise because this auxiliary assumption does not hold. However, *non-integration of plans*, or at least partial integration, is the typical experimental finding, so it is not an unreasonable auxiliary assumption; see for instance, Andersen et al. (2012). Fafchamps et al. (2014) find no evidence that subjects in experiments integrate asset returns in the lab with their real-life income/wealth, although winnings in one round may influence subsequent risk attitudes, which is reminiscent of the house money effect (see Part 7).

We now describe the anomalies of the EDU model. We will use the following terminology. An amount is “discounted less” (or is more *salient*) if the discount factor applied to such an amount is higher. For the EDU model, this corresponds to a higher value of δ , or equivalently, a lower value of θ (see (9.7)). The converse applies if we say that an amount is “discounted more.”

9.4.1 Hyperbolic discounting and the common difference effect

Evidence indicates that individuals exhibit a strong preference for immediate gratification that cannot be sufficiently accounted for by the impatience parameter, θ , under EDU. This desire for immediate gratification is so strong that it may lead to *preference reversals*, which cannot take place under EDU (see Section 9.3.2). Suppose that $z, z' \in Z$, and $t, \tau, t' \in \bar{T}$. The evidence indicates *preference reversals* of the following form.

$$(z, t) \succ (z', t') \text{ and } (z', t' + \tau) \succ (z, t + \tau); \tau > 0, t' > t, z' > z. \quad (9.28)$$

In (9.28), the decision maker prefers z to z' for one set of dates, but flips his preference when both dates are moved further away by the same amount. This contradicts the *constant discounting* feature of the EDU model. Preference reversals are a rejection of the EDU model because axiom

A5 on *stationarity* does not hold (see Definition 9.2). Following Loewenstein and Prelec (1992), we shall refer to a violation of the finding of constant discounting as the *common difference effect*.

Stated in terms of the EDU model, the preferences in (9.28) imply that

$$\delta^t u(z) \geq \delta^{t'} u(z') \text{ and } \delta^{t+\tau} u(z) \leq \delta^{t'+\tau} u(z'),$$

which cannot be jointly true if at least one of the preferences is strict. The preference in (9.28) holds, in particular, when $t = 0$ is the initial time period. This is the case for Thaler's (1981) apples example (see Example 9.1).

The evidence for preference reversals comes from several sources. Following Ainslie (1992), we choose here the three fold classification of the evidence.

1. When human and non-human subjects are given the choice between varying rewards with time varying delays (see e.g., (9.28)), then their choices are found by several researchers to be well described by the *hyperbolic discount function*

$$D(\tau) = \frac{1}{1 + k\tau}. \quad (9.29)$$

In (9.29), τ is the time delay between the current period, $t = 0$, and some future period $\tau > 0$, and $k > 0$ is a parameter. Using (9.4), (9.29), the corresponding discount rate per period is

$$\theta(\tau) = \frac{k}{1 + k\tau}, \quad (9.30)$$

which is plotted in Figure 9.1 for the case $k = 1.5$. Unlike EDU, which posits constant discount rates, hyperbolic discounting implies a pattern of hyperbolically declining discount rates. The implication is that the longer the time horizon before a reward is received, the lower is the per-period discount rate, so the more patient is the individual. The reader should not confuse the discount rate with the discount factor. From the perspective of period 0, the discount factor under EDU for an outcome received at time t is $\delta^t = \left(\frac{1}{1+\theta}\right)^t$, but the per-period discount rate is still θ , which is independent of time, unlike the discount rate under hyperbolic discounting in (9.30).

From (9.30), impatience is worst for very short horizons. Thus, the average implied annual discount rate under hyperbolic discounting over shorter horizons turns out to be larger (greater impatience) as compared to longer horizons. The hyperbolic discount function has been used extensively, and successfully, in behavioral and experimental psychology to fit animal and human behavior (Logue, 1988). Another natural candidate is the simplest hyperbolic function $D(t) = \frac{1}{t}$, used by Chung and Herrnstein (1967), Ainslie (1975), but (9.29) gives a better fit to the data.

Thaler (1981) asked subjects in an experiment, how much money in one month, one year, ten years, respectively, would make them indifferent to receiving \$15 now? The median response was \$20, \$50, and \$100, respectively. The implied annual discount rates for these three choices turn out to be 3.45, 1.2, 0.19, respectively.¹⁰ Hence, the longer the horizon, the

¹⁰ The implied annual discount rates can be calculated as follows. Suppose that individuals discounted at a constant rate. Then the first option implies that $15 = 20e^{-\theta/12}$, so the annual discount rate is $\theta = 3.45$. Proceeding analogously, the average annual discount rate implied by the other two choices can be found by solving $15 = 50e^{-\theta}$ and $15 = 100e^{-10\theta}$, which gives, respectively, $\theta = 1.2$ and $\theta = 0.19$.

Figure 9.1 A plot of the discount rate in (9.30) for the one-parameter hyperbolic discounting function with varying time delay.

smaller the implied annual discount rate (lower impatience). For some other supporting evidence, see Benzion et al. (1989), Loewenstein and Prelec (1992), and Laibson (1997). The evidence for hyperbolic discounting is reviewed in greater detail below.

2. In line with (9.28), when subjects in experiments are offered a choice between a smaller-sooner (SS) reward, and a larger-later (LL) reward available at some date in the future, then LL is preferred (i.e., $(z', t' + \tau) \succ (z, t + \tau)$). However, as the date of the SS reward approaches the present, the individual prefers the SS to the LL reward (i.e., $(z, t) \succ (z', t')$). The leading motivating example of this phenomenon is Thaler's (1981) apples example (Example 9.1). This pattern is found in several experimental studies. See Ainslie and Herrnstein (1981), Ainslie and Haendel (1983), Green et al. (1981), and Kirby and Herrnstein (1995).
3. When individuals have a choice between SS and LL rewards, they sometimes take actions to remove the SS choice from the menu, indicating a possible awareness of potentially harmful preference reversals in the future. This is also true for non-human subjects. We consider the possibility of such commitment devices below. Unless further auxiliary assumptions are made, such phenomena cannot be explained under EDU.

The evidence for hyperbolic discounting comes mainly from lab experiments. Chabris et al. (2008) consider the ability of lab evidence to predict 15 different kinds of field behavior such as BMI (body-mass index), smoking, drinking, exercise, saving, and gambling. They first measure the discount rates of individuals in the lab, using a *generalized hyperbolic function*, giving them alternative choices of the sooner-smaller, and larger-later type. They find that the correlation between the lab measured discount rates and field behavior is low. However, discount rates are still the most important determinants of field behavior when compared with other determinants such as age, depression, sex, cognitive ability, and education.

9.4.2 The gain-loss asymmetry

Under EDU, the discount rate is identical for gains and losses. Empirical evidence suggests that when choosing over outcome-time pairs, losses are more salient than gains. Thus, losses are

discounted less than gains, i.e., the discount rate applicable to losses is lower. Thaler (1981) estimated the discount rates for gains to be about three to ten times larger than the corresponding discount rates for losses. In fact, a substantial proportion of subjects prefer to incur a fixed loss immediately than to delay it.¹¹

The gain–loss asymmetry is not qualitatively inconsistent with the EDU model, or its axioms, provided we assume that u is concave (this is not required in the representation in Proposition 9.1). However, we show that the gain–loss asymmetry is quantitatively inconsistent with the EDU model. We follow Loewenstein and Prelec (1992) in illustrating this issue. Consider an initial consumption profile that provides consumption z at all points in time, i.e., $(z, z, \dots, z, \dots, z)$. Now construct a second consumption profile that gives the individual an extra z' units at time $t \geq 0$, i.e., $(z, z, \dots, z + z', \dots, z)$. We assume that the decision maker follows EDU, and has an increasing and concave utility function.

The effect on the individual's welfare can be found by using the method of *equivalent variation*. In this method, we adjust current consumption in the first profile by some monetary amount $q(z', t)$, so that the first and second consumption profiles yield the same intertemporal utility. Thus, under EDU, we get¹²

$$\text{Equivalent variation: } u(z + q) + \delta^t u(z) = u(z) + \delta^t u(z + z'). \quad (9.31)$$

Gain–loss asymmetry arises if the value of q is higher for losses relative to gains of an equal absolute amount, i.e., losses have relatively greater salience. From (9.31), solving out for q we get

$$q = u^{-1} [\delta^t u(z + z') + (1 - \delta^t) u(z)] - z. \quad (9.32)$$

The utility function is assumed to be concave (which is absent in the representation theorem in Proposition 9.1), and $\delta \in (0, 1)$ (which is a part of Proposition 9.1), hence,

$$\delta^t u(z + z') + (1 - \delta^t) u(z) \leq u(\delta^t(z + z') + (1 - \delta^t)z). \quad (9.33)$$

Since u^{-1} is an increasing function, using (9.32), (9.33), it follows that

$$\begin{aligned} u^{-1} [\delta^t u(z + z') + (1 - \delta^t) u(z)] &\leq u^{-1} [u(\delta^t(z + z') + (1 - \delta^t)z)] \\ &= z + \delta^t z'. \end{aligned} \quad (9.34)$$

From (9.32), (9.34) we get $q \leq z + \delta^t z' - z$, or

$$q \leq \delta^t z'. \quad (9.35)$$

Equation (9.31) must hold for all $t \geq 0$. Hence, for $z' > 0$, it must be that $q > 0$, while for $z' < 0$ it must be that $q < 0$. It follows from (9.35) that for gains, i.e., $z' > 0$ and $q > 0$,

$$\frac{q}{z'} = \left| \frac{q}{z'} \right| \leq \delta^t. \quad (9.36)$$

¹¹ For related findings, see for instance, Benzon et al. (1989), Loewenstein (1987), and Mischel et al. (1969).

¹² By contrast, under the method of *compensating variation*, we alter current consumption in the second consumption profile by an amount p so that the individual's intertemporal utility under the two consumption profiles is identical, i.e., $u(z) + \delta^t u(z) = u(z - p) + \delta^t u(z + z')$.

Analogously, for losses, i.e., $z' < 0$ and $q < 0$,

$$-q > -\delta^t z' \Rightarrow \frac{-q}{-z'} = \left| \frac{q}{z'} \right| \geq \delta^t. \quad (9.37)$$

Hence, from (9.36), (9.37), the required current compensation per unit is larger for losses of an equal absolute amount. Therefore, losses have relatively greater salience and EDU makes the correct qualitative prediction for the gain–loss asymmetry, provided we impose concavity of u , which is not a condition of the representation theorem in Proposition 9.1. We now show how this prediction is quantitatively wrong.

In going from (9.32) to (9.35), we use the concavity of the utility function; however, for perturbations of the initial consumption profile, for relatively small magnitudes (small z'), the utility function is likely to be approximately linear over the interval $(z - z', z + z')$. Hence, we cannot change the equality into an inequality as we move from (9.32) to (9.35). Therefore, the analogue of (9.35) for small perturbations is

$$q = \delta^t z'.$$

Thus, the gain–loss asymmetry disappears for small z' . Experimental evidence, however, suggests the opposite, i.e., the gain–loss asymmetry becomes stronger for small outcomes (Thaler, 1981).

9.4.3 The absolute magnitude effect

Under EDU, the discount rate is independent of the magnitudes of the outcomes. However, the evidence shows that larger monetary amounts are discounted less, i.e., the implied discount rate for larger amounts is lower. In Thaler (1981), subjects reported being indifferent to \$15 received now, and \$60 in a year's time; \$250 received now, and \$350 received in a year's time; and \$3000 received now, and \$4000 in a year's time. These choices imply the respective annual discount rates 1.39, 0.34, and 0.29. Thus, larger amounts are discounted less. Calculation of these discount rates is straightforward; for instance, $3000 = 4000e^{-\theta}$, so $\theta = \ln(4/3) \cong 0.29$. In other words, larger amounts have greater salience in an intertemporal consumption profile.

Suppose that the decision maker is risk neutral, and exhibits the following outcome–time choices: $(z_1, 0) \sim (z'_1, t)$, $(z_2, 0) \sim (z'_2, t)$, where $z'_2 > z'_1$. From the discussion in Section 9.3.3, we know that if marginal utilities are approximately constant (i.e., the outcomes are small), then, under EDU, the estimated discount factor is $\delta^t = \frac{z_1}{z'_1} = \frac{z_2}{z'_2}$. But the experimental evidence on the magnitude effect shows that $\frac{z_1}{z'_1} < \frac{z_2}{z'_2}$. This suggests that larger amounts are discounted less, and that the discount rate is magnitude dependent.¹³ We shall see below that the magnitude effect is also inconsistent with the hyperbolic discounting model, and generally with the DU model, unless one makes further assumptions on the utility function.

9.4.4 The delay–speedup asymmetry

For 2012, online e-sales exceeded 1 trillion USD, which exceeds the GDP of many countries. The following scenario is characteristic of such sales, say, from Amazon, or eBay. At date 0, Sam and

¹³ For the evidence, see Ainslie and Haendel (1983), Benzion et al. (1989), Green et al. (1994), Kirby et al. (1999), and Loewenstein (1987).

Dan have separately purchased an item online, and need to decide on a shipping option. Sam's shipping is scheduled in the near future, say, at time $s > 0$, but he has the option to delay his delivery to a future date, say, date $d > s$; in return, he receives some payment $\pi_{s \rightarrow d}$ (perhaps, a reduced shipping cost). Alternatively, Dan's shipping is scheduled for the later date, d , but he has the option to expedite his delivery to an earlier date, say, s , for an additional charge $\pi_{s \leftarrow d}$, due to more costly postage.

Suppose that we make two assumptions: (1) Individuals follow EDU, and (2) do not integrate new plans with existing plans; evidence, some reviewed above, seems to support the assumption of non-integration of plans.¹⁴ Under assumptions 1 and 2, it can be shown that $\pi_{s \rightarrow d} = \pi_{s \leftarrow d}$ (see below).

Loewenstein (1988) empirically tested to check if $\pi_{s \rightarrow d} = \pi_{s \leftarrow d}$. Subjects were asked the maximum amount they would pay for a Sony VCR with remote control (list price \$300) delivered today. They were then asked what minimum amount they would be willing to accept today to defer their receipt for the item by one year ($\pi_{s \rightarrow d}$)? In another question, subjects were asked the maximum amount they would pay for a Sony VCR with remote control (list price \$300) delivered a year from now. They were then asked what minimum amount they would be willing to pay today to speed up their receipt for the item by one year ($\pi_{s \leftarrow d}$)? It was found that $\pi_{s \rightarrow d} = \$126$, and $\pi_{s \leftarrow d} = \$54$. Following Loewenstein (1988), extensive empirical evidence shows that $\pi_{s \rightarrow d} > \pi_{s \leftarrow d}$.¹⁵ This gives rise to the *delay-speedup asymmetry*.

We now give a slightly more formal treatment. Consider three dates: $0 = r < s < d$. At date $r = 0$, an individual with initial wealth w is willing to pay the *maximum price* $p_\tau \leq w$ to contractually receive c units of the good at delivery time $\tau = s, d$ (respectively, contract- s , and contract- d). Any reasonable DU model that incorporates impatience should require $p_s > p_d$. We assume *non-integration of plans*, so that this buying decision is not integrated with existing consumption plans.

Following Loewenstein (1988), we make the simplifying assumption that the object is fully consumed at the delivery date, τ .¹⁶ Let consumption at dates s and d be denoted by c_s and c_d . A generic *consumption-time profile* is given by $(c_0, 0), (c_s, s), (c_d, d)$. Under contract- s , the consumption profile is $(w - p_s, 0), (c, s), (0, d)$, while under contract- d it is $(w - p_d, 0), (0, s), (c, d)$.

Let u be a time-invariant utility function, and we normalize $u(0) = 0$. Under EDU, we have

$$U((c_0, 0), (c_s, s), (c_d, d)) = u(c_0) + u(c_s)\delta^s + u(c_d)\delta^d.$$

The utility of the individual from the three actions, (i) not buying, (ii) signing contract- s , and (iii) signing contract- d , is respectively denoted by U_0, U_0^s , and U_0^d , where

$$\begin{cases} U_0 = U_0((w, 0), (0, s), (0, d)) = u(w). \\ U_0^s = U_0((w - p_s, 0), (c, s), (0, d)) = u(w - p_s) + u(c)\delta^s. \\ U_0^d = U_0((w - p_d, 0), (0, s), (c, d)) = u(w - p_d) + u(c)\delta^d. \end{cases} \quad (9.38)$$

Since p_τ is the *maximum price* that the individual is willing to pay to delay delivery to date $\tau = s, d$, it follows that $U_0 = U_0^s = U_0^d$, or

¹⁴ Consider, for instance, the following quote from Loewenstein (1988, p. 200): "Rather than integrating delayed consumption plans it appears that people often represent future consumption options as gains and losses or as a deviations from some standard, such as past levels of consumption."

¹⁵ For other evidence in support of the delay-speedup asymmetry, see Benzion et al. (1989), Shelley (1993), Malkoc and Zauberman (2006), and McAlvanah (2010).

¹⁶ The results also go through if the object depreciates over time, leading to a diminishing stream of consumption.

$$u(w) = u(w - p_s) + u(c)\delta^s = u(w - p_d) + u(c)\delta^d. \quad (9.39)$$

Consider an individual who has signed contract- s , and is asked to state the *minimum delay premium*, $\pi_{s \rightarrow d}$, received at time $r = 0$, to have receipt of the object delayed to time $t = d$.

Denoting the resulting lifetime utility by $U_0^{s \rightarrow d}$,

$$U_0^{s \rightarrow d} = U_0((w - p_s + \pi_{s \rightarrow d}, 0), (0, s), (c, d)) = u(w - p_s + \pi_{s \rightarrow d}) + u(c)\delta^d. \quad (9.40)$$

From the definition of $\pi_{s \rightarrow d}$, we get $U_0^s = U_0^{s \rightarrow d}$, or

$$u(w - p_s) + u(c)\delta^s = u(w - p_s + \pi_{s \rightarrow d}) + u(c)\delta^d. \quad (9.41)$$

From (9.39) and (9.41), we have $u(w - p_s + \pi_{s \rightarrow d}) = u(w - p_d)$, hence,

$$\pi_{s \rightarrow d} = p_s - p_d > 0. \quad (9.42)$$

Now consider someone who has chosen contract- d , and is asked to state the *minimum speedup premium*, $\pi_{s \leftarrow d}$, paid at time $r = 0$, to speed up the receipt of the object to time $t = s$. Denoting the resulting lifetime utility by $U_0^{s \leftarrow d}$,

$$U_0^{s \leftarrow d} = U_0((w - p_d - \pi_{s \leftarrow d}, 0), (c, s), (0, d)) = u(w - p_d - \pi_{s \leftarrow d}) + u(c)\delta^s. \quad (9.43)$$

Given the definition of $\pi_{s \leftarrow d}$ we have $U_0^d = U_0^{s \leftarrow d}$, so

$$u(w - p_d) + u(c)\delta^d = u(w - p_d - \pi_{s \leftarrow d}) + u(c)\delta^s. \quad (9.44)$$

From (9.39) and (9.44), we get $u(w - p_d - \pi_{s \leftarrow d}) = u(w - p_s)$, hence,

$$\pi_{s \leftarrow d} = p_s - p_d. \quad (9.45)$$

From (9.42), (9.45), under EDU, and non-integration of plans,

$$\pi_{s \rightarrow d} = \pi_{s \leftarrow d} = p_s - p_d > 0. \quad (9.46)$$

Any departure from (9.46) may be termed as the *delay-speedup asymmetry*. As noted above, the empirical finding of $\pi_{s \rightarrow d} > \pi_{s \leftarrow d}$, illustrates the delay-speedup asymmetry, which is not consistent with EDU.

9.4.5 Front-end delay dependence

Suppose that at time 0, an individual expresses the preference $(z, \tau) \succsim (z', \tau + d)$, where $\tau \geq 0, d > 0$. How is discounting affected across the interval $[\tau, \tau + d]$, if the front-end delay, τ , is altered? Fixing d , Read and Roelofsma (2003) find that the discount factor increases as one pushes the interval into the future by increasing τ . In particular, they looked at successive 13 week intervals $[0, 13]$, $[13, 26]$, $[26, 39]$, $[39, 52]$, and asked subjects in experiments what they would be

willing to receive at time τ in lieu of 200 Dutch Guilders at time $\tau + 13$. The elicited discount factors over the four intervals of equal length were respectively, 0.33, 0.4, 0.5, 0.52. Front-end delay dependence violates axiom A5 on stationarity (see Definition 9.2).

9.4.6 Subadditive discounting

Consider a time interval $[0, \tau_k]$ that is split up into k subintervals $[0, \tau_1], [\tau_1, \tau_2], [\tau_2, \tau_3], \dots, [\tau_{k-1}, \tau_k]$, where $0 < \tau_1 < \tau_2 < \dots < \tau_k$. Denote the discount factor over the interval $[\tau_j, \tau_{j+1}]$ by δ_j^{j+1} . Then, *subadditive discounting* implies that the total discounting is greater, or the applied discount rate is higher, when outcomes are discounted over subintervals, i.e.,¹⁷

$$\delta_0^k > \delta_0^1 \delta_1^2 \dots \delta_{k-1}^k. \quad (9.47)$$

Subadditive discounting implies that a future event is more salient when discounted over the whole interval, rather than its constituent subintervals. Under EDU, by contrast, we have $\delta_0^k = \delta_0^1 \delta_1^2 \dots \delta_{k-1}^k$. Subadditive discounting is a rejection of the stationarity axiom of EDU. Read (2001) finds evidence for subadditive discounting.¹⁸ Subadditive discounting is consistent with cyclical, i.e., non-transitive choice. An exercise asks you to show this.

9.4.7 Cyclical or non-transitive choices

The finding of *cyclical* or *non-transitive* choices is not new. Tversky et al. (1990) find evidence for cyclical choices for about 15% of the subjects in experiments after controlling for framing effects. Roelofsma and Read (2000) find cyclical choices to be pervasive in their data. Other evidence can be found in Read (2001) and Rubinstein (2003).¹⁹ Cyclical choices violate ordering, the first axiom in EDU preferences (see Definition 9.2). Such choices are also inconsistent with the hyperbolic discounting model that we consider in detail below. But other theories that we consider below are compatible with cyclical choices. These include Ok and Masatlioglu's (2007) *relative discounting model*, Manzini and Mariotti's (2006) *vague time preferences theory*, Read's (2001) *subadditive discounting*, and Rubinstein's (2003) *similarity relationship* for decision making.²⁰

The main objection to cyclical choices has been a practical one. The presence of non-transitivities seriously compromises the ability of most economic models to make predictions. Ok and Masatlioglu (2007) argue, on the other hand, that non-cyclical choices are perfectly reasonable. They give the following example. Suppose that a decision maker is willing to delay an outcome for one period, if compensated by \$50. But the same decision maker is unwilling to accept a delay of two weeks in return for an extra compensation of \$150. Then (assuming that time is measured in units of weeks, and starts at $t = 0$) the following preferences are perfectly reasonable

$$(100, 0) \succ (250, 2) \succ (200, 1) \succ (100, 0). \quad (9.48)$$

¹⁷ Subadditive discounting is similar to the idea of Tversky and Koehler (1994) who showed that the compound probability of an event is higher if it is partitioned into a greater number of subevents.

¹⁸ For other sources of evidence on subadditive discounting, see Read and Roelofsma (2003), Scholten and Read (2006a), Kinari et al. (2009), Zauberman et al. (2009), and McAlvanah (2010).

¹⁹ For a survey of non-transitive preferences in decision theory, see Fishburn (1991).

²⁰ Cyclical choices can also be explained under EDU when stationarity is replaced by Thomsen separability; see Fishburn and Rubinstein (1982).

Figure 9.2 Sequential choices for the Ok and Masatlioglu (2007) example.

Source: Reprinted from *Journal of Economic Theory*, 137(1): 214–45. Ok, E.A. and Masatlioglu, Y., “A theory of (relative) discounting.” Copyright © 2007, with permission from Elsevier.

The first strict preference follows because \$150 does not compensate for a delay of two weeks, the second because \$50 compensates for a delay of one week, and the third follows because if \$50 compensates for a delay of one week, then \$100 should too. Ok and Masatlioglu (2007) point out that non-transitive choices are problematic because the decision maker is asked to commit to making a choice *today*. What if the decision maker does not have to commit to a choice today, and realizes that choices will be made sequentially in the future? Figure 9.2 depicts these sequential choices.

The decision maker can predict that if he waited for one week, then he would end up waiting another week and choosing \$250. Faced with a choice of \$250 from waiting and \$100 from not waiting, the decision maker chooses “not waiting” because an extra \$150 is not worth the delay of two weeks. Hence, there is a unique predictable time consistent choice. Ok and Masatlioglu (2007) argue that it might be improper to disallow non-transitive choices at the outset through the imposition of the *order* axiom, and their own axiomatic framework does not impose the order axiom.

It might well be that if one accounts for time, context, and reference dependent temporal preferences, intransitivities may disappear, or weaken substantially; see Gintis (2009). For a formalization of this argument, based on reference dependent time preferences, see al-Nowaihi and Dhami (2008a, 2013). Their solution allows one to preserve the axiom of order, yet account for non-transitive choice. These issues are further considered in Sections 10.5 and 10.5.6.

9.4.8 Preferences for increasing sequences

The EDU model ascribes no preference for particular shapes of consumption profiles (see the property of *utility independence* above) provided that the exponentially discounted values of alternative consumption streams are identical. However, empirical evidence generally shows that, holding fixed the discounted values of consumption streams, people prefer increasing over decreasing sequences. So for instance, in most human cultures, the dessert follows the main meal. Furthermore, subjects in experiments indicate a preference for increasing wage profiles to flat, or declining profiles with the same discounted value (Loewenstein and Sicherman, 1991). Indeed, even when the economic benefits of decreasing wage profiles are explained to the subjects

(e.g., opportunity cost of interest forgone) there was only a very marginal decrease in the number who preferred an increasing wage profile from 76 to 69.

In another study by Hsee et al. (1991), an increasing wage profile was preferred to a decreasing one, albeit one with a higher present value. In a related phenomenon that bears a similar interpretation, Varey and Kahneman (1992) found that individuals preferred a sequence characterized by decreasing discomfort rather than increasing discomfort.²¹ Evidence indicates that monkeys also prefer increasing sequences, and in particular, sequences that have a large reward at the end (the *end bias*); see Blanchard et al. (2014).

9.4.9 *Violations of consumption independence*

Consumption independence is one of the properties of the EDU model (see Section 9.3.1, above). Loewenstein and Prelec (1993) report the following experiment. Subjects were asked where they would like to eat (French restaurant, Home, or at a Lobster restaurant) over the next five weekends from among the following two pairs of menus, A, B , where each menu has two choices, $A = \{A1, A2\}$ and $B = \{B1, B2\}$; these are shown in Table 9.1.

The fifth week choices are the same in each pair of menus. Using the consumption independence feature of EDU, the fifth week choices should, therefore, have no influence in either set of menus. Thus, leaving out week 5 in each menu, if someone chooses $A2$ in menu A , it implies that they must choose $B2$ in menu B . A majority of the respondents (89%) choose $A2$, perhaps because the consumption profile is better spread temporally. However, respondents are split almost equally between $B2$ and $B1$. Hence, almost half the respondents behave in a manner that violates EDU.

Using field data from teachers in California, Mayer and Russell (2005) show that teachers prefer their salaries to be spread out equally over a 12 month period, as compared to receiving 10 equal installments of the annual salary over a period of 10 months. Under EDU, one expects teachers to prefer the latter option because they could earn more interest. One interpretation of these results is that the 12 equal, monthly spaced, salary receipts allow one to exert better control over spending, an explanation that is consistent with hyperbolic preferences.

9.4.10 *Effects of individual-specific traits on the discount rate*

Variations in discount rates are associated with a range of individual traits as well as situations, contexts, and emotions; see Chabris et al. (2007) for a more detailed survey. The elicited

Table 9.1 Choices among temporal sequences of meals.

Options/Weekends	1	2	3	4	5
A1 (11%)	French	Home	Home	Home	Home

discount rates of individuals are negatively correlated with age, i.e., the older are more patient.²² Individuals with higher cognitive ability tend to be more patient.²³ The following categories of individuals are more impatient (i.e., have higher discount rates): gamblers,²⁴ smokers,²⁵ heavy alcohol drinkers,²⁶ and drug users.²⁷

CHAPTER 10

Behavioral Models of Time Discounting

10.1 Introduction

In this chapter, we turn to an explanation of the anomalies of the EDU model that we considered in Chapter 9. This naturally leads us to consider developments in behavioral models of time discounting.

Section 10.2 considers explanations of the *magnitude effect* and the *sign effect* (or *gain-loss asymmetry*). The magnitude effect arises because larger magnitudes are discounted less. The sign effect arises because losses are discounted less than gains. One may wish to explain these anomalies of EDU by putting the burden of adjustment on the discount function, or the utility function (or both). The explanation in Section 10.2.1 puts all the burden of adjustment on the utility function (Loewenstein and Prelec, 1992). Loewenstein–Prelec provided the first coherent explanation of these two effects. The magnitude effect is explained by assuming that the utility function is subproportional, and less elastic for outcomes of larger absolute magnitude. The sign effect is explained by adopting a utility function with greater elasticity for losses as compared to gains.

Loewenstein–Prelec’s explanation of the magnitude effect relies on an increasing elasticity of the utility function. However, several popular classes of utility functions violate this condition. These include CARA (constant absolute risk aversion), CRRA (constant relative risk aversion), HARA (hyperbolic absolute risk aversion), logarithmic, and quadratic. In Section 10.2.2, we give a class of utility functions that satisfy Loewenstein–Prelec’s conditions (al-Nowaihi and Dhami, 2008a, 2009). This class of utility functions is known as the *simple increasing elasticity*, SIE, class of utility functions.

A great deal of effort in behavioral economics has gone into explaining the *common difference effect*. The stationarity axiom in EDU implies that the discount rate over a time interval of fixed length is always constant, irrespective of the location of the interval. The common difference effect is a violation of the stationarity axiom. Section 10.3 considers the main explanations of the common difference effect.

Hyperbolic discounting, which we consider in Section 10.3.1, is one of the leading candidates for explaining the common difference effect. Hyperbolic discounting is the finding of hyperbolically declining discount rates. Since the discount rates are higher over shorter horizons, individuals appear to be particularly impatient over choices made over short horizons as compared to longer horizons. This gives rise to the well-known phenomenon of *present-biased preferences*; Chapter 11 is devoted to applications of this finding.

We consider two variants of hyperbolic discounting. The first is the *general hyperbolic discounting function* (Loewenstein and Prelec, 1992); our exposition of the general form of hyperbolic discounting relies on al-Nowaihi and Dhami (2006). The second variant is the *quasi-hyperbolic* or (β, δ) form (Phelps and Pollak, 1968; Laibson, 1997).

In the standard models of time discounting, the discount function is additive in the sense that splitting an interval into subintervals does not alter the extent of discounting. A violation of this feature can either lead to *subadditivity* (discounting over the bigger interval is lower), or its reverse, *superadditivity*. In Section 10.3.2, we consider an explanation for the common difference effect in terms of *subadditive discounting* (Read, 2001; Scholten and Read, 2006a). We also consider the *Read–Scholten discount function*, which is one of the most flexible discount functions available, and likely to be of great use in models of time discounting.

For whatever reasons, evolutionary, or otherwise, subjects in experiments on time discounting may view the future receipt of rewards as uncertain. One method of incorporating such uncertainty into the model is to combine expected utility theory with the EDU model (Halevy, 2008). The resulting model predicts that no common difference effect should arise. Thus, it would appear that the common difference effect is a joint rejection of EDU and expected utility theory. We consider these issues in Section 10.3.3. We also show that combining EDU with a non-expected utility model, prospect theory, predicts the common difference effect when there is “near certainty” (al-Nowaihi and Dhami, 2008a). However, the common difference effect reappears when we move away from near certainty situations. Hence, it is the *certainty effect* that seems to be causing the common difference effect, not non-expected utility per se. We also consider the work of Saito (2011) who generalizes the results in Halevy (2008) and Epper et al. (2011).¹

The outcome–time pairs which are compared in models of time discounting, consist of two natural *attributes*: time of delivery (time attribute), and the monetary value (outcome attribute). *Attribute models* attempt to explain temporal choices based on a trade-off between these two attributes. Section 10.4 considers three attribute-based models. In Section 10.4.1, we consider the *model of vague time preferences* (Manzini and Mariotti, 2006) that can explain the common difference effect. In this model, individuals use a hierarchical set of rules to make choices between outcome–time pairs. If the present discounted value of one pair is higher than a threshold, it is chosen, otherwise, a secondary criterion that compares the size of outcomes, or an earlier date is used to make choices. However, the choices are sensitive to the order in which the secondary criterion is exercised, i.e., time first, or outcome first.

Section 10.4.2 considers *similarity based relations* in choosing among outcome–time pairs (Rubinstein, 2003). When presented with a choice among alternatives, decision makers look for similarity along the various attribute dimensions. For instance, the outcome attribute, or the time attribute, in the two choices might be similar. Attributes where similarity is spotted are ignored. The choice is then made on the basis of the remaining attribute. Section 10.4.3 considers the *trade-off model of intertemporal choice* (Scholten and Read, 2006b). It can be shown that this attribute-based model belongs to the class of discounted utility models. i.e., the class of time preference models which are separable in time and outcomes (al-Nowaihi and Dhami, 2008a).

Section 10.5 considers a general theory of time discounting, the *reference time theory*, RT (al-Nowaihi and Dhami, 2008a, 2013, 2014). RT can explain all the main anomalies of the EDU model, namely, gain–loss asymmetry, magnitude effect, common difference effect, delay–speedup

¹ Part 1 of the book provides a separate and non-overlapping treatment of the interaction of risk preferences and time preferences.

asymmetry, apparent intransitivity of time preferences, and non-additivity of time discounting. It can also provide a framework for incorporating recent developments in time discounting such as uncertainty and attribute models. Essentially, RT combines generalized hyperbolic discounting with subadditive discounting. Furthermore, borrowing insights from prospect theory, it incorporates a reference point for time as well as a reference point for wealth. Preferences in RT are complete and transitive, yet it is able to explain apparent intransitivity of preferences. This is accomplished by a shift in the reference point for time. In the absence of such shifts in the reference time, what might just be an apparent intransitivity in preferences could be misconstrued as real intransitivity, as we show by an example.

10.2 Explaining the sign and magnitude effects

Loewenstein and Prelec (1992) (LP) provide the leading explanation of two anomalies of the EDU model: the *magnitude effect* and *gain-loss asymmetry*. However, none of the standard utility functions satisfy their conditions. Following al-Nowaihi and Dhami (2006, 2008b), we outline their work, and then provide a scheme for constructing the appropriate class of utility functions that satisfy the relevant conditions.

10.2.1 The Loewenstein-Prelec explanation

Consider a decision maker who, at time t_0 , formulates a plan to choose c_i at time $t_i \in [0, \infty]$. Let $v(c_t)$ be the instantaneous utility from consumption at time t . It is identical to the utility function under prospect theory as in Kahneman and Tversky (1979); see Chapter 2 for the details. Thus, among other properties such as loss aversion, v satisfies the following properties.

P1. $v : (-\infty, \infty) \rightarrow (-\infty, \infty)$ is continuous, and strictly increasing.

P2. $v(0) = 0$, and is differentiable except at 0, which is the reference point.

The *elasticity* of v is given by

$$\epsilon_v(c) = \frac{c}{v} \frac{dv}{dc}, c \neq 0. \quad (10.1)$$

Consider the following four assumptions, all with good experimental basis that are followed by an explanation.²

A0: Impatience: $D : [0, \infty) \rightarrow (0, 1]$ is a continuous, strictly decreasing function with $D(0) = 1$ and $D(t) \rightarrow 0$ as $t \rightarrow \infty$.³

A1: Gain-loss asymmetry: If $0 < z < z'$ and $v(z) = D(t)v(z')$, then $v(-z) > D(t)v(-z')$.

A2: Magnitude effect: If $0 < z < z'$, $v(z) = D(t)v(z')$ and $a > 1$, then $v(az) < D(t)v(az')$.

A3: Common difference effect: Let $0 < z < z'$, $v(z) = D(t)v(z')$. The common difference effect arises if there exists some $t' > 0$ such that $D(t')v(z) < D(t' + t)v(z')$.

Starting from the condition $v(z) = D(t)v(z')$, gain-loss asymmetry requires that losses are relatively more salient; thus, when gains turn into losses, the future loss bites relatively more.

² We make no use of the fifth assumption in LP: *delay-speedup asymmetry* (LP, p. 578).

³ We shall be mainly interested in discount functions that exhibit decreasing impatience. Bleichrodt et al. (2009) propose two classes of discount functions that allow for decreasing as well as increasing impatience.

Since, $v(-z) < 0$ and $v(-z') < 0$ (recall that v is a prospect theory utility function), A1 follows immediately. Similarly, the magnitude effect (A2) requires that starting from $v(z) = D(t) v(z')$, as z and z' are scaled up simultaneously, the larger future magnitude becomes more salient, hence, $v(az) < D(t) v(az')$. The common difference effect (A3) is a violation of the stationarity assumption of EDU. The decision maker flips his preferences as the outcomes are pushed further out into the future, while maintaining the time difference between the outcomes.

We now examine the implications of A0–A3 for the shape of the utility function. LP explain the sign and magnitude effects by putting the burden of adjustment entirely on the utility function, v (rather than on the discount function, D , or on both); the exact modeling strategy is an empirical question. Thus, we would like to find a utility function that satisfies assumptions A0–A3.⁴

Proposition 10.2 shows that the gain–loss asymmetry can be explained by using a utility function that is more elastic for gains as compared to losses.

Proposition 10.2 *Assumption A1 implies that the utility function is more elastic for losses than for gains: $z > 0 \Rightarrow \epsilon_v(-z) > \epsilon_v(z)$.*

Proof: By assumption, $0 < z < z'$ and $v(z) = D(t) v(z')$, hence,

$$\frac{v(z)}{v(z')} = D(t). \quad (10.2)$$

Using assumption A1, $v(-z) > D(t) v(-z')$. Since $-z' < 0$, and v is a prospect theory utility function, it follows that $v(-z') < 0$ and $v(-z) < 0$, hence,

$$\frac{v(-z)}{v(-z')} < D(t). \quad (10.3)$$

From (10.2), (10.3) we get that $\frac{v(-z)}{v(-z')} < \frac{v(z)}{v(z')}$. Since $v(-z) < 0$ and $v(-z') < 0$, we can rewrite the previous inequality as $\frac{-v(-z)}{-v(-z')} < \frac{v(z)}{v(z')}$. Taking logs on both sides we get that

$$\frac{\ln v(z') - \ln v(z)}{\ln z' - \ln z} < \frac{\ln(-v(-z')) - \ln(-v(-z))}{\ln z' - \ln z}. \quad (10.4)$$

Define $\tilde{z} = \ln z$ and $\tilde{z}' = \ln z'$. Letting v_+, v_- be, respectively, the utility function from gains and losses, define $\tilde{v}_+ = \ln v_+$ and $\tilde{v}_- = \ln v_-$. From (10.4), $\ln v$ is a concave function of $\ln z$, thus,

$$\frac{\tilde{v}_+(\tilde{z}') - \tilde{v}_+(\tilde{z})}{\tilde{z}' - \tilde{z}} < \frac{\tilde{v}_-(\tilde{z}') - \tilde{v}_-(\tilde{z})}{\tilde{z}' - \tilde{z}}.$$

Take limits as $\tilde{z}' \rightarrow \tilde{z}$, to get $\frac{d\tilde{v}_+}{d\tilde{z}} \leq \frac{d\tilde{v}_-}{d\tilde{z}}$, from which it follows that $\epsilon_v(z) \leq \epsilon_v(-z)$. ■

We now show that a necessary condition to explain the magnitude effect is that the elasticity of the utility function must increase as the absolute magnitude of outcomes increases.

⁴ We shall note the problems that such an explanation leads to, below, and the alternative explanation proposed by al-Nowaihi and Dhami (2008a).

Proposition 10.3 (Loewenstein and Prelec, 1992; al-Nowaihi and Dhami, 2008a): *Assumption A2 implies that the utility function is more elastic for outcomes of larger absolute magnitude, i.e.,*

$$(0 < z < z' \text{ or } z' < z < 0) \rightarrow \epsilon_v(z) < \epsilon_v(z').$$

10.2.2 The class of simple increasing elasticity utility functions

Loewenstein and Prelec (1992) do not give any example of a utility function that has the properties required in Propositions 10.2 and 10.3 to explain the sign and magnitude effects. al-Nowaihi and Dhami (2009) show that none of the standard utility functions, CARA, CRRA, HARA, logarithmic, and quadratic satisfy the properties in Propositions 10.2 and 10.3 (an exercise asks you to show this).

In order to resolve this problem, al-Nowaihi and Dhami (2009) provide a simple, tractable class of utility functions, the *simple increasing elasticity* (SIE) utility functions, that satisfies the properties required in Propositions 10.2 and 10.3. Furthermore, they provide a scheme for generating such utility functions. The following method can be used to generate candidates for the, as yet undetermined, SIE utility functions.

For some set of outcomes X , choose a function, h , satisfying,

$$0 < h(x) < 1, h'(x) > 0, x \in X. \quad (10.5)$$

Then solve the following differential equation for $u(x)$:

$$\frac{x}{u} \frac{du}{dx} = h(x). \quad (10.6)$$

This method only yields candidate utility functions, which then have to be verified. For example, choose

$$h(x) = \frac{ax}{b+x} + c; x \geq 0, a, b, c > 0, a + c \leq 1. \quad (10.7)$$

Substituting from (10.7) into (10.6), we get

$$\frac{x}{u} \frac{du}{dx} = \frac{ax}{b+x} + c.$$

Separating variables, then integrating, gives

$$\int \frac{du}{u} = a \int \frac{dx}{b+x} + c \int \frac{dx}{x}.$$

The solution is

$$\begin{aligned} \ln u &= a \ln(b+x) + c \ln x + \ln K. \\ \Rightarrow u &= e^{\ln(b+x)^a} e^{\ln x^c} e^{\ln K}. \end{aligned}$$

Since the logarithm and the exponential functions are inverses of each other, we can write this expression alternatively as,

$$u(x) = K(b+x)^a x^c. \quad (10.8)$$

Choosing $a = 1 - \gamma$, $b = \frac{\gamma\mu}{\theta}$, $c = \sigma$ and $K = \frac{\gamma}{1-\gamma} \left(\frac{\theta}{\gamma}\right)^{1-\gamma}$ produces a utility function:

$$u(x) = \frac{\gamma x^\sigma}{1-\gamma} \left(\mu + \frac{\theta}{\gamma} x\right)^{1-\gamma}, \quad x \geq 0. \quad (10.9)$$

The restrictions $a, b, c > 0$, $a + c \leq 1$ give: $0 < \sigma \leq \gamma < 1$ and $\mu/\theta > 0$. To ensure that $u' > 0$, take $\theta > 0$. Hence, $\mu > 0$. For $x < 0$, define $u(x)$ by $u(x) = -\lambda u(-x)$, where $\lambda > 1$.⁵ Putting all these together gives the candidate SIE utility function

$$u(x) = \begin{cases} \frac{\gamma x^\sigma}{1-\gamma} \left(\mu + \frac{\theta_+}{\gamma} x\right)^{1-\gamma} & \text{if } x \geq 0 \\ -\lambda \frac{\gamma (-x)^\sigma}{1-\gamma} \left(\mu - \frac{\theta_-}{\gamma} x\right)^{1-\gamma} & \text{if } x < 0 \end{cases}, \quad (10.10)$$

where $\mu > 0$, $\theta_\pm > 0$, $\lambda > 1$, $0 < \sigma \leq \gamma < 1$, and λ is the coefficient of loss aversion.

It may be interesting to note that (10.10) is a product of a CRRA function, x^σ , and a HARA function, $\frac{\gamma}{1-\gamma} \left(\mu + \frac{\theta_\pm}{\gamma} x\right)^{1-\gamma}$. From (10.10), it is straightforward to prove the next proposition

Proposition 10.4 (*al-Nowaihi and Dhami, 2009*). *For the utility function u defined in (10.10):*

- (a) $u : (-\infty, \infty) \rightarrow (-\infty, \infty)$, $u(0) = 0$, u is continuous, u is C^∞ except at $x = 0$.
- (b) The elasticity of the utility function, $\epsilon_u(x) = \frac{x}{u} \frac{du}{dx}$, is given by

$$\epsilon_u(x) = \begin{cases} \sigma + \frac{1-\gamma}{1 + \frac{\gamma\mu}{x\theta_+}} > 0 & \text{if } x > 0 \\ \sigma + \frac{1-\gamma}{1 - \frac{\gamma\mu}{x\theta_-}} > 0 & \text{if } x < 0 \end{cases}. \quad (10.11)$$

- (c) $\epsilon'_u(x) > 0$ for $x > 0$ and $\epsilon'_u(x) < 0$ for $x < 0$.
- (d) $x > 0 \Rightarrow \epsilon_u(x) < \epsilon_u(-x)$.

Comparing Proposition 10.2 with Proposition 10.4(d), the SIE utility function explains the sign effect, and comparing Proposition 10.3 with Proposition 10.4(c), the SIE utility function can also explain the magnitude effect. The following proposition gives some useful properties of $\epsilon_u(x)$. Some other properties of the SIE utility function are contained in an exercise at the end of this part of the book.

Proposition 10.5 (*al-Nowaihi and Dhami, 2009*) *From (10.11), we get that $\epsilon_u(x) \rightarrow \sigma$ as $x \downarrow 0$ and as $x \uparrow 0$. Hence, $\epsilon_u(x)$ is defined for all $x \in (-\infty, \infty)$, $\epsilon_u(x) = \sigma + \frac{1-\gamma}{1 + \frac{\gamma\mu}{x\theta_+}} > 0$, $\epsilon_u(x)$ is increasing in $|x|$ and $\epsilon_u(x) \rightarrow \sigma + 1 - \gamma \leq 1$, as $|x| \rightarrow \infty$.*

The SIE class of utility functions is compatible with any theory of time preferences where preferences are separable in time and outcomes. Among others, this includes the following models that we consider below: the general hyperbolic discounting model, the (β, δ) class of quasi-hyperbolic discounting models, the subadditive discounting models, models where uncertainty is

⁵ This imposes loss aversion in the domain of losses in the same manner as under prospect theory; see Part 1 of the book.

incorporated, attribute-based models, and the reference time theory. Hence, the SIE class should be very useful.

Like LP, we have explained the sign and magnitude effects through the utility function. We now examine the resulting implications for the parameter of loss aversion, through an example. To give a feel for the issues, use the following parameter values for the SIE class of utility functions: $\mu = 1, \theta = \frac{1}{2}, \lambda = 2, 0 < \sigma = \gamma = \frac{1}{2}$. These satisfy the restrictions on the parameters in (10.10). With these parameter values, the SIE utility function (10.10) takes the form:

$$u(x) = \begin{cases} x^{\frac{1}{2}} (1+x)^{\frac{1}{2}} & \text{if } x \geq 0 \\ -2u(-x) = -2(-x)^{\frac{1}{2}} (1-x)^{\frac{1}{2}} & \text{if } x < 0 \end{cases}. \quad (10.12)$$

The *generalized hyperbolic discount function* (see (10.16) below), is

$$D(t) = (1 + \alpha t)^{-\sigma/\alpha}, \alpha, \sigma > 0. \quad (10.13)$$

Let $\alpha = 1, \sigma = 2$, then (10.13) takes the form

$$D(t) = (1 + t)^{-2}. \quad (10.14)$$

Let $V_0(x, t)$ be the value of x received at time t , discounted back to time 0.

$$V_0(x, t) = D(t) u(x).$$

Then (10.12), (10.14) give:

$$V_0(x, t) = \begin{cases} (1+t)^{-2} \left(x^{\frac{1}{2}} (1+x)^{\frac{1}{2}} \right) & \text{if } x \geq 0 \\ (1+t)^{-2} \left(-2(1+t) (-x)^{\frac{1}{2}} (1-x)^{\frac{1}{2}} \right) & \text{if } x < 0 \end{cases}. \quad (10.15)$$

Comparing the two rows in (10.15), we see that gains and losses now have the same discount function, $D(0, t) = (1 + t)^{-2}$. But the parameter of loss aversion, $\lambda = 2(1 + t)$, depends on the time, t , when x is received. In particular, $\lambda \rightarrow \infty$ as $t \rightarrow \infty$. We know of no robust empirical evidence that supports this. al-Nowaihi and Dhami (2008a) propose an alternative explanation of the sign effect. Unlike LP, they do not put the burden of adjustment on the utility function. Rather, they posit different discount functions for gains and losses, which enables them to explain the sign effect. In particular, they keep the parameter of loss aversion fixed, which is consistent with the experimental evidence.

10.3 Explaining the common difference effect

The *common difference effect*, which is a violation of *stationarity* has already been described above. Stationarity requires that preferences over outcome–time pairs do not alter as we adjust all time intervals equally. Example 9.1 nicely illustrates a violation of stationarity, which gives rise to the common difference effect. This section examines alternative explanations for the common difference effect.

10.3.1 Hyperbolic discounting

Hyperbolic discounting is one of the leading candidates for explaining the common difference effect. In this section, we consider the *general form of hyperbolic discounting*, due to Loewenstein and Prelec (1992), and the *quasi-hyperbolic form*, also known as the (β, δ) form, due to Phelps and Pollak (1968) and later popularized by Laibson (1997) who also drew out a much richer set of implications.

THE GENERAL MODEL OF HYPERBOLIC DISCOUNTING

The discount function in the general hyperbolic discounting function is given by⁶

$$D(t) = (1 + \alpha t)^{-\sigma/\alpha}; \alpha, \sigma > 0. \quad (10.16)$$

It follows that

$$\begin{aligned} \lim_{\alpha \rightarrow 0} D(t) &= \lim_{\alpha \rightarrow 0} (1 + \alpha t)^{-\sigma/\alpha} \\ &= \lim_{m \rightarrow \infty} \left(1 + \frac{t}{m}\right)^{-\sigma m} \quad (\text{by defining } m = \alpha^{-1}) \\ &= e^{-\sigma t} \quad (\text{by using the definition of } e). \end{aligned}$$

Thus, when $\alpha \rightarrow 0$, the generalized hyperbolic function collapses to the exponential discounting function. For very large values of α , this discount function approximates a step function.

We now give the axiomatic derivation in al-Nowaihi and Dhami (2006) for the generalized hyperbolic discounting function. Consider the following axioms, the first of which, impatience, has already been introduced above as A0:

B0: Impatience: $D : [0, \infty) \rightarrow (0, 1]$ is a continuous and strictly decreasing function with $D(0) = 1$ and $D(t) \rightarrow 0$ as $t \rightarrow \infty$.

B1: Common difference effect with quadratic time delay: If $0 < z < z'$, $v(z) = D(t) v(z')$ and $t' > 0$, then $D(t') v(z) = D(t' + t + \alpha t' t) v(z')$, $\alpha > 0$.

Notice that in EDU, $\alpha = 0$, hence, EDU violates B1. Under quadratic delay, relative to EDU, the value of the current reward increases disproportionately more as we approach the present, starting from some point in the future.

Proposition 10.6 (al-Nowaihi and Dhami, 2006): *B0 and B1 imply that the discount factor is a generalized hyperbola: $D(t) = (1 + \alpha t)^{-\frac{\sigma}{\alpha}}$, $\sigma > 0$, $t \geq 0$, where α is given in B1.*

Proof: Let

$$0 < z < z'. \quad (10.17)$$

Assume that an individual is indifferent between receiving the amount z now and receiving the amount z' , t periods from now. Then, letting v be the utility function and D the discount factor, we get

⁶ See also Harvey (1986) for an earlier development.

$$v(z) = D(t) v(z'). \quad (10.18)$$

Multiply (10.18) by $D(t')$, where $t' > 0$, to get

$$D(t') v(z) = D(t') D(t) v(z'). \quad (10.19)$$

Axiom B1, (10.17) and (10.18) give

$$D(t') v(z) = D(t' + t + \alpha t' t) v(z'), \alpha > 0. \quad (10.20)$$

Equations (10.19) and (10.20) give

$$D(t' + t + \alpha t' t) = D(t') D(t). \quad (10.21)$$

Let

$$X = 1 + \alpha t', Y = 1 + \alpha t, \quad (10.22)$$

hence,

$$t' = \frac{X-1}{\alpha}, \quad t = \frac{Y-1}{\alpha}, \quad t' + t + \alpha t' t = \frac{XY-1}{\alpha}. \quad (10.23)$$

Define the function $G : [1, \infty) \rightarrow (0, \infty)$ by

$$G(X) = D\left(\frac{X-1}{\alpha}\right). \quad (10.24)$$

Hence,

$$G(Y) = D\left(\frac{Y-1}{\alpha}\right), \quad G(XY) = D\left(\frac{XY-1}{\alpha}\right). \quad (10.25)$$

From (10.21), (10.23), (10.24), and (10.25)

$$G(XY) = D\left(\frac{XY-1}{\alpha}\right) = D(t' + t + \alpha t' t) = D(t') D(t) \quad (10.26)$$

$$= D\left(\frac{X-1}{\alpha}\right) D\left(\frac{Y-1}{\alpha}\right) = G(X) G(Y). \quad (10.27)$$

Define the function $h : [0, \infty) \rightarrow (0, \infty)$ by

$$h(z) = G(e^z), \quad z \geq 0. \quad (10.28)$$

Hence, and in the light of axiom B0, and (10.24), (10.27), $h : [0, \infty) \rightarrow (0, \infty)$ is strictly decreasing (in an arbitrarily small interval), and

$$h(z + z') = h(z) h(z'). \quad (10.29)$$

It is well known, and readily checked,⁷ that the solution of the functional equation (10.29) is the exponential function.

$$h(z) = e^{cz}, \quad z \geq 0, \quad c < 0. \quad (10.30)$$

From (10.28), (10.30) we get that

$$G(e^z) = e^{cz} = (e^z)^c \Leftrightarrow G(Y) = Y^c. \quad (10.31)$$

From (10.23), (10.25) we get

$$G(Y) = D\left(\frac{Y-1}{\alpha}\right) = D(t). \quad (10.32)$$

From (10.22), $Y = 1 + \alpha t$. Using this, in conjunction with (10.31), (10.32) we get that

$$D(t) = (1 + \alpha t)^c. \quad (10.33)$$

Let

$$\sigma = -\alpha c. \quad (10.34)$$

Equations (10.33), (10.34) give

$$D(t) = (1 + \alpha t)^{-\frac{\sigma}{\alpha}}, \quad \alpha, \sigma > 0, \quad t \geq 0, \quad (10.35)$$

where $\sigma > 0$ because $\alpha > 0$ and $c < 0$. Thus, under the axioms B0, B1, the discount function takes the general hyperbolic form, as claimed. ■

Recall the definition of the discount rate $\theta(t)$ in (9.4). Corollary 10.1 below derives the implications of hyperbolic discounting for the discount rate.

Corollary 10.1 *B0 and B1 imply that $\theta(t) = -\frac{\dot{D}}{D} = \frac{\sigma}{1+\alpha t}$. Hence, the discount rate, $\theta(t)$, is positive and declining in t .*

Corollary 10.1 establishes the result on declining discount rates, which is consistent with the evidence in Section 9.4.1 above.

THE QUASI-HYPERBOLIC MODEL

A simpler and more tractable method for modeling declining discount rates is the *quasi-hyperbolic form*, which is also popularly known as the (β, δ) form of hyperbolic discounting. Under quasi-hyperbolic discounting, a dated stream of consumption $(c_0, c_1, \dots, c_T)$ is evaluated in the following manner.

⁷ See, for example, Corollary 1.4.11 in Eichhorn (1978).

$$U(c_0, c_1, \dots, c_T) = u(c_0) + \beta \sum_{t=1}^T \delta^t u(c_t), 0 < \beta < 1. \quad (10.36)$$

The functional form in (10.36) was originally introduced by Phelps and Pollak (1968). Laibson (1994, 1997) is to be largely credited for reviving interest in it and developing several new implications. In this formulation, δ plays the same role that it plays in the EDU model. The innovation is the presence of the term $\beta \in (0, 1)$ that shrinks the value of future lifetime utility relative to current utility, thereby creating an additional *present bias for current consumption*. This feature leads to the time inconsistency problem. When making a choice between two dates $t > 0$ and $t' > t$, the parameter β washes out, and choices are made as under EDU. However, when these choices are brought forward by t periods, i.e., between two dates 0 and $t' - t$, then the present bias for consumption kicks in through the parameter β , potentially reversing the earlier choice. Hence, this gives rise to a common difference effect.

The discount factor between time periods 0 and 1 is $\beta\delta = \frac{1}{1+\theta_0}$, where θ_0 , the effective one-period discount rate between times 0 and 1, is

$$\theta_0 = \frac{1 - \beta\delta}{\beta\delta}. \quad (10.37)$$

By contrast, the discount factor between time periods $\tau > 0$ and $\tau + 1$ is $\delta = \frac{1}{1+\theta_\tau}$, so the effective discount rate, θ_τ , between these two periods is

$$\theta_\tau = \frac{1 - \delta}{\delta}, 0 < \tau \leq T. \quad (10.38)$$

From (10.37), (10.38), and using $0 < \beta < 1$, it follows that $\theta_\tau < \theta_0$. It also follows that the discount rate is a step function. The discount rate that applies to current (time 0) choices, θ_0 , is high, but for subsequent choices, it permanently steps down to a lower value, θ_τ , $\tau = 1, 2, 3, \dots$

The main difference between the general form of hyperbolic discounting and the (β, δ) form is the following. As we approach the present, having started off at some time in the future, the general hyperbolic form exhibits continuously increasing impatience, while in the (β, δ) form, there is a sudden and discontinuous increase in impatience at the initial time. We plot in Figure 10.1, the sequence of discount factors for the exponential discount function $(\delta, \delta^2, \dots)$, the quasi-hyperbolic discount function $(1, \beta\delta, \beta\delta^2, \dots)$, and the generalized hyperbolic discount function $(1, (1 + \alpha)^{-\sigma/\alpha}, (1 + 2\alpha)^{-\sigma/\alpha}, \dots)$.⁸ These discount factors are shown, respectively, by the continuous bold curve, the lighter step function, and the dashed curve. We use the following calibration values for the discount factors suggested by Laibson (1994): $\delta = 0.95$ for the exponential, $(\beta, \delta) = (0.5, 0.975)$ for the quasi-hyperbolic, and $(\alpha, \sigma) = (3, 1)$ for the generalized hyperbolic. Of these, only the quasi-hyperbolic discount factor is discontinuous, and plots as a step function. All three discount factors corresponding to the three different discount functions are decreasing functions. However, the two discount factors corresponding to the hyperbolic functions show relatively much steeper initial drops, and then flatten out. Comparing the exponential and the general hyperbolic functions, the latter exhibits a much steeper increase in impatience as one approaches the present time period.

⁸ Figure 10.1 plots the discount factors. It is not to be confused with Figure 9.1, which plots the discount rate for different time delays in rewards.

Figure 10.1 The discount factors for various discount functions: Exponential (continuous bold curve), quasi-hyperbolic (lighter step function), and generalized hyperbolic (dashed curve).

Example 10.2 (*Explanation of Thaler's example*): Let us use quasi-hyperbolic discounting to explain Thaler's (1981) apples example (Example 9.1, above). Let $u(x)$ be the utility from outcome x . Under quasi-hyperbolic discounting, the preference for one apple today to two apples tomorrow implies that

$$u(1) > \beta \delta u(2). \quad (10.39)$$

The preference for two apples in 51 days to one apple in 50 days implies that

$$u(1) < \delta u(2). \quad (10.40)$$

(10.39) and (10.40) imply that

$$\beta \delta u(2) < u(1) < \delta u(2). \quad (10.41)$$

(10.41) can be consistent with hyperbolic discounting. For instance, the values for the parameters used in Figure 10.1 above, $(\beta, \delta) = (0.5, 0.975)$, and an identity utility function, $u(x) = x$, satisfy (10.41).

EMPIRICAL EVIDENCE ON HYPERBOLIC DISCOUNTING

We shall only briefly survey the extensive evidence on hyperbolic discounting.⁹ Cropper et al. (1992) considered the trade-off between lives saved today and in the future, from implementing environmental cleanup programs. The cleanup of hazardous waste is costly, and while it may save some lives today, there is a greater likelihood of saving a larger number of lives in the future. They

⁹ The interested reader can consult the extensive survey in Frederick et al. (2002). A very large number of studies support hyperbolic discounting. See, for instance, Ainslie (1975), Thaler (1981), Loewenstein and Prelec (1992), Green and Myerson (1996), Kirby (1997), and Kim and Zauberman (2009).

put subjects in experiments in the role of social planners, and elicited their discount rates from the choices among hypothetical alternatives.

A total of 3,200 subjects were given choices of the following form. Without new environmental programs, 100 people will die this year from pollution, and 200 people will die $\tau > 0$ years from now. Subjects have to choose between two programs that have identical costs. Program A will save 100 lives now. Program B will save y lives τ years from now. Time τ was varied in units of years, $\tau = 5, 10, 25, 50, 100$. The number of lives saved in the future, y , was also varied, but typically $y = 200$. The main finding is that people exhibit higher discount rates for short horizons, and lower discount rates for longer horizons. There is also heterogeneity in discount rates among individuals, but no relation was found between elicited discount rates and individual characteristics, such as age, sex, marital status, education, or income.

The authors then fitted two piecewise linear discount rate curves. The first was for data pooled over $\tau = 5, 10$, and the second was for data pooled over $\tau = 25, 50$. The latter curve was significantly flatter. Henderson and Bateman (1995) fitted the data in Cropper et al. (1992) to the more general hyperbolic curve in (9.29). By normalizing $D(0) = 1$, they find that a good fit to the data is given by the hyperbolic discount function $D(\tau) = \frac{1}{1+(0.21)\tau}$.

Viscusi and Huber (2006) use survey evidence and find a declining trend in the discount rate for public goods as the time delay increases, which is consistent with hyperbolic discounting. Ahumada and Gregnani (2007) use quarterly consumer expenditure data from Argentina and test for exponential as well as hyperbolic discounting.¹⁰ They find evidence that consumers procrastinate, as predicted by the hyperbolic discounting model; see Section 11.5 below for the effects of hyperbolic discounting on procrastination. For the time period 2002–2005, a hyperbolic discounting function fits the data quite well. For an earlier period, however, exponential discounting appears more suitable.

Viscusi et al. (2008) give hypothetical choices to a large number of respondents. The respondents are asked to choose among alternative programs to improve the water quality in their regions. In each program, by paying a current cost, respondents can choose a level of improvement in water quality with a time delay. Programs differ in terms of the current cost, level of improvement, and the time delay before the improvement sets in. When the data is fitted to the quasi-hyperbolic model, the estimates of the parameter β range from 0.48 to 0.61.

Using a sample of 2987 Japanese adults, Ikeda et al. (2010) first measure the body mass index (BMI) of the respondents. Then they elicit their discount rates over different horizons by giving subjects a choice between smaller–sooner, and larger–later rewards. There are two main findings. A higher BMI leads to (1) greater impatience that takes the hyperbolic form, and (2) a lower magnitude of the gain–loss asymmetry or sign effect (subjects who exhibit the sign effect have a lower probability of being obese).

Fang and Silverman (2009) consider the 1979 youth cohort of the National Longitudinal Survey of Youth (NLSY). They were interested in the labor force participation and welfare program participation decision of never-married women. Using semi-parametric estimation methods for dynamic discrete choice models, they find evidence of quasi-hyperbolic discounting. In particular, they find that the fitted parameters of the quasi-hyperbolic function are $\beta = 0.338$ and $\delta = 0.88$.

Fang and Wang (2010) allow for the possibility that hyperbolic decision makers may be *naive*. A formal definition is given below in Section 11.5. A hyperbolic decision maker is *naive* if he

¹⁰ They use the generalized method of moments applied to a Euler equation derived in Harris and Laibson (2001a). We derive, below, the Euler equations in macroeconomic models with hyperbolic discounting.

believes that in the future, he has EDU preferences. Such a decision maker underestimates future self-control problems. They find evidence of naivety, and the parameter β in the quasi-hyperbolic model equals 0.72.

Salois and Moss (2011) use annual data on farmland valuations and returns in the US from a 43 year panel. Their estimation equation derives from the change in the value of farmlands between two successive periods. They find that exponential discounting is rejected for six out of their eight panel regions, while quasi-hyperbolic discounting provides a good fit to their data. The parameter β ranges from 0.304 to 0.637 over the eight regions.

Using a variety of time-delay questions, typically of the smaller-sooner versus larger-later choice variety, Benhabib et al. (2010) propose a fixed cost of time delay. Suppose that (z, t) denotes a reward z to be received at time t . Using an incentive compatible elicitation mechanism, they estimate the following discount function, D , that nests several possibilities.

$$D(z, t; \nu, r, \alpha, b) = \begin{cases} 1 & \text{if } t = 0 \\ \alpha [1 - (1 - \nu) rt]^{\frac{1}{1-\nu}} - \frac{b}{z} & \text{if } t > 0 \end{cases}.$$

A simple calculation shows that

$$D(z, t; 1, r, 1, 0) = e^{-rt}; D(z, t; 2, r, 1, 0) = \frac{1}{1 + rt}; D(z, t; 1, r, \alpha, 0) = \alpha e^{-rt}. \quad (10.42)$$

From (10.42), we get the following cases: (i) For $\nu = 1, \alpha = 1, b = 0$, we get exponential discounting. (ii) For $\nu = 2, \alpha = 1, b = 0$, we get hyperbolic discounting. (iii) For $\nu = 1, \alpha < 1, b = 0$, we get quasi-hyperbolic discounting. (iv) For the most general case with $b > 0$, we have a fixed cost of receiving a future reward. The larger the reward, z , the smaller is this cost. Not surprisingly, this formulation can account for the magnitude effect described above. Let us call this case *discounting with fixed cost*. But there is no presumption that this discount function can explain several other anomalies such as subadditivity, although the sign effect can be explained if one uses the SIE utility function in conjunction with this discount function. Obviously, it can also explain the common difference effect.

The main findings of Benhabib et al. (2010) are as follows. (1) Exponential discounting is rejected. (2) The discount rate is declining over time, which indicates the presence of a *present bias* in time preferences. (3) The most general formulation, discounting with fixed costs ($b > 0$), is preferred to hyperbolic discounting. The authors are careful to stress that (p. 223) “Experiments with relatively large rewards are needed to confirm the fixed cost representation of present bias that we identify in the experimental data.” By contrast, Andersen et al. (2011) show that their experimental results with 413 adult Danes are consistent with exponential discounting, and the elicited discount rates are quite low. They find no evidence of quasi-hyperbolic discounting, or of discounting with fixed costs.

Tanaka et al. (2010) estimate the Benhabib et al. (2010) discount function using high stakes experiments in Vietnam in a tightly controlled set of experiments. They find evidence for quasi-hyperbolic discounting. The estimated value of β is 0.644, which is consistent with the typical estimates of this parameter. Interestingly, the present bias is found irrespective of the level of incomes, or the economic circumstances of the subjects.

Kosse and Pfeiffer (2013) focus on the quasi-hyperbolic (β, δ) model. They examined the possibility of intergenerational transmission of patience between mother and child. They first elicit the β, δ parameters for 213 mothers, using choices between smaller-sooner and larger-later rewards

in an incentive compatible manner. Then they elicit the same discounting parameters for the children. Children were given a choice of receiving a pack of gummy bears at the start of the mother's interview or two packs at the end of the interview. A probit regression was then run in which the child's β parameter was the dependent parameter, and the mother's elicited β, δ parameters were the independent variables. A higher value of the mother's β parameter (recall that $\beta = 1$ gives the EDU model) was found to significantly, and positively, influence the probability that the child would choose the delayed reward (i.e., exhibit greater patience).

An emerging literature explores the relation between risk preferences and time preferences. We consider this issue in more detail in Section 10.3.3 below; see also Part 1 of the book for a consideration of these issues. The basic idea is that subjects in experiments may consider future rewards to be uncertain, even when no such uncertainty can be inferred from the instructions in the experiment. Hence, in making choices between, say, smaller-sooner and larger-later rewards, perceived uncertainty of the larger-later reward may distort the elicited time preferences. Thus, the claim is that time preferences can potentially be reversed when risk preferences are added to the problem and vice-versa (Keren and Roelofsma, 1995; Weber and Chapman, 2005; Baucells and Heukampf, 2010). Greater risk aversion may also be associated with greater impatience (Anderhub et al., 2001).

A range of studies allow for the simultaneous presence of uncertainty and time delay, and find significant interaction effects between the two.¹¹ Epper et al. (2011) allow for non-linear probability weighting under uncertainty, and consider the interaction effects between uncertainty and time delay. An incentive compatible mechanism is used to elicit choices. They find that their data is best described by non-linear probability weighting and hyperbolic time delay. Subjects who exhibit more pronounced departures from linear weighting of probabilities also display a greater departure from exponential discounting.

In summary, the weight of the evidence supports declining discount rates. There may be less agreement about whether the pattern of declining rates is hyperbolic, or not. The estimated β parameter in (β, δ) models is typically below 1 ($\beta = 1$ corresponds to EDU), suggesting that present bias is present in the data. More realistic models may need to interact hyperbolic discounting with risk preferences; this is already an active area of research that we report on extensively in this book.

10.3.2 Subadditive discounting

The explanation of further developments in time discounting requires a slightly more formal definition of a discount function. Suppose that we are interested in the discount function between time periods $r \geq 0$ and $t \geq r$, then the following definition of an *interval discount function* is suitable.

Definition 10.3 (*Interval discount functions*): Let

$$\Delta = \{(r, t) \in \mathbb{R} \times \mathbb{R} : 0 \leq r \leq t\}. \quad (10.43)$$

A discount function is a mapping, $D : \Delta \rightarrow (0, 1]$, satisfying:

- (i) For each $r \in [0, \infty)$, $D(r, t)$ is a strictly decreasing function of $t \in [r, \infty)$ into $(0, 1]$ with $D(r, r) = 1$.

¹¹ See, for instance, Abdellaoui et al. (2011), Coble and Lusk (2010), Baucells and Heukampf (2010), Anderson and Stafford (2009), Weber and Chapman (2005), and Keren and Roelofsma (1995).

- (ii) For each $t \in [0, \infty)$, $D(r, t)$ is a strictly increasing function of $r \in [0, t]$ into $(0, 1]$. Furthermore, if D satisfies (i) with “into” replaced with “onto,” then we call D a continuous discount function.

As one expands the interval $[r, t]$, the discount factor applied to the interval falls. This can happen in one of two ways: an increase in t (Definition 10.3(i)) and a decrease in r (Definition 10.3(ii)). A continuous discount function $D(r, t)$ is continuous in t ; see al-Nowaihi and Dhami (2008a) for a formal proof. We leave the proof of the next proposition as an exercise.

Proposition 10.7 (al-Nowaihi and Dhami, 2008a): Let D be a continuous discount function and let $v(x)$ be the utility from outcome x . Suppose $r \geq 0$. If $0 < x \leq y$, or if $y \leq x < 0$, then $v(x) = v(y) D(r, t)$ for some $t \in [r, \infty)$.

Read (2001) and Scholten and Read (2006a) found experimental evidence for *subadditivity*, which we now formally define in terms of the interval discount function.

Definition 10.4 (Additivity): A discount function, $D(r, t)$, is:

$$\begin{cases} \text{Additive if} & D(r, s) D(s, t) = D(r, t), & \text{for } r \leq s \leq t, \\ \text{Subadditive if} & D(r, s) D(s, t) < D(r, t), & \text{for } r < s < t, \\ \text{Superadditive if} & D(r, s) D(s, t) > D(r, t), & \text{for } r < s < t. \end{cases}$$

In Definition 10.4, additivity implies that discounting a quantity from time t back to time s , and then further back to time r , is the same as discounting that quantity from time t back to time r in one step. In other words, breaking an interval into subintervals has no effect on discounting. However, in the other two cases, it does have an effect. Under subadditive discounting, there is more discounting over the subdivided intervals (future utilities are shrunk more), while the converse is true under superadditive discounting.

Example 10.3 Consider the following example that illustrates the importance of subadditive discounting. Consider three dates, $0 \leq r < s < t$. A risk neutral investor faces an investment opportunity to invest \$ a at date r that materializes at date t and yields the amount \$ c . At date r , the investor is assumed to have no opportunity cost of his funds.

Suppose that there are two kinds of investors. Investor 1 discounts over the whole interval $[r, t]$, so he invests if $a < D(r, t)c$. By contrast, investor 2 uses subadditive discounting and first discounts the final amount from time t to s and then back from time s to r . Thus, investor 2 invests if $a < D(r, s) D(s, t) c$. If the following condition holds

$$D(r, s) D(s, t) c < a < D(r, t) c,$$

then investor 1 invests, but investor 2 does not invest.

Under exponential discounting, if we move a fixed interval of time, say, $[r, s]$, $r < s$, to another date, $[r + t, s + t]$, where $t \geq 0$, then discounting over that interval stays the same (constant impatience). However, two other possibilities may also arise. In making decisions about time intervals of a fixed size, that recede into the future, one may become more patient (*declining impatience*), as in models of hyperbolic discounting. The converse of this is *increasing impatience*. We formalize these concepts in the next definition.

Definition 10.5 A discount function, $D(r, s)$, exhibits:¹²

¹² Some authors use “present bias” for what we call “declining impatience.” But other authors use “present bias” to mean that the discount function, $D(s, t)$ is declining in t . So we prefer “declining impatience” to avoid confusion.

$$\begin{cases} \text{declining impatience if} & D(r, s) < D(r + t, s + t), & \text{for } t > 0 \text{ and } r < s, \\ \text{constant impatience if} & D(r, s) = D(r + t, s + t), & \text{for } t \geq 0 \text{ and } r \leq s, \\ \text{increasing impatience if} & D(r, s) > D(r + t, s + t), & \text{for } t > 0 \text{ and } r < s. \end{cases}$$

Based on the empirical evidence, Scholten and Read (2006a) developed a specific interval discount function, which we shall call the *RS-discount function*; this is stated below.

$$D(r, t) = [1 + \alpha(t^\tau - r^\tau)^\rho]^{-\frac{\beta}{\alpha}}, 0 \leq r \leq t, \alpha > 0, \beta > 0, \rho > 0, \tau > 0. \quad (10.44)$$

The RS discount function is extremely flexible, and depending on various parameter values, it can incorporate additivity, subadditivity, superadditivity, declining impatience, constant impatience, and increasing impatience; see al-Nowaihi and Dhami (2008a) for the relevant proofs. On account of its generality relative to the other discounting functions, we state some of its properties in the following proposition (one of the exercises asks you to prove it).

Proposition 10.8 (*al-Nowaihi and Dhami, 2008a*) Let $D(r, t)$ be the RS-discount function in (10.44), then:

- (a) If $0 < \rho \leq 1$, then D is subadditive.
- (b) If $\rho > 1$, then D is neither subadditive, additive, nor superadditive.
- (ci) If $0 < \tau < 1$, then D exhibits declining impatience.
- (cii) If $\tau = 1$, then D exhibits constant impatience.
- (ciii) If $\tau > 1$, then D exhibits increasing impatience.

We can now see the interpretation of the parameters τ and ρ in the RS-discount function (10.44).¹³ The parameter τ controls impatience, independently of the values of the other parameters α, β, ρ . In particular, $0 < \tau < 1$ gives declining impatience, $\tau = 1$ gives constant impatience, and $\tau > 1$ gives increasing impatience. If $0 < \rho \leq 1$, then we get subadditivity, irrespective of the values of the other parameters α, β, τ . However, if $\rho > 1$, then (10.44) can be neither subadditive, additive, nor superadditive. Depending on the particular values, we may have declining impatience, constant impatience, or increasing impatience.

Example 10.4 Consider the Read–Scholten discount function that we define in (10.44), with $\tau = 1$, $\rho = 0.6$, $\alpha = \beta = 0.5$. Let the utility function be $u(x) = x$ for $x \geq 0$. We can then compute

$$D(0, 4) = (1 + 0.5(4)^{0.6})^{-1}, D(4, 10) = (1 + 0.5(6)^{0.6})^{-1}, D(0, 10) = (1 + 0.5(10)^{0.6})^{-1},$$

which respectively, equal 0.46540, 0.40567, 0.33439. As expected, $D(0, t)$ is declining in t , and $D(r, 10)$ is increasing in r (see Definition 10.3). Let the unit of time be months. Then a decision maker who discounts over the entire interval $[0, 10]$ is indifferent between receiving \$15 in 10 months time and \$5.0159 at date $r = 0$ because

$$5.0159 = D(0, 10) 15.$$

It is common to use “stationarity” for what we call “constant impatience.” We prefer the latter, to be in conformity with “declining impatience” and “increasing impatience.”

¹³ Another reason for stating Proposition 10.8 formally is that there are several errors in the original exposition. Scholten and Read (2006a), bottom of p. 1425, state erroneously that $\alpha > 0$ implies subadditivity and $\rho > 1$ implies superadditivity. Their statement that $0 < \tau < 1$ implies declining impatience is correct but incomplete.

However, unlike the additivity assumption made in the exponential discount function, we have subadditive discounting,

$$D(0, 4) D(4, 10) = 0.1888 < D(0, 10) = 0.33439.$$

Thus, \$15 discounted back to time $r = 0$ using the two subintervals $(0, 4)$ and $(4, 10)$ leads to a lower present value $D(0, 4) D(4, 10) 15 = 2.832 < 5.0159$. It follows that under subadditive discounting, two different decision makers, one who uses a longer interval to discount and another who uses the two smaller subintervals, may make very different decisions. Since $\tau = 1$, we have from Proposition 10.8(cii) that the discount function exhibits constant impatience. For instance, $D(0, 4) = D(0 + 4, 4 + 4) = 0.46540$.

Example 10.5 (Explanation of Thaler's apples example using subadditivity; al-Nowaihi and Dhami, 2008a): Consider the explanation of the common difference effect, using subadditivity of the discount function, and Thaler's apples example. Denote by $u(x)$, the utility from outcome x . A decision maker prefers one apple today to two apples tomorrow, so that

$$u(1) > D(0, 1)u(2). \quad (10.45)$$

However, the decision maker, today, prefers to receive two apples in 51 days time to receiving one apple in 50 days time, so that

$$D(0, 50)u(1) < D(0, 51)u(2). \quad (10.46)$$

From (10.45) and (10.46) we get

$$D(0, 1)D(0, 50) < D(0, 51). \quad (10.47)$$

If we assume additivity (as in hyperbolic discounting and in the EDU model), then $D(0, 51) = D(0, 50)D(50, 51)$. Hence, under additivity, (10.47) implies that

$$D(0, 1) < D(50, 51),$$

so, under additivity, the discount function of the decision maker must exhibit declining impatience (see Definition 10.5) in order to explain the common difference effect.

An alternative explanation of the common difference effect is to relax additivity, and suppose instead that the discount function exhibits subadditivity. To see this, assume constant impatience (see Definition 10.5) of the discount function, so that $D(0, 1) = D(50, 51)$. Then (10.47) gives

$$D(0, 50)D(50, 51) < D(0, 51),$$

which is exactly the definition of subadditivity given in Definition 10.4, above. Thus, an alternative explanation of the common difference effect is to assume constant impatience (as in the EDU model), but assume subadditivity of the discount function (unlike the EDU model). It is possible that the common difference effect could be due to both declining impatience and subadditivity. Read (2001) conducted a series of experiments that tested for the common difference effect, and the experimental design could also discriminate between subadditivity and declining impatience. He found support for the common difference effect and for subadditivity, but rejected declining impatience in favor of constant impatience.

10.3.3 Uncertainty

A test of a theory (T) is always a test of T plus auxiliary assumptions (A). Thus, a refutation of T and A may be a refutation of A, rather than T. However, since A is often left implicit, a refutation of T and A may be misconstrued as a refutation of T, rather than A. A case in point may be T = “exponential discounting” and A = “uncertainty is not relevant.” Halevy (2008) argues that the common difference effect may, in fact, be a refutation of expected utility (EU) rather than exponential discounting.

Despite the experimenters’ best efforts to eliminate uncertainty, there may be a residual risk in the minds of subjects that they will not receive their promised payoffs. This could be a purely evolutionary instinct in which subjects associate the future with a risk that the outcomes might not materialize (supply side uncertainty). Or there might be a probability that the decision maker himself is not alive to receive the outcome in the future (demand side uncertainty). Tanaka et al. (2010) use an experimental design that minimizes such uncertainty by giving the money to be distributed to subjects in experiments, up-front, to a trusted third party. Further, they require the trusted third party to sign documents that the money will indeed be given to the subjects in experiments. However, this level of experimental control is not a feature of most time discounting experiments.

If subjects are EU maximizers, then risk does not matter (Example 10.6, below). However, if subjects overweight low probabilities and underweight high probabilities (as in many non-EU theories), then risk matters (Example 10.7, below). Moreover, surprisingly, the *lower* the residual risk, the *greater* will be its effect (Example 10.8, below).¹⁴

Consider the following three examples. They all involve a choice between receiving \$1000 now, or \$1100 next year, and a second choice between receiving these two sums 10 and 11 years from now, respectively. There is some probability that a future payoff is not received. We use the SIE utility function (10.12), so that

$$u(1000) = 1000.5 \text{ and } u(1100) = 1100.5. \quad (10.48)$$

Let the discount function be $D(s, t)$. We shall invoke EU and some non-EU theories of decision making in these examples; the details of the relevant decision theories can be found in Part I of the book. Let the probability weighting function be $w(p)$, where p is the probability that the outcome will actually materialize one year from now. In the special case of EU, $w(p) = p$. We assume independence of probabilities across time, so that the probability of receiving the payoff t years from now is p^t . We take the current level of wealth, w_0 , as reference wealth, and the present time to be $r = 0$.

Thus, if there is no common difference effect, then

$$(1100, 1) \prec (1000, 0) \Rightarrow (1100, 11) \prec (1000, 10). \quad (10.49)$$

Consider first the choice between periods 0 and 1. There is a probability $p \geq 0$ that the amount in period 1 will not be received. Using Definition 10.3, under *rank dependent utility* (RDU) and

¹⁴ So, experimenters, by doing their best to reduce residual risk with the aim of getting a sharper refutation of exponential discounting may, actually, be achieving the opposite.

prospect theory (PT), the present discounted utility of (1100, 1) is $D(0, 1) w(p) u(1100)$, thus¹⁵

$$(1100, 1) \prec (1000, 0) \Leftrightarrow D(0, 1) w(p) u(1100) < u(1000). \quad (10.50)$$

Similarly, the probability of receiving the amounts in periods 10 and 11 is, respectively, p^{10} and p^{11} , hence,

$$(1100, 11) \prec (1000, 10) \Leftrightarrow D(0, 11) w(p^{11}) u(1100) < D(0, 10) w(p^{10}) u(1000). \quad (10.51)$$

Example 10.6 (EDU with EU; al-Nowaihi and Dhami 2008a): Assume that the decision makers use (i) EDU, so $D(s, t) = e^{-\theta(t-s)}$, $\theta > 0$, and (ii) EU, so $w(p) = p$. Substitute in (10.50), (10.51) to get:

$$(1100, 1) \prec (1000, 0) \Leftrightarrow e^{-\theta} p u(1100) < u(1000), \quad (10.52)$$

$$(1100, 11) \prec (1000, 10) \Leftrightarrow e^{-11\theta} p^{11} u(1100) < e^{-10\theta} p^{10} u(1000), \quad (10.53)$$

(10.53) is equivalent to:

$$(1100, 11) \prec (1000, 10) \Leftrightarrow e^{-\theta} p u(1100) < u(1000). \quad (10.54)$$

From (10.52) and (10.54), we see that $(1100, 1) \prec (1000, 0) \Leftrightarrow (1100, 11) \prec (1000, 10)$. Thus, (1) payoff risk about the future, (2) EDU, and (3) EU imply no common difference effect. Hence, the observation of a common difference effect is a rejection of the joint hypothesis of payoff risk, EDU, and EU. Thus, it would imply the rejection of one or the other (or all three), but not, necessarily, EDU.

Example 10.7 (EDU with non-EU; al-Nowaihi and Dhami 2008a): We take cumulative prospect theory (Tversky and Kahneman, 1992) as our model of non-EU, while continuing to assume EDU and payoff risk. Take $D(r, t) = e^{-\theta(t-r)}$, $\theta = 0.04$, and $w(p) = e^{-(\ln p)^{0.5}}$ (the Prelec (1998) probability weighting function with $\beta = 1$, $\alpha = 0.5$; see Chapter 2 for the details). Let $p = 0.98$, so payoff risk is quite low. Substitute in (10.50), (10.51), using the utility values in (10.48), to get:

$$(1100, 1) \prec (1000, 0) \Leftrightarrow e^{-0.04} e^{-(\ln 0.98)^{0.5}} 1100.5 < 1000.5, \quad (10.55)$$

$$(1100, 11) \prec (1000, 10) \Leftrightarrow e^{-0.44} e^{-(\ln(0.98)^{11})^{0.5}} 1100.5 < e^{-0.4} e^{-(\ln(0.98)^{10})^{0.5}} 1000.5. \quad (10.56)$$

A simple calculation shows that the inequality in (10.55) holds, while the corresponding inequality in (10.56) does not hold. Hence, $(1100, 1) \prec (1000, 0)$, but $(1100, 11) \succ (1000, 10)$, so the common difference effect is found. Thus, it is quite possible that the finding of a common difference effect is not a refutation of EDU, but of payoff uncertainty and EU.

¹⁵ As in EU, one can define outcomes relative to a reference point under RDU. However, EU and RDU make no distinction in human behavior in the domain of gains and losses. By contrast, PT fundamentally distinguishes between behavior in gains and losses. The arguments below do not hinge on this difference. Hence, the reader may either take u to be the standard utility function under EU and RDU with the caveat that all outcomes are expressed relative to the reference wealth, w_0 . Or, the reader may imagine that the decision maker uses PT to deal with risk, in which case, u is the usual utility function under PT.

Example 10.8 (It's the certainty effect that's doing the work; al-Nowaihi and Dhami 2008a): Recall that in Example 10.7 there was near certainty because $p = 0.98$. We call this the certainty effect. Consider the same structure as for Example 10.7, except that now we remove the certainty effect by reducing the probability of non-receipt of the reward to $p = 0.4$, rather than $p = 0.98$. Substitute in (10.50), (10.51), and using the utility values in (10.48), to get:

$$(1100, 1) < (1000, 0) \Leftrightarrow e^{-0.04} e^{-(\ln 0.4)^{0.5}} 1100.5 < 1000.5. \quad (10.57)$$

$$(1100, 11) < (1000, 10) \Leftrightarrow e^{-0.44} e^{-(\ln(0.4)^{11})^{0.5}} 1100.5 < e^{-0.4} e^{-(\ln(0.4)^{10})^{0.5}} 1000.5. \quad (10.58)$$

A simple calculation shows that both inequalities, (10.57) and (10.58), are satisfied. Hence, $(1100, 1) < (1000, 0)$ and $(1100, 11) < (1000, 10)$. Thus, the common difference effect is due to the certainty effect in particular (as in Example 10.7), rather than uncertainty as such (as in the current example).

The typical empirical exercises use EU in conjunction with EDU. Tanaka et al. (2010) relax both these assumptions. They estimate a prospect theory utility function with the Benhabib et al. (2010) discount function that can nest the EDU and the quasi-hyperbolic functions. Conducting high stakes experiments in Vietnamese villages they find that there is no correlation in the degree of concavity of the utility function (which measures risk under EU) with income. However, mean income in the villages is correlated with loss aversion.

Examples 10.7 and 10.8 suggest that if the common difference effect is due to the certainty effect alone, rather than a combination of the certainty effect and non-exponential discounting, then the phenomenon should disappear for probabilities around 0.4. A second issue is the relevance of risk for experimental settings when outcome–time pairs are offered. Do subjects mistrust that the experimenter (typically a university researcher) will pay?¹⁶ Do subjects invoke misplaced heuristics and mistakenly believe that future payments may not be made? These questions are deserving of further exploration.

Saito (2011) generalizes the results in Halevy (2008). Saito assumes that as the delay increases, the perceived probability by the decision maker of receiving the outcome, declines. Recall, from Part I of the book, the definitions of the *common ratio effect* and the *certainty effect*. Here, we state these definitions in terms of preferences.

Denote by $X \subset \mathbb{R}$, the set of monetary outcomes. Consider binary atemporal lotteries of the form $(x, p; 0, 1 - p)$, where $x \in X$, and $p \in [0, 1]$ is the perceived probability of receiving x . We are first interested in *risk preferences*, $\succeq^r$, over atemporal lotteries. Denote the preference relation “at least as good as” over the set of such binary lotteries by $\succeq^r$, and let $\sim^r$ and $>^r$ denote, respectively, the corresponding indifference and strict preference relations.

Definition 10.6 (*Common ratio effect*): For any $x, y \in X$, $x < y$, $\bar{p} \in [0, 1]$ and $\mu \in [0, 1]$, let $(x, \bar{p}) \sim^r (y, \mu\bar{p})$. Preferences, $\succeq^r$, exhibit the common ratio effect if

$$\begin{cases} (x, p) <^r (y, \mu p) & \text{for all } 0 < p < \bar{p} \\ (x, p) >^r (y, \mu p) & \text{for all } \bar{p} \leq p \leq 1 \end{cases}.$$

In Definition 10.6, the ratio of probabilities in the two lotteries is always identical. Yet, starting from indifference at $\bar{p}$, a fall in $\bar{p}$ switches preferences towards the lottery with the higher outcome,

¹⁶ Most experiments make clear that there is no risk of not getting the reward; see for instance Thaler (1981, p. 203). See also the remark on Tanaka et al. (2010), above.

but an increase switches preferences to the lottery with the lower outcome. For the special case of $\bar{p} = 1$, the common ratio gives rise to the certainty effect.

Definition 10.7 (*Certainty effect*): For any $x, y \in X$, $x < y$, and $\mu \in [0, 1]$, let $(x, 1) \sim^r (y, \mu)$. Preferences, $\succeq^r$, exhibit the certainty effect, if for $\eta \in (0, 1)$ we have

$$(x, \eta) \prec^r (y, \mu\eta).$$

In Definition 10.7, keeping the ratio of probabilities fixed, the *certainty effect* arises when individuals switch preferences towards the smaller outcome if it is received with certainty. When even a small degree of uncertainty is introduced, the decision maker shifts to the higher outcome.

From a consideration of risk preferences, let us now move on to time preferences. Consider the sequence of dates shown in Figure 10.2. Suppose that a decision maker has time preferences $\succeq_0$ between outcome–time pairs at *time* 0, such that $0 \leq d < t < s$. The outcome–time pairs at time 0 are summarized in the set

$$T_0(X) = \{(x, t) \mid x \in X, t \in \mathbb{R}_+ \text{ and } t \geq 0\}. \quad (10.59)$$

Let $p(t)$ be the probability of receiving an outcome at time t ; this arises on account of the uncertainty about receiving an outcome in the future. The assumption that the probability of receiving a future reward diminishes as one moves further out into the future is formalized as follows:

A1: There is certainty of receiving a current outcome, i.e., $p(0) = 1$. (ii) $p(t)$ is a decreasing and continuous function, and $p(\infty) = 0$.

Let $p(t \mid d)$ be the probability of receiving the outcome at time $t \geq d$, conditional on the decision maker being alive at time d . Thus, $p(t \mid d) = \frac{p(t)}{p(d)}$. Conditional on the individual having survived until time d , define the analogue of (10.59) by

$$T_d(X) = \{(x, t) \mid x \in X, t \in \mathbb{R}_+ \text{ and } t \geq d\}.$$

The corresponding time preferences at time d are denoted by $\succeq_d$. We now focus on the time preferences, $\succeq_d$, of the decision maker over $T_d(X)$, taking into account the future uncertainty of receiving the prize. This also clarifies the relation between $\succeq_d$ (time preferences over outcome–time pairs at time d) and $\succeq^r$ (risk preferences over atemporal lotteries).

Definition 10.8 (*Time preference*): For all times $d \in \mathbb{R}_+$ and $(x, t), (y, s) \in T_d(X)$,

$$(x, t) \succeq_d (y, s) \Leftrightarrow (x, p(t \mid d)) \succeq^r (y, p(s \mid d)).$$

We are now in a position to define quasi-hyperbolic and hyperbolic discounting.

Definition 10.9 (*Quasi-hyperbolic discounting*): Suppose that $x, y \in X$, $t, s \in \mathbb{R}_+$ such that $x < y$ and $t < s$. if $(x, t) \sim_t (y, s)$, then preferences, $\succeq_d$, exhibit quasi-hyperbolic discounting if

Figure 10.2 Sequence of outcome–time pairs.

Source: Saito (2011).

$$(x, t) \prec_d (y, s) \text{ for all } d < t.$$

In Definition 10.9, there are two decision times, t and d such that $d < t$. At time d , the decision maker reports that at the future time period t , he will choose the larger–later option (a patient choice). However, once time t arrives, he switches his preference towards the smaller–sooner option, (x, t) (an impatient choice).

We now define hyperbolic discounting.

Definition 10.10 (*Hyperbolic discounting*): Let $x, y \in X$, $\bar{d}, t, s \in \mathbb{R}_+$ such that $\bar{d} < t < s$, and $x \prec y$. If $(x, t) \sim_{\bar{d}} (y, s)$, then preferences, $\succeq_d$, exhibit hyperbolic discounting if¹⁷

$$\begin{aligned} (x, t) \prec_d (y, s) & \text{ for all } d < \bar{d} \\ (x, t) \succ_d (y, s) & \text{ for all } \bar{d} < d \leq t \end{aligned}$$

The definition of hyperbolic discounting has the following features. (i) A decision maker may at some time $d < \bar{d}$ claim that he will prefer a larger–later reward $((x, t) \prec_d (y, s))$. (ii) However, when time $\bar{d}$ arrives, he professes indifference between (x, t) and (y, s) $((x, t) \sim_{\bar{d}} (y, s))$. (iii) At any time $\bar{d} < d \leq t$, the decision maker becomes sufficiently impatient that he prefers the smaller–sooner reward.

Lemma 10.1 (*Saito, 2011*): If $\succeq_d$ exhibits hyperbolic discounting, it also exhibits quasi-hyperbolic discounting.

We now state the main result that relates risk attitudes to time preferences. This is a generalization of the result in Halevy (2008) and Epper et al. (2011). The reader is asked to prove the result in the problem set.

Proposition 10.9 (*Saito, 2011*): Suppose that Assumption A1 holds.

- (a) $\succeq^r$ exhibits the common ratio effect if and only if $\succeq_d$ exhibits hyperbolic discounting.
- (b) $\succeq^r$ exhibits the certainty effect if and only if $\succeq_d$ exhibits quasi-hyperbolic discounting.

The importance of Proposition 10.9 is that it relates what was traditionally considered the subject matter of risk (common ratio effect) with the subject matter of time discounting (hyperbolic discounting). Since the Allais paradox can be stated as a common ratio violation (see Part I of the book), one intriguing interpretation of Proposition 10.9 is that the Allais paradox causes hyperbolic discounting, a possibility that is already noted in Halevy (2008) and Epper et al. (2011). Yet, and as the author notes, this is not the only possibility. Assumption A1 captures *regular uncertainty*; however, *non-regular uncertainty* (e.g., probability of receiving a future outcome may be drawn from a Poisson distribution) as in Dasgupta and Maskin (2005), may also explain hyperbolic discounting. It is also possible that the Allais paradox and hyperbolic discounting are both caused by a third factor; see for instance, Fudenberg and Levine (2009).

10.4 Attribute-based models

The outcome–time pairs that are to be compared by decision makers may be thought of as consisting of two natural attributes: time of delivery and monetary value. One can then consider the trade-off between the two attributes to determine which time–money pair will be chosen.

¹⁷ This definition also goes through with $\bar{d} \leq t \leq s$ but we wish to make the comparison particularly stark; a similar remark also applies to Definition 10.9, which also goes through with $t \leq s$.

10.4.1 Vague time preferences model

Manzini and Mariotti (2006) develop a theory of *vague time preferences* and discuss the psychological foundations for such an approach. They argue that the choice between, say, receiving \$1000 now and \$1100 next year is *clearer* than the choice between these two sums received 10 and 11 years from now, respectively. Three criteria are proposed to choose between two future outcome–time pairs (x, t) and (y, s) .¹⁸

The *primary criterion* requires that if the difference between the present discounted utility of (x, t) and (y, s) is *not similar* or it is *significantly different*, then choose the alternative that has the higher value. If the two present discounted values are *similar*, then the subject invokes the *secondary criterion* to choose the alternative that has the highest monetary value. If they have the same monetary values, so that the secondary criterion fails, then the subject behaves according to the *tertiary criterion*: “choose the outcome that is delivered sooner.” If all three criteria fail, then the subject is indifferent among the two alternatives.

This model achieves a complete, but intransitive, preference ordering. In particular, indifference here is not an equivalence relationship.¹⁹ In order to make the model operational, we require a definition of the similarity of present values of two outcome–time pairs (see the primary criterion, above). Suppose that two present values are *significantly different* if their difference is greater than $\sigma > 0$. We can state the criteria in this model, formally, as follows by using the interval discount function $D(r, t)$ (Definition 10.3).

Let $<_V$ be the binary relation induced by the vague time preferences model. Let outcomes $x, y \in \mathbb{R}$ and let r, s, t be three time periods such that $0 \leq r < t, r < s$. Then $(x, t) <_V (y, s)$ at time r , if and only if, one of the following holds:

1. (Primary criterion) $D(r, s)u(y) - D(r, t)u(x) > \sigma$, or
2. (Secondary criterion) $D(r, s)u(y) - D(r, t)u(x) \leq \sigma$, and $x < y$, or
3. (Tertiary criterion) $D(r, s)u(y) - D(r, t)u(x) \leq \sigma$, $x = y$, and $s < t$.

One can similarly state the conditions for $(y, s) <_V (x, t)$. More generally, σ can be a “vague-ness function” rather than a scalar; see the original paper for the details. Obviously, if x and y are vectors, then extra criteria can be added. In this model, present utility values whose difference is less than σ are regarded as not significantly different. This could be because, for example, the decision maker is vague about the appropriate objective function, or discount function to use. Therefore, the decision maker does not want the decision to depend too critically on the choice of these functions. On the other hand, the decision maker might be absolutely sure that more is better than less and sooner is better than later. Example 10.9, below, shows how this theory can explain the common difference effect.

Example 10.9 (*al-Nowaihi and Dhami, 2008a*): Consider the choice between receiving \$1000 now and \$1100 next year, and the choice between these two sums received 10 and 11 years from now, respectively. We use the SIE utility function (10.12), so that the utilities of the outcomes are given in (10.48): $u(1000) = 1000.5$ and $u(1100) = 1100.5$. We use the exponential discount function $D(r, t) = e^{-\theta(t-r)}$ with $\theta = 0.1$ and $r = 0$, so $D(0, t) = e^{-0.1t}$.

¹⁸ For an attribute-based model that applies to the problem of cyclic temporal choices, see Manzini and Mariotti (2007).

¹⁹ An equivalence relation on a set is a binary relation that satisfies reflexivity, symmetry, and transitivity. For instance, consider the set of students in a large university and define the equivalence relation: “having the same year of birth as.”

We take $\sigma = 3$. Using these values, we get $u(1000) - u(1100)e^{-0.1} = 1000.5 - 1100.5e^{-0.1} = 4.7264 > 3$. Hence, the primary criterion holds and the decision maker prefers \$1000 now to \$1100 next year.

Let us now consider the choice between the two sums received 10 and 11 years from now,

$$|e^{-1.1}u(1100) - e^{-1}u(1000)| = |e^{-1.1}1100.5 - e^{-1}1000.5| = 1.7388 < 3.$$

Hence, the primary criterion fails, and the decision maker considers the second criterion. Since $1000 < 1100$, the second criterion requires that the decision maker prefer \$1100 received 11 years from now to \$1000 received 10 years from now. We then have an illustration of the common difference effect using the model of vague time preferences.

The experimental results of Roelofsma and Read (2000) supported “sooner is better than later” against “larger is better than sooner.” However, if the order of the secondary criterion in the vague time preference model is reversed, so that sooner is better than larger, then, in Example 10.9, \$1000 received 10 years from now would be better than \$1100 received 11 years from now, and we would not get a common difference effect.

The validity of this explanation of the common difference effect is ultimately an empirical question. However, the main contribution of the model lies in directing the attention of theorists towards the use of primary and secondary criteria. Casual empiricism suggests that this may not be an unreasonable proposal.

10.4.2 The similarity relation and time preference

Rubinstein (2003) argues that hyperbolic discounting is a conservative extension of EDU. He proposes an even more radical departure from EDU that attempts to open the black box of human decision making by relying on the *procedural aspects of decision making*. Based on his earlier work in decision theory (see Rubinstein, 1988), he proposes the use of a *similarity relationship* in evaluating outcome–time pairs. Suppose that an economic agent must compare two outcome–time alternatives: (z_1, t_1) and (z_2, t_2) . There are two *attributes* in such decisions. *Size* of the prizes, z_1, z_2 , and the *time delays*, t_1, t_2 . A decision maker who uses the similarity relation, applies the following three stage procedure.

1. If $z_1 > z_2$ and $t_2 > t_1$, then the larger prize is available at an earlier date, hence, (z_1, t_1) is the preferred alternative.
2. If there is *similarity* in one attribute dimension, then the choice is made by comparing the two alternatives in the remaining attribute dimension. So, for instance, if z_1 and z_2 are similar, then the decision maker chooses the alternative that is available earlier ($\min\{t_1, t_2\}$). Similarly, if t_1 and t_2 are perceived to be similar, then the chosen alternative is the one that offers a larger prize ($\max\{z_1, z_2\}$).
3. If there is no similarity in either dimension, then no decision criterion is provided by the theory. Hence, the preference relationship in this model is incomplete.

This model is a promising step, insofar as it attempts to open the black box of human decision making. However, it needs further development, as is illustrated in the first of three examples in Rubinstein (2003) that is based on hypothetical payoffs.²⁰

²⁰ A small sample of the participants were selected and paid a fee of \$20 that was independent of their choices in the experiment.

Example 10.10 *The experiment was conducted in Fall 2002. The students in the experiment were randomly allocated to one of two questions.*

Q1: Choose among one of the two options:

A. Receive \$467.00 on June 17 2004.

B. Receive \$607.07 on June 17 2005.

Q2: Choose among one of the two options:

A. Receive \$467.00 on June 16 2005.

B. Receive \$467.39 on June 17 2005.

In Q1, 55% chose the delay option (B) while in Q2, 46% chose the delay option (B).

Rubinstein (2003) argued that the choices made in the experiment are not consistent with hyperbolic discounting, but are consistent with the use of the similarity procedure. To see this, assume that the utility function is $u(x) = \ln x$, and the discount function is of the hyperbolic form, given in (9.29) with $k = 1.5$.

Questions Q1 and Q2 are not explicit about the date at which students should consider their choices. Assume that the date of the experiment is the relevant date. However, the exact date is not given, so we take September 1, 2002, the start of Fall in 2002, as the decision date. There are 655 days till June 17, 2004, 1020 days until June 17, 2005, and so on. Using this information, and measuring time in days, we get that the decision maker chooses the no delay option (A) in both cases because²¹

$$\frac{1}{1 + 1.5(655)} \ln(467) > \frac{1}{1 + 1.5(1020)} \ln(607.07),$$

$$\frac{1}{1 + 1.5(1019)} \ln(467) > \frac{1}{1 + 1.5(1020)} \ln(467.39).$$

No standard error figures are given, hence, it is not possible to know if the proportions of the students choosing the no-delay option are significantly different between the two questions. In Q2, hyperbolic discounting explains more than half the choices and in Q1, it explains less than half the choices.

The similarity relation can be used to explain the no-delay choice (A) in Q2 in the following manner. The two amounts differ only by 39 cents, so they could be perceived to be *similar*. The decision maker then chooses the earlier option, which is A. This raises the question of what exactly is “similar”? From the two questions, it appears that the smallest unit of time is a day. Hence, one may argue that there is similarity in the time dimension in Q2, in which case the decision maker should choose the larger amount associated with option B. Thus, depending on what one means by similarity, one may justify any of the available choices, which is problematic for theory.

There are also other issues with making the similarity relation operational. First, the similarity relationship does not specify how close two entities must be in order to qualify to be *similar*. Second, the procedure does not apply to choice situations when there is no similarity in either dimension (see stage 3 of the similarity procedure above). Third, the procedure becomes less suitable as the number of choice pairs (x_i, t_i) increase, because the order in which choices are compared may become important in this case. Fourth, it is not clear which attribute to choose first in order to use the similarity relation. Hence, although the similarity relationship seems to be a

²¹ This conclusion is not altered if we choose the simplest discount function, $D(t) = \frac{1}{t}$.

promising choice heuristic, its domain of application would appear to be limited. As such, barring further development, it does not seem to be in a position to replace hyperbolic discounting in terms of the analytical convenience to model problems of present-biased preferences; a point also recognized by Rubinstein (2003).

10.4.3 Trade-off attribute model of intertemporal choice

We now consider the multiple attribute model of Scholten and Read (2006b), the *trade-off model of intertemporal choice* that focuses on a “trade-off” between the time dimension and the outcome dimension.

Suppose that a decision maker has a choice between a smaller-sooner (SS) reward, (z_S, t_S) , and a larger-later (LL) reward, (z_L, t_L) , such that $0 < z_S < z_L$ and $t_S < t_L$. The advantage of the SS reward, denoted by $a_S(t_S, t_L)$, is that it arrives earlier. The disadvantage of the SS reward, denoted by $d_S(z_S, z_L)$, is that one forgoes the larger outcome in the future. Now consider the case of losses $z_L < z_S < 0$. Here, $a_L(t_S, t_L)$ is the advantage of the LL loss because it occurs at a later time, so discounted losses feel smaller. Similarly, $d_L(z_S, z_L)$ is the disadvantage of the LL loss because the absolute magnitude of the loss is larger.

In the simplest form, suppose that the functional forms for a, d are given by:²²

$$\begin{cases} a_S(t_S, t_L) = \kappa(t_L - t_S); d_S(z_S, z_L) = z_L - z_S & \text{if } 0 < z_S < z_L \\ a_L(t_S, t_L) = \kappa(t_L - t_S); d_L(z_S, z_L) = \lambda |z_L - z_S| & \text{if } z_L < z_S < 0 \end{cases}, \quad (10.60)$$

where $\kappa > 0$ ensures compatibility between the units in which time and outcomes are measured. For instance, moving from time units of weeks to months increases κ by a factor of four. $\lambda > 1$ is akin to the parameter of loss aversion in prospect theory.

Let $\sim$ denote the indifference relation, and $>$ the strict preference relation. In the trade-off model of intertemporal choice, the decision maker uses the following decision rule for $0 < z_S < z_L$:

$$\begin{aligned} a_S(t_S, t_L) = d_S(z_S, z_L) & \text{ then } SS \sim LL \\ a_S(t_S, t_L) > d_S(z_S, z_L) & \text{ then } SS > LL \\ a_S(t_S, t_L) < d_S(z_S, z_L) & \text{ then } LL > SS \end{aligned} \quad (10.61)$$

z_S, z_L are measured relative to some reference point. If the reference point is current wealth, then the amounts offered in experiments may be thought to constitute gains and losses relative to current wealth.

This model can explain the magnitude effect, present bias, and the sign effect. Suppose that $a_S(t_S, t_L), d_S(z_S, z_L)$ are given by (10.60), $a_S(t_S, t_L) = d_S(z_S, z_L)$, and $z_S > 0, z_L > 0$. Then, the trade-off model predicts $SS \sim LL$. Starting with $a_S(t_S, t_L) = d_S(z_S, z_L)$, consider the following three possible perturbations.

1. Suppose that both outcomes $z_S > 0, z_L > 0$ are multiplied by a factor, $\gamma > 1$. Then, we compare the two outcome-time pairs $(\gamma z_S, t_S), (\gamma z_L, t_L)$. Since $a_S(t_S, t_L) = d_S(z_S, z_L)$, we get from (10.60) that $a_S(t_S, t_L) < d_S(\gamma z_S, \gamma z_L)$. Using (10.61), we get $LL > SS$, as predicted by the magnitude effect.

²² We consider here only the linear version of the model that is not able to take account of declining sensitivity of gains and losses. A non-linear extension is also available.

2. Suppose that the decision maker reveals at some time $t < t_S$ that $a_S(t_S, t_L) = d_S(z_S, z_L)$. Now suppose that we bring time t_S closer to t by multiplying t_S by $\rho < 1$ to generate a new pair of choices $(z_S, \rho t_S), (z_L, t_L)$. From (10.60), we now get that $a_S(\rho t_S, t_L) > d_S(z_S, z_L)$, so (10.61) implies that $SS > LL$. This prediction is consistent with models of present bias such as hyperbolic discounting; as rewards are brought closer to the present, the decision maker switches preferences to the more immediate reward.
3. Initially we have $0 < z_S < z_L$ and $a_S(t_S, t_L) = d_S(z_S, z_L)$, so (10.61) implies that $SS \sim LL$. Now suppose that the signs of z_S, z_L are reversed and we have the situation $z_L < z_S < 0$. Since $\lambda > 1$ we now get that $a_L(t_S, t_L) < d_L(z_S, z_L)$, therefore, we have $SS > LL$. Thus, losses are more salient, which is consistent with the sign effect.

10.5 The reference time theory (RT)

Within the class of discounted utility models, what should a general theory of time preference aspire to? Two desirable elements seem to present themselves. First, it should be able to explain the main anomalies of the EDU model, namely, gain-loss asymmetry, magnitude effect, common difference effect, delay-speedup asymmetry, apparent intransitivity of time preferences, and non-additivity of time discounting. Second, it should provide a framework that can incorporate some of the recent developments in time discounting such as uncertainty and attribute models.

al-Nowaihi and Dhami (2008a, 2013, 2014) incorporate both these desirable elements in their *reference time theory* (RT). RT is a synthesis of three earlier lines of work, namely, LP (Loewenstein and Prelec, 1992), PPL (Phelps and Pollak, 1968; Laibson, 1994, 1997), and RRS (Roelofsma and Read, 2000; Read, 2001; Scholten and Read, 2006a). In a nutshell, RT is basically LP extended to allow for non-additive time discounting by incorporating a reference point for time and reference point for outcomes.

LP introduced reference dependence for outcomes in the DU model. Suppose that a decision maker, at time $t = 0$, takes an action that gives rise to the sequence of outcome-time pairs: $(w_1, t_1), (w_2, t_2), \dots, (w_n, t_n)$, where w_i is the outcome at time t_i , $i = 1, 2, \dots, n$. LP proposed the following intertemporal utility function for the decision maker:

$$U = \sum_{i=1}^n v(w_i - w_0) D(0, t_i). \quad (10.62)$$

In (10.62), v is the utility function under prospect theory, due to Kahneman and Tversky (1979). v is defined over outcomes relative to a reference point, $x_i = w_i - w_0$, where w_0 is the reference outcome level. When $x_i \geq 0$, the individual is said to be in the *domain of gains*, and if $x_i < 0$, the individual is in the *domain of losses*. In LP, $D(0, t)$ is the general hyperbolic discounting function that discounts the utility at time $t \geq 0$ back to the present, time $t = 0$.

In RT, a *reference time* is introduced, in addition to the reference outcome level. In LP, there is a reference outcome level, but, by default, the time period 0 is the reference time to which all outcomes are discounted back. In many cases, it may be desirable to have a reference time, $r \geq 0$. Consider the following two examples.

Example 10.11 At time 0, a business may be contemplating an investment in a new plant that will become operational at time $t_1 > 0$. In calculating the viability of the investment, the business may wish to compare the future profits and costs from the investment discounted back to time t_1 , which then becomes the reference time.

Example 10.12 At time 0, a student starting a three year degree may wish to use a government loan to finance the degree. The government may require loan repayments to be made only upon completion of the degree (as in the UK). The student may wish to calculate the future benefits and costs of this action at time 0, discounted back to the time at which the degree is completed, t_1 , which then becomes the reference time.

RT alters the LP framework in two ways. First, it augments it to allow for a reference time as well as a reference outcome level. Second, a general class of discount functions, D , is considered that allows for declining impatience, subadditivity, or a combination of both. We show that if the discount function is *additive* (Definition 10.4), then preferences do not depend on the reference time. Then we show that some (not all) of the observed intransitivities in outcome–time pairs may be due to reference time shifts. One’s reference time may depend on the different binary choices under consideration.

The trade-off model of Scholten and Read (2006b) can be accommodated within RT. Using examples we also show that the treatment of uncertainty in Halevy (2007) and the vague time preference model of Manzini and Mariotti (2006) can also be incorporated within RT. Finally we compare our model with the model of intransitive preferences proposed in Ok and Masatlioglu (2007).

10.5.1 A basic description of RT

Consider a decision maker who, at time t_0 , takes an action that results in the outcome w_i at time t_i , $i = 1, 2, \dots, n$, where

$$t_0 \leq r \leq t_1 < \dots < t_n.$$

Time r is the *reference time*. It is the time back to which all values are to be discounted, using a discount function, $D(r, t)$ (see Definition 10.3). The reference time r need not be the same as t_0 (recall Examples 10.11, 10.12). Without loss of generality, we normalize the time at which the decision is made to be $t_0 = 0$.

As in LP, the decision maker has a *reference outcome level*, w_0 , relative to which all outcomes are to be evaluated. Letting $x_i = w_i - w_0$, the utility of outcome x_i is $v(x_i)$, where v is the prospect theory utility function that has four main properties: *reference dependence*, *monotonicity*, *declining sensitivity*, and *loss aversion*.

Definition 10.11 The properties of v are:

- (i) $v : (-\infty, \infty) \rightarrow (-\infty, \infty)$ is increasing (monotonicity).
- (ii) $v(0) = 0$ (reference dependence).
- (iii) For $x > 0$: $-v(-x) > v(x)$ (loss aversion).
- (iv) v is concave for gains, $x \geq 0$, but convex for losses, $x \leq 0$ (declining sensitivity).
- (v) v is continuous, and twice differentiable except at 0.

For each *reference outcome* and *reference time* pair $(w_0, r) \in (-\infty, \infty) \times [0, \infty)$, the decision maker has a complete and transitive preference relation, $\preceq_{w_0, r}$ on $(-\infty, \infty) \times [r, \infty)$ given by

$$(w_1, t_1) \preceq_{w_0, r} (w_2, t_2) \Leftrightarrow v(w_1 - w_0) D(r, t_1) \leq v(w_2 - w_0) D(r, t_2). \quad (10.63)$$

Let S be a non-empty set of outcome–time sequences from $(-\infty, \infty) \times [0, \infty)$ of the form $(x_1, t_1), (x_2, t_2), \dots, (x_i, t_i), \dots$, where outcomes are expressed relative to the reference outcome.

Using (10.63), we extend $\preceq_{w_0, r}$ to a complete transitive preference relation on sequences in S , as follows (this also holds for infinite sequences, provided the sums in (10.64) converge):

$$\begin{aligned} ((x_1, s_1), (x_2, s_2), \dots, (x_m, s_m)) &\preceq_{w_0, r} ((y_1, t_1), (y_2, t_2), \dots, (y_n, t_n)) \\ \Leftrightarrow \sum_{i=1}^m v(x_i) D(r, t_i) &\leq \sum_{i=1}^n v(y_i) D(r, t_i). \end{aligned} \quad (10.64)$$

Thus, the decision maker's intertemporal utility function is given by:

$$V_r((w_1, t_1), (w_2, t_2), \dots, (w_n, t_n) \mid w_0) = \sum_{i=1}^n v(x_i) D(r, t_i) \quad (10.65)$$

Comparing (10.65) to the utility function (10.62), proposed by LP, and successfully employed to explain several anomalies in intertemporal choice, we see that LP implicitly set $r = 0$. Also, LP implicitly assume that the discount function is additive (Definition 10.4), in which case, as we show below, there is no loss in assuming $r = 0$. To accommodate the empirical evidence, however, we allow the discount function to be non-additive, in which case the choice of reference time does matter.

We now consider the determination of the reference point for time, r . Let

$$T = \{t \in [0, \infty) : t = t_i \text{ for some sequence } \{(x_1, t_1), (x_2, t_2), \dots, (x_i, t_i), \dots\} \text{ in } S\}. \quad (10.66)$$

Since T is bounded below by 0 and non-empty, it follows that T has a greatest lower bound, r . We make the following assumption for reference time that is motivated by the status-quo justification of reference points, as the time closest to, or identical to the current time that an individual contemplates a decision (Kahneman and Tversky, 2000).

A0: Given S , T , r , as described above, the decision maker takes r (the greatest lowest bound of T) as the reference point for time.

A0 should be regarded as a tentative assumption, whose implications are to be more fully explored. However, the theory is flexible enough to allow for other reference points for time.

Example 10.13 *If a decision maker wishes to compare (x, s) with (y, t) , $s \leq t$, then $S = \{(x, s), (y, t)\}$ and $T = \{s, t\}$. Thus, A0 implies that $r = s$. If $v(x) < v(y) D(s, t)$, then the decision maker chooses (y, t) over (x, s) ; note from Definition 12, $D(s, s) = 1$.*

10.5.2 The implications of additivity of discount functions for RT

We first show that if the discount function is additive, then the choice of the reference point for time is irrelevant.

Proposition 10.10 *(al-Nowaihi and Dhami, 2008a, 2013): Suppose that the discount function is additive (Definition 10.4), then $(x_1, t_1) \preceq_{w_0, r} (x_2, t_2)$ if, and only if, $(x_1, t_1) \preceq_{w_0, 0} (x_2, t_2)$.²³*

Proof: First suppose that $(x_1, t_1) \preceq_{w_0, r} (x_2, t_2)$ and recall that $x_i = w_i - w_0$, $i = 1, 2$. Then we get

²³ This proposition can be easily extended to sequences of time outcome pairs. For instance, al-Nowaihi and Dhami (2013) prove the following result. If $D(r, t)$ is additive, then

$$\begin{aligned} ((x_1, s_1), (x_2, s_2), \dots, (x_m, s_m)) &\preceq_{w_0, r} ((y_1, t_1), (y_2, t_2), \dots, (y_n, t_n)) \\ \Leftrightarrow ((x_1, s_1), (x_2, s_2), \dots, (x_m, s_m)) &\preceq_{w_0, 0} ((y_1, t_1), (y_2, t_2), \dots, (y_n, t_n)). \end{aligned}$$

$$D(r, t_1) v(x_1) \leq D(r, t_2) v(x_2). \quad (10.67)$$

From Definition 10.3, $D(0, t) > 0$ for any finite t , hence, multiplying both sides of (10.67) by $D(0, r) > 0$ we get

$$D(0, r)D(r, t_1) v(x_1) \leq D(0, r)D(r, t_2) v(x_2). \quad (10.68)$$

Additivity (Definition 10.4) implies that

$$D(0, r)D(r, t) = D(0, t). \quad (10.69)$$

Using (10.68), (10.69) we get that

$$D(0, t_1)v(x_1) \leq D(0, t_2)v(x_2) \Rightarrow (x_1, t_1) \preceq_{w_0, 0} (x_2, t_2).$$

Now assume that $(x_1, t_1) \preceq_{w_0, 0} (x_2, t_2)$, then (10.67) implies that

$$D(0, t_1) v(x_1) \leq D(0, t_2) v(x_2). \quad (10.70)$$

Using (10.69), (10.70) we get

$$D(r, t_1) v(x_1) \leq D(r, t_2) v(x_2) \Rightarrow (x_1, t_1) \preceq_{w_0, r} (x_2, t_2). \blacksquare$$

In contrast to the result in Proposition 10.10, if the discount function is non-additive, then the choice of the reference point for time matters. RT uses this feature to explain (apparent) intransitivity in preferences as a framing effect due to a change in the reference point for time.

10.5.3 Explanation of intransitive preferences under RT

We now illustrate one possible resolution of apparent intransitivity of preferences using the RT theory (al-Nowaihi and Dhami, 2008a). This argument is similar in spirit to Gintis (2009) who argues that apparent intransitivities may be explained by taking account of the context, frame, and the state of the world. Let the decision time be the current period, $t = 0$, and consider the following preferences over outcome–time pairs.

$$(1, 0) \prec (3, 2); (3, 2) \prec (2, 1); (2, 1) \prec (1, 0). \quad (10.71)$$

Take the reference point for wealth to be the current level of wealth, so each outcome in (10.71) is regarded as a gain relative to current wealth. Evaluated from the perspective of the current time, $t = 0$, the stated preferences in (10.71) satisfy $V_0(1, 0) < V_0(3, 2) < V_0(2, 1) < V_0(1, 0)$, where V_0 (for $r = 0$) is defined in (10.65). Thus, preferences are intransitive. Ok and Masatlioglu (2007, p.215) use a similar example to motivate their intransitive theory of relative discounting.

Alternatively, we may view the preference pattern in (10.71) as due to a framing effect that results in a shift in the reference point for time. Assume that, in conformity with Assumption A0, the choice of reference time in each pairwise comparison is the sooner of the two dates (the status-quo argument for a reference point). Thus, (10.71) implies the following reference points

in pairwise comparisons reading from left to right: $r = 0$, $r = 1$, and $r = 0$. Then, recalling the definition of V_r in (10.65), (10.71) can be formalized as follows.

$$\begin{aligned} V_0(1, 0) &< V_0(3, 2), \\ V_1(3, 2) &< V_1(2, 1), \\ V_0(2, 1) &< V_0(1, 0). \end{aligned} \tag{10.72}$$

There is no intransitivity in (10.72). Thus, the apparent intransitivity in (10.71) arises from conflating $V_0(3, 2)$ with $V_1(3, 2)$ and $V_1(2, 1)$ with $V_0(2, 1)$. The following example shows that (10.72) is consistent with RT.

Example 10.14 (*al-Nowaihi and Dhami, 2008a*): Take the utility function to be a SIE utility function as in (10.12):

$$v(x) = x^{0.5} (1 + x)^{0.5}, \quad x \geq 0. \tag{10.73}$$

Thus (working to five significant figures),

$$v(1) = 1.414\,2, \quad v(2) = 2.449\,5 \text{ and } v(3) = 3.464\,1. \tag{10.74}$$

As our discount function, we take the Read-Scholten discount function (10.44) above, with $\alpha = \beta = 1$ and $\rho = \tau = 0.5$:

$$D(r, t) = \left(1 + (t^{0.5} - r^{0.5})^{0.5}\right)^{-1}. \tag{10.75}$$

Thus,

$$D(0, 1) = 0.5, \quad D(1, 2) = 0.608\,42 \text{ and } D(0, 2) = 0.456\,79. \tag{10.76}$$

From (10.74) and (10.76) we get

$$V_0(1, 0) = v(1) D(0, 0) = 1.414\,2, \tag{10.77}$$

$$V_0(3, 2) = v(3) D(0, 2) = 1.582\,4, \tag{10.78}$$

$$V_1(3, 2) = v(3) D(1, 2) = 2.107\,6, \tag{10.79}$$

$$V_1(2, 1) = v(2) D(1, 1) = 2.449\,5, \tag{10.80}$$

$$V_0(2, 1) = v(2) D(0, 1) = 1.224\,8. \tag{10.81}$$

From (10.77) to (10.81), we get

$$V_0(1, 0) < V_0(3, 2); \quad V_1(3, 2) < V_1(2, 1); \quad V_0(2, 1) < V_0(1, 0), \tag{10.82}$$

confirming (10.72).

As indicated by Proposition 10.10, no additive discount function (e.g., exponential, (β, δ) form of hyperbolic discounting, or LP's generalized hyperbolic discounting) can explain apparently intransitive choices as exhibited in (10.71). The reason is that with an additive discount function, all utilities are necessarily discounting back to the same base period (typically time $t = 0$), hence, showing up apparent intransitivities.

Table 10.1 Examples of discount functions when there is a reference point for time.

Type	$D(r, t)$
Exponential	$e^{-\beta(t-r)}, \beta > 0.$
PPL	$\begin{cases} 1 & \text{if } r = t = 0 \\ e^{-(\delta+\beta t)}, \beta > 0, \delta > 0, & \text{if } 0 = r < t \\ e^{-\beta(t-r)} & \text{if } 0 < r \leq t \end{cases}$
LP	$\left(\frac{1+\alpha t}{1+\alpha r}\right)^{-\frac{\beta}{\alpha}}, t \geq 0, r \geq 0, \alpha > 0, \beta > 0.$
RS	$[1 + \alpha(t^\tau - r^\tau)^\rho]^{-\frac{\beta}{\alpha}}, 0 \leq r \leq t, \alpha > 0, \beta > 0, \rho > 0, \tau > 0.$
GRS	$e^{-Q[w(t)-w(r)]}, 0 \leq r \leq t, \text{ where}$ $Q : [0, \infty) \xrightarrow{\text{onto}} [0, \infty) \text{ is strictly increasing,}$ $w : [0, \infty) \xrightarrow{\text{onto}} [0, \infty) \text{ is strictly increasing.}$

10.5.4 Recasting common discount functions in terms of RT

In theories of time discounting that do not have a reference time, the discount functions are stated under the implicit assumption that $r = 0$. In the presence of reference time, we first need to restate the main discount functions for the case $r > 0$. We extend five common discount functions for the case $r > 0$. The standard versions of these functions can simply be obtained by setting $r = 0$.

The first three discount functions in Table 10.1 have already been discussed above. These are, respectively, the *exponential discount function* proposed by Samuelson (1937), the $\beta - \delta$ or *quasi-hyperbolic discount function* proposed by Phelps and Pollak (1968) and Laibson (1997), and the *generalized hyperbolic discount function* proposed by Loewenstein and Prelec (1992). The labels PPL and LP reflect the names of the authors who proposed these functions. These three discount functions are *additive* (Definition 10.4). They can account for the common difference effect through declining impatience (Definition 10.5), but they cannot account for either non-additivity, or intransitivity.

The RS interval discount function in Table 10.1 was introduced by Read (2001) and Scholten and Read (2006a). It can account for both non-additivity and intransitivity. It can account for the common difference effect through declining impatience, subadditivity, or a combination of both.

Note that the LP approaches the exponential as $\alpha \rightarrow 0$. In general, neither of LP, or RS is a special case of the other. However, for $r = 0$ (and only for $r = 0$), RS reduces to LP when $\rho = \tau = 1$. While ρ, τ are parameters, r is a variable. Hence, neither discount function is a special case of the other.²⁴

It is straightforward to check that each of exponential, LP, RS, and generalized RS is a continuous discount function in the sense of Definition 10.3. It is also straightforward to check that PPL is a discount function. The reason the latter is not a *continuous* discount function is that $\lim_{t \rightarrow 0+} D(0, t) = e^{-\delta} < 1 = D(0, 0)$.

²⁴ Scholten and Read (2006a) report incorrectly that the LP discount function is a special case of the RS discount function.

10.5.5 Explanation of the EDU anomalies in RT

The RT theory is able to explain the six main anomalies of the EDU model in one unified framework. We only explain here the thrust of these explanations. These anomalies are: gain–loss asymmetry, magnitude effect, common difference effect, delay–speedup asymmetry, apparent intransitivity of time preferences, and non-additivity of time discounting. We now outline the intuition behind RT’s explanation of the anomalies; for the details, see al-Nowaihi and Dhami (2008a, 2013, 2014).

RT explains the magnitude and sign effects as in LP (see Section 10.2). However, it employs the SIE class of value functions, which are due to al-Nowaihi and Dhami (2009), that satisfy the requirements in LP. RT can also explain the sign effect by using different discount functions for gains and losses.

RT can explain the common difference effect as due to either declining impatience (Definition 10.5), subadditivity (Definition 10.4), or a combination of both. However, the approach of RT is more general, as RT can also explain the common difference effect as due to the presence of a small amount of irremovable uncertainty, as in Halevy (2008), or as a consequence of multiple decision criteria, as in Manzini and Mariotti (2006). Several of the attribute-based models considered in Section 10.4 can be incorporated within RT. We shall not consider these issues here but the interested reader can consult al-Nowaihi and Dhami (2008a). Thus, RT can accommodate all the known explanations of the common difference effect. In the spirit of scientific inquiry, RT leaves it to empirical evidence to select the correct explanation.

Here, we give an updated exposition of RT theory from al-Nowaihi and Dhami (2014).²⁵ We specify our axioms in terms of three functions: The *delay function*, Ψ , the *speedup function*, f , and the *generating function*, φ . Each of these functions can be uniquely elicited from behavior. Ψ determines stationarity and the common difference effect (Proposition 10.13, below). f determines whether impatience is declining, constant, or increasing (Proposition 10.14, below). Ψ and f jointly determine whether the preferences are subadditive, additive, or superadditive (Proposition 10.15, below). The f and φ functions jointly determine a unique discount function. Conversely, a continuous discount function determines unique f and φ .²⁶

DELAY FUNCTION, Ψ

Let the reference time be $r \geq 0$. Suppose that a decision maker is indifferent between x received at time r and y received at time $t \geq r$, thus,

$$v(x) = v(y) D(r, t). \quad (10.83)$$

Now suppose that the receipt of x is *delayed* to time s . We ask, at what time, T , will y received at time T be equivalent to x received at time s , i.e., for what T does the following hold?

$$v(x) D(r, s) = v(y) D(r, T). \quad (10.84)$$

²⁵ For an earlier version of the theory, see al-Nowaihi and Dhami (2008a). The main difference between the two papers is that in the later version, al-Nowaihi and Dhami (2014) use only three underlying functions, each of which can be elicited from observed behavior, but they are able to reproduce all the results from the earlier paper. By contrast, al-Nowaihi and Dhami (2008a) employ four underlying functions, one of which may be difficult to elicit from behavior.

²⁶ We do not formally state this result below but the interested reader may wish to construct the proof; the proofs are available in al-Nowaihi and Dhami (2014).

Figure 10.3 The delay and the speedup functions.

Let us conjecture that T depends on r, s, t through a functional relation, say, $T = \Psi(r, s, t)$; see Figure 10.3. From (10.83), (10.84) we get that $\Psi(r, s, t)$ must satisfy

$$D(r, s) D(r, t) = D(r, \Psi(r, s, t)). \quad (10.85)$$

We shall call the function $\Psi(r, s, t)$, if it exists, a delay function (see Definition 10.12). For the exponential discount function (see Table 10.1), $\Psi(r, s, t) = s + t$.

Definition 10.12 (Delay functions): Let D be a discount function. Suppose that the function, Ψ , has the property $D(r, s) D(r, t) = D(r, \Psi(r, s, t))$, $s \geq r, t \geq r$. Then we call Ψ a delay function corresponding to the discount function, D .

Next, we show that a delay function exists, is unique, and depends on r, s, t .

Proposition 10.11 (Existence and properties of a delay function; al-Nowaihi and Dhami, 2014):

- (i) Let D be a discount function and Ψ a corresponding delay function. Then, Ψ has the following properties:
 - (a) Ψ is unique,
 - (b) $\Psi(r, s, t)$ is strictly increasing in each of s and t ,
 - (c) $\Psi(r, s, t) = \Psi(r, t, s)$,
 - (d) $\Psi(r, r, t) = \Psi(r, t, r) = t$,
 - (e) $v(x) = v(y) D(r, t)$ if and only if, $v(x) D(r, s) = v(y) D(r, \Psi(r, s, t))$.
- (ii) A continuous discount function has a unique delay function, $\Psi(r, s, t)$. $\Psi(r, s, t)$ is continuous in s, t .

SPEEDUP FUNCTION, f

Suppose that the decision maker is indifferent between x received at time r and y received at time t , $0 \leq r \leq t$, where time r is the reference time. Then, recalling that $D(r, r) = 1$ we have

$$v(x) = v(y) D(r, t). \quad (10.86)$$

Suppose that the receipt of x is brought forward from time r to time 0, where time 0 is the new reference time. We ask, at what time, T , will y received at time T be equivalent to x received at time 0? Or, for what time, T , will the following hold?

Table 10.2 The delay function, speedup function, and generating function corresponding to common discount functions.

	$\varphi(t)$	$f(r, t)$	$\Psi(r, s, t)$
Exponential	$e^{-\beta t}$	$t - r$	$s + t$
PPL ($r = t = 0$)	1	0	s
PPL ($0 = r < t$)	$e^{-(\delta + \beta t)}$	t	$\frac{\delta}{\beta} + s + t$
PPL ($0 < r \leq t$)	$e^{-\beta t}$	$t - r$	$s + t$
LP	$(1 + \alpha t)^{-\frac{\beta}{\alpha}}$	$\frac{t-r}{1+\alpha r}$	$s + t + \alpha st$
RS	$[1 + \alpha t^{\tau\rho}]^{-\frac{\beta}{\alpha}}$	$(t^{\tau} - r^{\tau})^{\frac{1}{\tau}}$	$[s^{\tau\rho} + t^{\tau\rho} + \alpha(st)^{\tau\rho}]^{\frac{1}{\tau\rho}}$
Generalized RS	$e^{-Q[w(t)]}$	$w^{-1}[w(t) - w(r)]$	$w^{-1}Q^{-1}[Q(w(s)) + Q(w(t))]$

$$v(x) = v(y) D(0, T). \quad (10.87)$$

For the exponential discount function, we have $T = t - r$. More generally, let us conjecture that T depends on r, t , so that we can write $T = f(r, t)$, where $f: \Delta \rightarrow [0, \infty)$ will be called the *speedup function* (Δ is given in Definition 10.3); see Figure 10.3.

Definition 10.13 (*Speedup function*): Let $f: \Delta \rightarrow [0, \infty)$ satisfy:

- (a) For each $r \in [0, \infty)$, $f(r, t)$ is a strictly increasing function of $t \in [r, \infty)$ into $[0, \infty)$, with $f(r, r) = 0$.
- (b) For each $t \in [0, \infty)$, $f(r, t)$ is a strictly decreasing function of $r \in [0, t]$ into $[0, t]$, with $f(0, t) = t$.

Then we call f a *speedup function*. If, in (a), “into” is replaced with “onto,” then we call f a *continuous speedup function*.

A “continuous speedup function,” $f(r, t)$, is continuous in t .

THE GENERATING FUNCTION

Our third useful function is the generating function, φ . Like the delay function, Ψ , and the speedup function, f , the generating function, φ , can be uniquely elicited from behavior.

Definition 10.14 (*The generating function*): Let $\varphi: [0, \infty) \rightarrow (0, 1]$ be a strictly decreasing function with $\varphi(0) = 1$. Then we call φ a *generating function*. If, in addition, φ is onto, we call φ a *continuous generating function*.

On account of reference dependence of the prospect theory utility function, $v(0) = 0$. Such a function is measurable on the ratio scale, i.e., u and v represent the same prospect theory preferences if, and only if, $u = \alpha v$ for some positive constant, α . The following proposition is an immediate consequence of this.

Proposition 10.12 (*Uniqueness of the generating function; al-Nowaihi and Dhami, 2014*): The generating function, φ , is uniquely determined by behavior.

Example 10.15 Table 10.2 gives the generating function, φ , and the speedup function, f , of each of the discount functions $D(r, t)$, given in Table 10.1.

CHARACTERIZING OBSERVED BEHAVIOR FROM THE UNDERLYING FUNCTIONS

We now show how restrictions on the three functions, delay, speedup, and generating functions, can be used to characterize many of the important behaviors in Part 3. Among others, these include stationarity, common difference effect, declining impatience, and subadditivity.

Proposition 10.13 (*al-Nowaihi and Dhami, 2014*): A continuous discount function with the delay function, Ψ , exhibits:

- (a) Stationarity if, and only if, $\Psi(r, s, t) = s + t$, for all $r \geq 0, s \geq r, t \geq r$.
- (b) The common difference effect if, and only if, $\Psi(r, s, t) > s + t$, for all $r \geq 0, s > r, t > r$.

Proposition 10.14 (*al-Nowaihi and Dhami, 2014*): A continuous discount function with the speedup function, f , exhibits:

- (a) Declining impatience if, and only if, $f(r, s) > f(r + t, s + t)$, for all $t > 0, s > r$.
- (b) Constant impatience if, and only if, $f(r, s) = f(r + t, s + t)$, for all $t \geq 0, s \geq r$.
- (c) Increasing impatience if, and only if, $f(r, s) < f(r + t, s + t)$, for all $t > 0, s > r$.

Proposition 10.15 (*al-Nowaihi and Dhami, 2014*): A continuous discount function with delay function, Ψ , and speedup function, f , exhibits:

- (a) Subadditivity if, and only if, $f(r, t) < \Psi(0, f(r, s), f(s, t))$, for all $0 \leq r < s < t$.
- (b) Additivity if, and only if, $f(r, t) = \Psi(0, f(r, s), f(s, t))$, for all $0 \leq r \leq s \leq t$.
- (c) Superadditivity if, and only if, $f(r, t) > \Psi(0, f(r, s), f(s, t))$, for all $0 \leq r < s < t$.

Let us provide a brief summary of these results. Each of the four discount functions in Table 10.1, PPL, LP, RS (with $\rho \leq 1$ and $\tau\rho \leq 1$), and generalized RS, when combined with the SIE utility function (10.10), satisfies the following anomalies of the EDU model: The magnitude effect, the gain–loss asymmetry, common difference effect, delay–speedup asymmetry, and apparent intransitivity of preferences. If one is interested in incorporating departures from additivity, then Proposition 10.15 gives the relevant conditions for the delay and speedup functions. As an example, recall Proposition 10.8. Whether preferences exhibit stationarity or the common difference effect is determined by Ψ . Whether impatience is declining, constant, or increasing is determined by f . Ψ and f jointly determine whether preferences are subadditive, additive, or superadditive.

10.5.6 Intransitive preferences and relative discounting

Ok and Masatlioglu (2007) develop a theory of intransitive time preferences. At time 0, a decision maker has a binary relationship, $\preceq$, on the set $\chi = X \times [0, \infty)$, where X is a non-empty set. Let $x, y \in X$ and $s, t \in [0, \infty)$, then $(x, s) \preceq (y, t)$ is to be interpreted in the following manner. If the individual is asked at time 0 to commit to a choice between (x, s) and (y, t) he states that “ y received at time t is (weakly) preferred to x received at time s .” For this reason, $\preceq$ may be described as representing the *commitment preferences* of the individual.

Let $\sim$ and $<$ be the symmetric and asymmetric parts of $\preceq$, respectively. For each $t \in [0, \infty)$, $\preceq_t$ is the t -th time projection of $\preceq$ onto X , i.e., $x \preceq_t y$, if, and only if, $(x, t) \preceq (y, t)$. In particular, $\preceq_0$ is the projection of $\preceq$ onto X at time 0 (and, similarly, for $\sim_t$ and $<_t$). Thus, $\preceq_0$ describes the undated preferences of the individual in the present, i.e., time 0.

If X is a metric space, then further structure can be imposed on $\preceq$.

Definition 10.15 (*Time preferences; Ok and Masatlioglu, 2007, p. 218*): Let X be a metric space, then $\preceq$ is a time preference on χ if

- (i) $\preceq$ is complete and continuous,
- (ii) $\preceq_0$ is complete and transitive,
- (iii) $\preceq_t = \preceq_0$ for each $t \in [0, \infty)$.

In Definition 10.15, note that transitivity is imposed on the undated present preferences $\preceq_0$ (and, hence, also on $\preceq_t$), but transitivity is not imposed on the commitment preferences $\preceq$. In other words, static preferences $(\preceq_t, \preceq_0)$ are always transitive, but intransitivity may arise with the passage of time. Hence, neither $\prec$ nor $\sim$ are, necessarily, transitive. In particular, $\sim$ is *not*, in general, an equivalence relationship.

Example 10.16 Suppose that $x, y, z \in X$. Then Definition 10.15(ii) implies that if $(x, 0) \preceq_0 (y, 0)$ and $(y, 0) \preceq_0 (z, 0)$, then, by transitivity, we get $(x, 0) \preceq_0 (z, 0)$. Further, from Definition 10.15(iii) we get that for any $t \in [0, \infty)$ the t -th time projection of $\preceq$ onto X satisfies: if $(x, t) \preceq_t (y, t)$ and $(y, t) \preceq_t (z, t)$, then, $(x, t) \preceq_t (z, t)$. However, from Definition 10.15(i) we may have for $s, t, u \in [0, \infty)$: $(x, s) \preceq (y, t)$ and $(y, t) \preceq (z, u)$, but $(z, u) \not\preceq (x, s)$, which violates transitivity.

OM introduce a set of six properties, P1–P6. We only give a heuristic discussion of these properties because our focus is on the representation theorem that follows from them. *Time sensitivity* (P1) requires that any outcome can be made less desirable than another outcome by postponing it for a sufficiently long period. *Outcome sensitivity* (P2) requires that any delay can be compensated by a high enough prize. *Monotonicity* (P3) requires that $\preceq$ be increasing in outcomes and decreasing in time. Suppose that $(x, 0) \sim (y, 1)$ and $(z, 0) \sim (w, 1)$, then define the *delay premium* in these respective cases by $y - x$ and $w - z$. *Separability* (P4) requires that if the delay premium for delaying a reward x at any time $t \in [0, \infty)$ for an time interval of length, l , is $y - x$, then over the same interval, $w - z$ is the delay premium for delaying a reward of z at time t . *Path independence* (P5) is less persuasive as compared to the other properties. It requires that for any outcomes $x, y, w, z \in X$ and times $t_1, t_2, t_3 \in [0, \infty)$ if $(x, t_1) \sim (y, t_2) \sim (w, t_3)$, then $(x, t_2) \sim (z, t_3)$ where $(z, t_1) \sim (w, t_2)$. Finally *monotonicity in outcomes* (P6) requires that someone who uses the preference $\preceq_0$ prefers a higher to a lower amount.

The next proposition studies the implications of these properties. Let $\mathbb{R}$ be the set of real numbers, $\mathbb{R}_+$ the set of non-negative reals and $\mathbb{R}_{++}$ the set of positive reals. Recall that a homeomorphism is a mapping that is 1-1, onto, continuous, and its inverse is also continuous.

Proposition 10.16 (Ok and Masatlioglu (2007), Theorem 1): Let X be an open interval in $\mathbb{R}$ and $\preceq$ a binary relation on X . $\preceq$ is a time preference (Definition 10.15) on X that satisfies properties P1–P6 if, and only if, there exists an increasing homeomorphism $U : X \rightarrow \mathbb{R}_{++}$ and a continuous map $D : \mathbb{R}_+^2 \rightarrow \mathbb{R}_{++}$ such that, for all $x, y \in X$ and $s, t \in [0, \infty)$,

$$(x, s) \preceq (y, t) \text{ iff } U(x) \leq U(y) D(s, t), \quad (10.88)$$

where (i) for given s , $D(s, t)$ is decreasing in t with $D(s, \infty) = 0$, and (ii) $D(t, s) = 1/D(s, t)$.

Suppose $s \leq t$. Then (10.88) says that y received at time t is (weakly) preferred to x received at time s if, and only if, the (undated) utility of x is less or equal to the (undated) utility of y discounted from time t back to time s by the discount factor $D(s, t)$. In this case, part (i) of Proposition 10.16 implies the following. Fix the time, s , at which x is received. Let the time, t , at which y is received, recede into the future. Then the value of the utility of y , discounted back to time s , decreases. In the limit, as the receipt of y is indefinitely postponed, the value of its utility,

discounted back to time s , approaches zero. Part (ii) of Proposition 10.16 says that compounding forward, from time s to time t , is the inverse of discounting backwards from time t to time s .

For each $r \in [0, \infty)$, let $\preceq^r$ be the restriction of $\preceq$ to $X \times [r, \infty)$, i.e., to times $t \geq r$. Thus, for $r \leq s$ and $r \leq t$, $(x, s) \preceq^r (y, t)$ if, and only if, $(x, s) \preceq (y, t)$. We can now point to the main differences between RT and the theory proposed by Ok and Masatlioglu.

First, note that U in Proposition 10.16 can take only positive values while v in the RT theory, which uses prospect theory, takes both positive and negative values.²⁷ To bypass this problem, we consider only the domain of strictly positive gains. Let w_0 be the reference point for wealth. Take $X = \{w - w_0 : w > w_0\} = (0, \infty)$ and let $\preceq$ satisfy the conditions of Proposition 10.16. Let (U, D) be the representation of $\preceq$ guaranteed by Proposition 10.16, where U is the utility function and D is the interval discount function.

From Section 10.5.1 recall that, under RT, for each $r \in [0, \infty)$, $\preceq_{w_0, r}$ is a complete transitive order on $(-\infty, \infty) \times [r, \infty)$ and, hence, also on $X \times [r, \infty)$. Thus, in general, $\preceq_{w_0, r}$, unlike $\preceq^r$, is *not* the restriction to $X \times [r, \infty)$ of some complete binary relationship on $X \times [0, \infty)$. Thus the proposal by Ok and Masatlioglu and RT are not compatible and neither is a special case of the other.

Third, $\preceq_{w_0, r}$ is *transitive* while, in general, $\preceq^r$ is *not transitive*. To elaborate this point, consider (x, r) , (y, s) , and (z, t) , where $x, y, z \in X$ and $s, t \in [r, \infty)$. Suppose $(x, r) \preceq_{w_0, r} (y, s)$ and $(y, s) \preceq_{w_0, r} (z, t)$. Since $\preceq_{w_0, r}$ is transitive, we can conclude that $(x, r) \preceq_{w_0, r} (z, t)$. Now, suppose that $(x, r) \preceq^r (y, s)$ and $(y, s) \preceq^r (z, t)$. Since $\preceq^r$ is not, in general, transitive, we *cannot* conclude that $(x, r) \preceq^r (z, t)$.²⁸ More generally, given a compact subset $C \subset X \times [r, \infty)$, there is no guarantee in Ok and Masatlioglu that it has a maximum under $\preceq^r$ (i.e., an $m \in C$ such that $c \preceq^r m$ for all $c \in C$). This, obviously, will cause great difficulty for any economic theory formulated in the OM framework. On the other hand, in RT, if D is continuous, C will always have a maximum under $\preceq_{w_0, r}$.

Fourth, and finally, these problems with OM can all be resolved in the special case where $\preceq$ is transitive. But then $\preceq$ would also be additive. In this case, OM would reduce to the standard discounting model.

²⁷ Hence, in its present formulation, the proposal by Ok and Masatlioglu cannot explain *gain-loss asymmetry*. However, it can explain the *magnitude effect* using the SIE value function (see Proposition 10.4).

²⁸ As Ok and Masatlioglu clearly explain, it is for this reason that we should think of $D(s, t)$ in their theory as the *relative* discount function between times s and t .

CHAPTER 11

Applications of Present-Biased Preferences

11.1 Introduction

In the two previous chapters we saw that humans have a much greater bias towards the present relative to traditional models of discounting, such as EDU. In particular, most evidence indicates that the discount rate increases (equivalently impatience increases) as the delay with which an outcome is received, is shortened. Models where the degree of impatience increases, hyperbolically, or otherwise, when the delay of an outcome falls, are termed as models of *present-biased preferences*. This chapter considers applications of such models with particular emphasis on models of quasi-hyperbolic discounting.¹ The applications that we consider range from issues of optimal lifetime consumption, optimal retirement decisions, procrastination, choice between alternative gym memberships, and optimal taxes on activities that cause harm to the individual (sin taxes).

In applications of present-biased preferences, it is typical to consider a decision maker as a succession of *multiple selves*, one for each time period. Suppose that all selves exhibit hyperbolic discounting. This leads to a *taste for immediate gratification*, so it is not surprising that it may cause *self-control problems*. The first feature of models of multiple selves is that current selves have imperfect control over future selves. Hence, future selves may take actions that are contrary to the current self's own interest.

As an example, a future self may splurge and undersave because of present-biased preferences. This leads to a smaller pension pot, which causes concern to the current self. However, the current self may take actions that indirectly influence the future selves. For instance, the current self may invest in illiquid assets, which constrains the ability of future selves to splurge on consumption. A second feature of such models is that there might be *limited awareness* on the part of the current selves about the self-control problems of their future selves.

In Section 11.2, we consider two classes of models. In the *planner–doer model*, a long-lived current planner-self of an individual takes actions to influence the actions of future, short-lived, myopic-selves (Thaler and Shefrin, 1981). We show that this model can predict inadequacy of savings, as well as variation in the marginal propensity to consume out of permanent income. The second class of models considers the basic machinery of the models of multiple selves, by

¹ We do not delve into the reasons why humans exhibit hyperbolic discounting. For evolutionary arguments that justify hyperbolic discounting, see Dasgupta and Maskin (2005).

distinguishing among various assumptions about the degree of self-awareness of future self-control problems (O'Donoghue and Rabin, 2001).

Section 11.3 applies hyperbolic discounting and alternative assumptions about the degree of awareness of future self-control problems to a standard life-cycle model (Laibson, 1997, 1998). The present bias of individuals leads to greater current consumption and lower savings, relative to the benchmark case of time consistent behavior under the EDU model. Such a model can explain a range of puzzles that are difficult to explain in the standard model. These include the following. Why does consumption track income so closely? Why do individuals undersave for retirement? Why is there a sharp drop in consumption at retirement? Why do individuals hold illiquid assets and credit card debt simultaneously? Why have national savings rates been declining? Why is marginal propensity to consume asset specific? We also derive the Euler equation under the behavioral life-cycle model (*behavioral Euler equation*), show why high consumption variability is not associated with high consumption growth, and clarify the relation between intertemporal substitution and risk.

Section 11.4 considers the retirement decision under present-biased preferences (Diamond and Köszegi, 2003). The present bias of future selves might induce them to retire too early. The current self might disagree with this decision because longer horizon discount rates under hyperbolic discounting are lower. However, the current self cannot *directly* influence the future selves. One *indirect* method of influencing the future selves may be to *strategically undersave* now and, so, force the future selves to work rather than retire. If such an approach does not work, then, the current self may have to engage in *resigned oversavings*, i.e., save “too much” for the subsequent selves. We also examine the effect of employment legislation, such as mandatory, or flexible retirement policies, on the savings and retirement decisions.

Why do we procrastinate on important tasks, or sometimes give in to temptation (O'Donoghue and Rabin, 1999a, 1999b, 2001)? We consider these issues in the framework of quasi-hyperbolic discounting and different degrees of awareness of future self-control problems.² Section 11.5 considers two generic cases. First, the case of *delayed rewards*, such as the decision to quit smoking, in which costs must be incurred now, but rewards accrue in the future. Second, the case of *delayed costs*, such as credit card debt, and vacation decisions, in which rewards are received now, but costs accrue in the future. The appropriate equilibrium concept here is one of a *perception-perfect strategy*. For immediate costs, lack of awareness of future self-control problems leads to greater current *procrastination*, because (i) present bias makes current costs more salient, relative to future gains, and (ii) lack of awareness of future self-control problems reduces the perceived costs of procrastination. For the case of immediate rewards, the converse result obtains.

Section 11.6 examines the effect of market competition on the propensity to procrastinate (Brocas and Carillo, 2001). Suppose, for instance, that there are two employees who have to complete a task and face a “winner takes all” incentive scheme. Procrastination by any of the employees is now doubly costly if the other employee does not procrastinate. This induces greater work effort from both employees. This is the case if costs of procrastination are low. However, for intermediate costs of procrastination, conditional on the beliefs of any employee about the other's procrastination, a multiplicity of equilibria can arise.

In standard public economics, *Pigouvian taxes* are often advocated in order to reduce the level of a harmful externality that one individual imposes on another. However, when individuals consume a *sin-good*, such as smoking, and use hyperbolic discounting, there are additional issues to

² An alternative approach to issues of self-control, the Gul-Pesendorfer approach to temptation preferences, that uses the revealed preference framework, can be found in Part 6.

take into account (O'Donoghue and Rabin, 2006). In a multiple selves framework, the current self of an individual, on account of his present bias, may consume far in excess of what a patient long-lived self would advocate. Pigouvian taxes can then be levied on the current self of the individual, in order to protect the future selves. Section 11.7 explores these issues in a formal model.

In Section 11.8, we consider the take-up of alternative pricing plans for *investment goods* and *leisure goods* (DellaVigna and Malmendier, 2004). Investment goods have current costs and future benefits (e.g., health club memberships). Leisure goods, conversely, have current benefits, but future costs (e.g., credit card borrowing). For instance, consider a potential visitor to a health club who has hyperbolic preferences and is sophisticated about his future self-control problems. He will know that the future selves, on account of their self-control problems, will not use the club membership if the monthly fee is too high. Hence, he may be willing to pay a larger up-front lump-sum payment (membership fee) in return for a smaller unit price (such as the monthly fee) for later visits. Furthermore, a unit price below marginal cost is optimal for the health club. The evidence presented by DellaVigna and Malmendier (2004) confirms these results. By using a converse set of arguments, one can show that optimal price is above marginal costs for leisure goods. In each of these cases, the variation in the price, relative to the neoclassical model, allows individuals with self-control problems to gain access to a commitment device.

A range of other applications of hyperbolic discounting is briefly described in Section 11.9. This section highlights an expanding set of problems to which hyperbolic discounting can be applied in a tractable manner to address important issues.

11.2 Two frameworks for modeling present-biased preferences

This section describes two frameworks for modeling models of *multiple selves* in the presence of hyperbolic discounting. Consider an individual who lives through several time periods. Drawing on an influential idea from psychology, suppose that a *distinct self* of the same individual lives in any particular period. Hence, over time, there are *multiple selves* of the same individual.³ The individual in period t is fully described by *self* t of the individual.

In the first of these frameworks, considered in Section 11.2.1, Thaler and Shefrin (1981) envisage the current self as a *long-sighted planner* who cares about the utilities of all future selves, and the future selves as *myopic doers* who care only about their own utilities. The planner can take actions that directly constrain the actions of the doers, or even directly influence the utility of the doers. However, in any period t , other than the initial period in which the planner takes the action, it is the doer corresponding to period t that decides on the action to be taken. For instance, the planner-self of a smoking addict might commit, in period 0, to pay a non-refundable fee in return for enrollment at a smoking clinic in period 1. This constrains the choices of the myopic doer in period 1, although it is the doer who must make the smoking decision in period 1. The idea that future selves have a potential self-control problem that a current self might rectify, sometimes known as the *two-selves models*, can also be found in Elster (1979), Margolis (1982), and Schelling (1984).

The second of the two frameworks of multiple selves that we consider in Section 11.2.2 has proved to be very useful in applications of present-biased preferences. On account of the present

³ We consider further motivation for models of multiple selves and models of *dual selves* in Part 6 of the book on emotions.

bias of each self in any period, different selves typically put different weights on future outcomes. However, unlike planner–doer models, none of the selves can *directly* control their future selves. A major question in this literature, therefore, is the following. Can the current self take any actions that, *indirectly*, influences future selves to internalize better the preferences of the current self?

An important issue, which we examine in Section 11.2.2, is the *degree of awareness* that a current self has about the present bias of one's own future selves. While experimental evidence is inconclusive, it appears that completely *sophisticated behavior*, i.e., full awareness of future self-control problems, and the polar extreme of completely *naive behavior*, are less likely relative to the intermediate case of *partial awareness* of self-control problems in the future.

11.2.1 Planner–doer models

Within a life-cycle model, suppose that the current self takes the form of a *planner*, and cares for the utility of all the subsequent selves. The subsequent selves, one for each time period, termed as the *doers*, are myopic in the sense that they care only about maximizing their own utility. Thaler and Shefrin (1981) term models with these features as *Behavioral Life-Cycle Models* (BLC) that we now discuss. We present a modified version of the model of Thaler and Shefrin (1981) in which there is strategic substitutability between the actions of the planner and the doers. There is no presumption that this modification would be agreed to by the authors of the BLC model, but it allows for an elegant and simple illustration of the model.

The planner–doer framework can be used to describe several types of behaviors in which the current planner may take potentially costly actions to bind the actions of future myopic doers. Consider the following examples.

1. In the case of alcohol addiction, the planner may take a drug (e.g., antabuse) that makes the future selves ill if they drink alcohol.
2. The planner-self of an academic might agree to present a paper at a conference at a future date, which binds the behavior of future selves.
3. The planner-self in a life-cycle model might inculcate a *debt ethic* (no borrowing under most circumstances) that gradually becomes a habit and, in models of habit formation, constrain the future selves.

Consider a three-period model; the time periods are $t = 0, 1, 2$. In the initial period, period 0, the planner chooses some action $\theta \in [0, \bar{\theta}] \subset R$ that influences the utility of the subsequent selves. The interpretation of $\theta = 0$ is that the planner takes no action, and $\bar{\theta}$ is the maximum action that can be taken. The cost of taking action θ to the planner is $\phi(\theta)$, which is increasing and convex: $\phi_1 > 0$ and $\phi_{11} \geq 0$, where subscripts denote partial derivatives.

Call the self in period $j = 1, 2$ as self j (or doer j). For pedagogical simplicity, the parameter, θ , chosen by the planner affects only self 1, but not self 2. The individual works in the second period, inelastically supplying one unit of labor, and earning labor income, y . The individual is retired at the end of period 1, and earns no income in period 2. Hence, the income profile over the three periods is $(0, y, 0)$. Consumption in period $j = 1, 2$ is denoted by c_j .

The planner's problem is to choose θ in order to maximize the sum of utilities of selves 1 and 2, giving equal weights to both. Self 2 is retired, has no economically meaningful decision to make, and is unaffected by the planner's action, θ . So, for pedagogical simplicity, we assume that period 2 utility is given by

$$U_2(c_2) = c_2.$$

The utility function of self 1 is given by

$$U_1(s, \theta) = u(c_1, \theta) + \eta U_2(c_2), \quad 0 < \eta < 1. \quad (11.1)$$

So, as compared to the planner who puts equal weights on the utilities of the two future selves, self 1 is myopic in the sense that he puts relatively greater weight on his own utility. Self 1 is also influenced by the planner's choice of θ . The own utility function of self 1, u , has continuous partial derivatives of order 2. Other properties of u are (subscripts on u denote partial derivatives):

$$u_1 > 0; u_{11} < 0; u_2 < 0; u_{12} < 0. \quad (11.2)$$

Hence, u is increasing in consumption, but at a diminishing rate. By choosing a higher action, θ , the planner can reduce the utility of self 1, i.e., $u_2 < 0$. Furthermore, there is *strategic substitutability* between the action chosen by the planner and the consumption of self 1, i.e., $u_{12} < 0$. Hence, the planner has the ability to alter the level of utility and the marginal utility of self 1.

The next set of assumptions ensure an interior solution.

$$(i) \eta < u_1(y, 0). (ii) \forall \theta > 0: (a) \eta > u_1(y, \theta), \text{ and } (b) \eta > u_1(0, \theta). \quad (11.3)$$

The budget constraint of self 1 is given by

$$c_1 + s = y, \quad (11.4)$$

where $s \in [0, y]$, is the savings made by self 1.

The solution to the problem is by backward induction. Self 2 has no economically meaningful decision to make and relies entirely on the savings of self 1, so $U_2(c_2) = s$. Substituting this and (11.4) in (11.1), the unconstrained maximization problem of self 1 is to choose s , given θ , i.e.,

$$s^* = \arg \max_{s \in [0, y]} U_1(s, \theta) = u(y - s, \theta) + \eta s.$$

It follows that

$$\frac{dU_1(s, \theta)}{ds} = -u_1(y - s, \theta) + \eta. \quad (11.5)$$

Since u is a continuous and strictly concave function over a compact set, we have a unique solution, $s^*(\theta)$, to the problem of self 1. Substituting s^* in (11.4), the optimal consumption choice is $c_1^*(\theta) = y - s^*(\theta)$.

If the planner undertakes no costly action, $\theta = 0$, then, using the first inequality in (11.3), and (11.5), it is optimal for self 1 to consume all of the current income, because $\frac{dU_1(s, \theta)}{ds} < 0$. Thus, in the absence of any intervention from the planner, $s^*(0) = 0$, and self 2 has zero income. This is the sense in which self 1 is *present-biased*.

However, for any $\theta > 0$, (11.3) and (11.5) imply that $s^* > 0$. The last inequality in (11.3), and (11.5) imply a unique interior optimal solution $0 < s^*(\theta) < y$. The optimal consumption $c_1^*(\theta) = y - s^*(\theta)$, is also interior so implicitly differentiating (11.5) at equality, we get

$$\frac{dc_1^*}{d\theta} = -\frac{ds^*}{d\theta} = \frac{u_{12}}{-u_{11}} < 0. \quad (11.6)$$

The sign in (11.6) follows because of strategic substitutability, $u_{12} < 0$. Thus, an increase in the planner's action increases savings made by self 1.

The planner's objective is to maximize the sum of utilities of selves 1 and 2, hence, anticipating correctly the subsequent choices, the unconstrained problem of the planner is,

$$\theta^* \in \arg \max U_0(\theta) = u(y - s^*(\theta), \theta) + \eta s^*(\theta) + s^*(\theta) - \phi(\theta); \theta \in [0, \bar{\theta}].$$

Using the envelope theorem, we can write

$$\frac{dU_0(\theta)}{d\theta} = U'_0 = u_2(y - s^*(\theta), \theta) + \frac{ds^*(\theta)}{d\theta} - \frac{d\phi(\theta)}{d\theta}. \quad (11.7)$$

U_0 is a continuous function on a compact set, $[0, \bar{\theta}]$, so it has a maximum. The maximum is unique if $U'_0 < 0$. Given (11.2) and (11.6), the first term on the RHS of (11.7) is negative and the second is positive. These terms capture, respectively, the marginal cost arising from the reduction in consumption of self 1, and the marginal benefit arising from an increase in the consumption of self 2. The third term is the marginal cost to the planner of using the action, θ . These terms reflect the basic trade-off faced by the planner. Let us now consider some predictions of the planner–doer models.

1. **Savings inadequacy:** Consider the case where self 1 has to subscribe to some mandatory retirement savings plan. In the life-cycle model, individuals smooth income perfectly over their lifetime, so issues of savings inadequacy arising from self-control problems are absent. However, in the planner–doer framework, it is natural to ask if the actions taken by the planner ensure that the future selves make sufficient savings. The answer depends on the nature of marginal benefits and costs shown in (11.7). Kotlikoff et al. (1982) find the answer in the negative. Diamond and Hausman (1984) also find that savings are inadequate. Hence, in this model, mandatory pension, and social security contributions, seem empirically important to supplement the effort of the planner to control the doers.
2. **Non-proportionality:** In Friedman's permanent income hypothesis, individuals consume a fixed fraction of their permanent income. This fraction does not vary with the magnitude of permanent income. Friedman called this the *proportionality principle*. Shefrin and Thaler (1988) report evidence against the proportionality principle; see also, Diamond and Hausman (1984). In the planner–doer framework, there is no presumption that the proportionality principle holds because each of the doers is myopic and does not smooth consumption as well as is required in the neoclassical model. Further, the actions of the doers are controlled imperfectly by a planner through a costly choice of θ that potentially reflects willpower (Shefrin and Thaler, 1988). Thus, individuals at different levels of permanent income (y in the model above) consume different fractions of it.

The planner–doer model has played a lesser role in the subsequent literature in economics relative to the model of multiple selves that we consider next. For this reason, we do not consider the planner–doer model any further; this should not be taken, in any way, as an adverse judgment on the model.

11.2.2 Multiple selves and the degree of awareness

We now describe the workhorse model of *multiple selves* in the presence of quasi-hyperbolic discounting. This section outlines the basics of this framework, followed by a range of applications in subsequent sections. Suppose that time $t \in \Gamma = \{0, 1, 2, \dots, T\}$. Let there be multiple selves of the same individual—one for each period. Each self who lives in any time period $t \in \Gamma$ has quasi-hyperbolic preferences given by.

$$U_t(c_t, c_{t+1}, \dots, c_T) = u(c_t) + \beta \sum_{\tau=t+1}^{\tau=T} \delta^\tau u(c_\tau), 0 < \beta < 1. \quad (11.8)$$

The parameter β in (11.8) creates a bias towards immediate gratification for each self, and $\delta > 0$ is the discount factor in the EDU model. In making economic decisions, the self at time $t \in \Gamma$ must form beliefs about the behavior of all the future selves. Such beliefs reflect the *degree of self-awareness* of the current self at any time $t \in \Gamma$. Self t has beliefs that the preferences of all the future selves at time $k > t$ are given by

$$U_k(c_k, \dots, c_T) = u(c_k) + \hat{\beta} \sum_{\tau=k+1}^{\tau=T} \delta^\tau u(c_\tau), t < k \leq T - 1. \quad (11.9)$$

The relation between the actual impatience parameter of self t , β , and his beliefs about the impatience parameter of a future self, $\hat{\beta}$, is crucial for current decisions. In a more general model, one's beliefs about the present bias of all the future selves may be heterogeneous. Thus, there could be a sequence of $\hat{\beta}_k$ values $t < k \leq T - 1$, but we simplify by setting $\hat{\beta}_k = \hat{\beta}$ for all k . O'Donoghue and Rabin (2001) propose the following classification.

1. *Time consistent*: People with standard time consistent preferences behave as if they are using the EDU model, so

$$\beta = \hat{\beta} = 1. \quad (11.10)$$

These individuals imagine that none of their future selves ever has a present bias (over and above that caused by the presence of δ).

2. *Sophisticates*: Sophisticates know that they have a bias towards immediate gratification, and believe that their future selves will also have an identical bias, i.e.,

$$\beta = \hat{\beta} < 1. \quad (11.11)$$

3. *Partial naifs*: Partial naifs know that they have a bias towards immediate gratification, but believe (mistakenly) that their future selves will have a smaller, but non zero, bias, i.e.,

$$\beta < \hat{\beta} < 1. \quad (11.12)$$

4. *Naifs*: Naifs know that their current selves are present-biased, but believe that their future selves will have no bias towards immediate gratification, i.e., they believe that future selves are time consistent, hence

$$\beta < \hat{\beta} = 1. \quad (11.13)$$

The existing evidence is not conclusive, but O'Donoghue and Rabin (2001) feel that people lie in between the two extremes of sophisticates and naifs, i.e., most people are probably partial naifs. This suggests checking for the robustness of results with respect to this proposed classification.

Example 11.17 (*The snooze button in alarm clocks*): Many of us set the alarm to wake up in the morning. Let us term the self who sets the alarm at night, the night-self, and the self that wakes up in the morning, the morning-self. We may often find it difficult to precommit to waking up on the alarm, because the night-self cannot predict fully how the morning-self will react to the alarm. It is possible for the morning-self to just switch the alarm off, with possibly negative consequences for both selves. In this case, the night-self might desire some commitment technology that disciplines the morning-self.

The makers of alarm clocks seem aware of the problem, so they supply us with alarm clocks that have a snooze button that reactivates the alarm to set-off after a short interval. This acts as a disciplining device on the morning-self, and also provides the night-self with some degree of precommitment.

An even stronger precommitment from the night-self would be to place the alarm clock away from the bed, increasing the cost of the morning-self to reverse the night-self's decision. Perhaps the night-self does not often engage in this strong precommitment because it acts as a partial naif, and underestimates the self-control problems that the morning-self will have.

11.3 Optimal consumption under hyperbolic discounting

Consider a simple three period life-cycle model of consumption with multiple selves and quasi-hyperbolic discounting. We show that in the presence of hyperbolic discounting, there are lower savings due to the present bias of individuals. The results on the relation between the degree of awareness (naif, partial naif, and sophisticates), and the shape of the consumption profile, are interesting, but are dependent on the functional forms used; the Euler equations corresponding to the more general life-cycle model are considered below in Section 11.3.4. A more direct aim of the simple model is to expose the reader to the method of solution under hyperbolic discounting and limited awareness.

These sorts of models have provided an important starting point for the emerging and exciting new discipline of *behavioral macroeconomics*. For a fuller treatment in a more general model, the reader may wish to consult Laibson et al. (1998) and Angeletos et al. (2001). A calibrated economy in which consumers use hyperbolic discounting explains much better the data on consumption, illiquid assets, and credit card debt, relative to a model where consumers use exponential discounting. In a follow-up paper, Laibson et al. (2005) estimate the quasi-hyperbolic parameters (on an annual basis) to be: $\beta \approx 0.7$ and $\delta \approx 0.96$. For a more general model with infinite horizon and uncertainty, Harris and Laibson (2001a,b) show that the derived consumption functions may exhibit discontinuities and non-monotonicity. However, when the model is calibrated at empirically plausible parameter values, such pathologies do not arise. Judd (2003) looks into further issues using asymptotic theory and perturbation methods to examine the existence and uniqueness of the solution under hyperbolic discounting.

Let the time periods be 1, 2, and 3, so $\Gamma = \{1, 2, 3\}$. The preference of self t , $t \in \Gamma$, are given in (11.8). We set $\delta = 1$; this is also known as $(\beta, 1)$ preferences. Beliefs about the future selves

are given in (11.9). Self 1 has exogenously given labor income $y > 0$, but subsequent selves have no labor income; this can be relaxed, but it is not essential for the results. Consumption in the three periods is denoted by c_1, c_2, c_3 . We assume that the individual can only save in one-period financial instruments, such as one-period bonds. For simplicity, the interest rate is normalized to zero. We relax some of these assumptions below. For instance, we will consider the possibility of saving in assets with a longer maturity, and the use of illiquid assets.

The preferences of self 1 are given by

$$U_1 = u(c_1) + \beta u(c_2) + \beta u(c_3), \quad (11.14)$$

where u is a strictly increasing and concave utility function. The problem of self 1 is to choose savings in the first period, $s_1 \in [0, y]$. For pedagogical ease, we focus only on interior solutions. The budget constraints in each time period are given by:

$$\begin{cases} c_1 = y - s_1, & s_1 \in [0, y], \\ c_2 = s_1 - s_2, & s_2 \in [0, s_1], \\ c_3 = s_2, \end{cases} \quad (11.15)$$

where s_2 is the savings made by self 2, which we restrict to be non-negative. Except for the first period, consumption in any of the two remaining periods is only made possible by savings carried over from the previous period in the form of a one-period financial instrument that bears zero rate of interest.

11.3.1 Benchmark case: time consistent preferences

In the classical case, decision makers follow the EDU model, which we know from Section 9.3.2 gives rise to time consistent choices. Denote the optimal values in this case by the superscript c (for the “consistent” solution). From (11.10), in this case, $\beta = \hat{\beta} = 1$. Substitute $\beta = 1$ and (11.15) in (11.14) to get the following unconstrained problem.

$$s_1^c, s_2^c \in \arg \max_{s_1 \in [0, y]; s_2 \in [0, s_1]} u(y - s_1) + u(s_1 - s_2) + u(s_2).$$

The first order conditions at the interior solution are

$$s_1 : u'(c_1) = u'(c_2), \quad (11.16)$$

$$s_2 : u'(c_2) = u'(c_3). \quad (11.17)$$

From (11.16), (11.17), we get that along the optimal consumption path, since the interest rate is zero and $\delta = 1$, marginal utilities are equated. Thus, $u'(c_1) = u'(c_2) = u'(c_3)$, which in conjunction with the budget constraints in (11.15), implies that the optimal solution is given by

$$c_1^c = c_2^c = c_3^c = \frac{y}{3}. \quad (11.18)$$

Hence, an individual with time consistent preferences perfectly smooths consumption across the three periods.

11.3.2 The solution under limited awareness

Consider now any of the cases of different degrees of awareness described in Section 11.2.2. When maximizing (11.14), subject to the budget constraint in (11.15), self 1 knows that self 2 will choose s_2 . Self 1 holds the belief that the impatience parameter of self 2 is $\hat{\beta}$. The relation between β and $\hat{\beta}$ is given by (11.11), (11.12), and (11.13), respectively, for *sophisticates*, *partial naifs*, and *naifs*. Let superscript $j = s, p, n$ on the optimal solution denote, respectively, sophisticates, partial-naifs, and naifs. Hence, self 1 believes that the preferences of self 2 are given by

$$U_2 = u(c_2) + \hat{\beta}u(c_3). \quad (11.19)$$

Substituting (11.15) in (11.19), self 1 believes that the unconstrained problem of self 2 is given by

$$s_2^j \in \arg \max_{0 \leq s_2 \leq s_1} u(s_1 - s_2) + \hat{\beta}u(s_2); j = s, p, n. \quad (11.20)$$

In (11.20), self 2 takes as given, the choice of the first period saving, s_1 , made by self 1. The first order condition to the problem in (11.20) is given by

$$u'(c_2) = \hat{\beta}u'(c_3). \quad (11.21)$$

The optimal solution to (11.21) is given by $s_2^j(s_1)$. The higher is $\hat{\beta}$, the greater is the weight placed on the utility of self 3, hence, the greater is s_2^j .

Self 1 now maximizes (11.14), given the budget constraints in (11.15), and the subsequent behavior of self 2, encapsulated in the reaction function $s_2^j(s_1)$. Substituting these constraints into (11.14), the unconstrained problem of self 1 is given by

$$s_1^j \in \arg \max_{s_1 \in [0, y]} u(y - s_1) + \beta u(s_1 - s_2^j(s_1)) + \beta u(s_2^j(s_1)); j = s, p, n.$$

The first order condition is given by

$$-u'(y - s_1) + \beta u'(s_1 - s_2^j(s_1)) \left(1 - \frac{ds_2^j(s_1)}{ds_1}\right) + \beta u'(s_2^j(s_1)) \frac{ds_2^j(s_1)}{ds_1} = 0. \quad (11.22)$$

In saving an extra dollar, self 1 faces a reduction in own utility (first term), but a benefit in terms of an increased utility for self 3 (third term). The marginal effect on self 2 depends on whether s_1 offsets s_2^j more than, or less than one for one.

In order to obtain analytical results, let us assume that the instantaneous utility function is of the CRRA type, i.e.,

$$u(c) = \left(\frac{1}{1-\gamma}\right) c^{1-\gamma}; 0 < \gamma \text{ and } \gamma \neq 1. \quad (11.23)$$

Pollak (1968) showed that the degree of awareness has no effect in the case of log preferences, hence, we restrict (11.23) to the case $\gamma \neq 1$. For CRRA preferences, the first order condition of self 2, (11.21), simplifies to

$$s_2^j(s_1) = \widehat{\mu}(s_1 - s_2^j(s_1)), \text{ where } \widehat{\mu} = \widehat{\beta}^{\frac{1}{\gamma}}. \quad (11.24)$$

Hence,

$$s_2^j(s_1) = \frac{\widehat{\mu}}{1 + \widehat{\mu}} s_1. \quad (11.25)$$

We can now use (11.25) in (11.22) to find the optimal savings made by self 1, s_1^j , $j = s, p, n$. These values can then be substituted in the budget constraints in (11.15) to determine the optimal values of consumption, c_1^j, c_2^j, c_3^j , $j = s, p, n$. The next proposition states the results of this simple exercise.

Proposition 11.17 *Suppose that preferences take the CARA form. Let $\mu = \beta^{1/\gamma}$ and $\widehat{\mu} = \widehat{\beta}^{\frac{1}{\gamma}}$. Then the following solution arises in the three-period life-cycle model.*

(a) *When self 1 is a naif, so $\beta < \widehat{\beta} = 1$ (see (11.13)), then*

$$c_1^n = (1 - \theta_1) y; c_2^n = c_3^n = \frac{\theta_1}{2} y, \text{ where } \theta_1 = \left(1 + \frac{1}{2\mu}\right)^{-1}. \quad (11.26)$$

(b) *When self 1 is a partial naif, so $\beta < \widehat{\beta} < 1$ (see (11.12)), then*

$$c_1^p = (1 - \theta_2) y; c_2^p = \left(\frac{\theta_2}{1 + \widehat{\mu}}\right) y; c_3^p = \left(\frac{\widehat{\mu}\theta_2}{1 + \widehat{\mu}}\right) y, \quad (11.27)$$

where

$$\theta_2 = \left(1 + \frac{1}{\mu} \left(\left(\frac{1}{1 + \widehat{\mu}}\right)^{1-\gamma} (1 + \widehat{\mu}^{1-\gamma})\right)^{-1/\gamma}\right)^{-1}.$$

(c) *When self 1 is a sophisticate, so $\beta = \widehat{\beta} < 1$ (see (11.11)), then*

$$c_1^s = (1 - \theta_3) y; c_2^s = \left(\frac{\theta_3}{1 + \mu}\right) y; c_3^s = \left(\frac{\theta_3\mu}{1 + \mu}\right) y, \quad (11.28)$$

where

$$\theta_3 = \left(1 + \frac{1}{\mu} \left(\left(\frac{1}{1 + \mu}\right)^{1-\gamma} (1 + \mu^{1-\gamma})\right)^{-1/\gamma}\right)^{-1}.$$

Comparing (11.18), (11.26), and using $\beta^{1/\gamma} < 1$, it follows that $c_1^n > c_1^c$. Hence, as one would expect, the relatively greater desire of the naif for immediate gratification as compared to a time consistent individual, leads to greater current consumption. Thus, a naif engages in a lower degree of consumption smoothing.

Table 11.1 Optimal consumption profiles for two values of the coefficient of relative risk aversion, 0.5 (columns 2–4) and 1.5 (columns 5–7).

Individual type	c_1	c_2	c_3	c_1	c_2	c_3
Time consistents	333.3	333.3	333.3	333.3	333.3	333.3
Sophisticates	731.9	197.1	71.0	499.6	292.4	208.0
Partial naifs	790.9	127.5	81.6	515.1	260.4	224.4
Naifs	581.4	307.8	110.81	412.8	343.14	244.1

Partial naifs are more aware than naifs that they will have future self-control problems. Does relatively greater self-awareness, as compared to the naifs, lead the partial naifs to consume less in the first period? Comparing (11.26), (11.27), the answer ultimately depends on the values taken by the parameters. For instance, when $\hat{\beta} = 0.8$ and $\gamma = 0.5$, a simple calculation shows that $c_1^p > c_1^n$. Hence, for these illustrative values, the greater awareness of partial naifs of the self-control problems of their future selves, reduces their current savings. This result is not robust to all utility functions and other applications below deal with this issue.

We now report some calibration results from O'Donoghue and Rabin (2003). Let us normalize $y = \$1000$. Table 11.1 reports illustrative results for first period consumption for various values of $\hat{\beta}$, and for different values of the coefficient of relative risk aversion, γ . In columns 2–4, $\gamma = 0.5$, and in columns 5–7 we have $\gamma = 1.5$. In general, the relation between the degree of self-awareness and over-consumption relative to the benchmark case of time consistent consumers, depends on the shape of the utility function. However, present bias, in general, leads to overconsumption because the first period consumption of the time consistents is lower relative to any of the other types with potential self-control problems.

11.3.3 Mitigating self-control problems in the life-cycle model

The most robust feature of Table 11.1 is the self-control problem (in terms of lower savings) faced by all three types of individuals who exhibit hyperbolic discounting, relative to individuals with time consistent preferences. Can individuals who have self-control problems take some actions to influence the choices of the future selves? One possibility, suggested by Angeletos et al. (2001), is investment in *illiquid assets*; we give below an analytical solution for a simpler model.

Suppose that, in the three period model considered above, self 1 can invest in some illiquid asset, z , that has a maturity of two periods, so it matures in period 3. The asset is illiquid in the sense that self 2 cannot sell it, nor borrow against it in the second period. Such an asset gives self 1 an opportunity to control the behavior of self 2. We continue to assume that utility takes the CRRA form in (11.23).

SOLUTION IN THE PRESENCE OF COMMITMENT

As a benchmark, we first derive the optimal consumption profile of self 1 under *commitment*. In the presence of commitment, the current self can directly specify the actions of future selves, and the specified actions are binding. Since direct control is possible, self 1 does not need to make a costly commitment decision using illiquid assets. Substituting (11.15) in (11.14), we get the following unconstrained problem of self 1.

$$s_1^*, s_2^* \in \arg \max_{s_1 \in [0, y]; s_2 \in [0, s_1]} u(y - s_1) + \beta u(s_1 - s_2) + \beta u(s_2).$$

On account of the commitment technology, self 1 can directly choose s_1, s_2 . A simple proof that is omitted gives the next proposition.

Proposition 11.18 *Let $\mu = \beta^{1/\gamma}$ and utility be of the CRRA form in (11.23). The optimal solution to the problem of self 1 under commitment is given by*

$$s_1^* = \left(1 + \frac{1}{2\mu}\right)^{-1} y. \quad (11.29)$$

$$s_2^* = \left(1 + \frac{1}{2\mu}\right)^{-1} \frac{y}{2}. \quad (11.30)$$

The corresponding optimal consumption profile is given by

$$c_1^* = y \left[1 - \left(1 + \frac{1}{2\mu}\right)^{-1}\right]. \quad (11.31)$$

$$c_2^* = c_3^* = s_2^* = \left(1 + \frac{1}{2\mu}\right)^{-1} \frac{y}{2}. \quad (11.32)$$

Despite the availability of commitment, an individual who has present-biased preferences does not perfectly smooth consumption, unlike a time consistent individual (see (11.18)).

ILLIQUID ASSETS AND ABSENCE OF COMMITMENT

Suppose that no commitment technology is available to self 1. We shall now show that self 1 can use a long-term, two-period, illiquid asset, z , to implement the consumption profile given in (11.31), (11.32). Investment in illiquid assets could take several forms, such as housing and defined pension contributions (for instance the 401k plan in the US). This alters the budget constraint of self 3, given in (11.15), to $c_3 = s_2 + z$. Since the problem of self 3 is trivial, we first solve the optimization problem of self 2 in the presence of illiquid assets.

Self 2 takes as given s_1, z , which are chosen by self 1, and solves

$$s_2^j \in \arg \max_{(0 \leq s_2 \leq s_1)} u(s_1 - s_2) + \widehat{\beta} u(s_2 + z); j = s, p, n. \quad (11.33)$$

The objective function in (11.33) is identical to (11.20), except that c_3 now includes the illiquid asset, z , that was invested in the first period, but matures in the third. Given the nature of the illiquid asset, the individual cannot borrow against z in the second period.⁴ A simple calculation shows that for the case of CRRA preferences, the solution is given by

$$s_2^j(s_1, z) = \max \left\{ 0, \frac{1}{1 + \widehat{\mu}} (s_1 - \widehat{\mu} z) \right\}, \text{ where } \widehat{\mu} = \widehat{\beta}^{\frac{1}{\gamma}}. \quad (11.34)$$

Given the subsequent behavior of self 2, as captured in (11.34), self 1 now takes two main financial decisions. How much to invest in short-term savings, s_1 , and how much to invest in the long-term

⁴ If, for instance, self 2 could cash a fraction λ of the asset, then his objective function would be $u(s_1 + \lambda z - s_2) + \widehat{\beta} u(s_2 + (1 - \lambda)z)$.

illiquid asset, z ? Lacking a commitment technology, self 1 cannot directly control the behavior of self 2, but he can do so indirectly by a choice of z . We now show how the optimal consumption profile given in (11.31), (11.32) can be implemented; the solution is derived recursively.

Suppose that the solution to (11.34) is $s_2^j = 0$. Hence, self 2 is unable to alter the consumption profile chosen by self 1. This implies that $c_3 \equiv z$. To ensure that $c_3 = c_3^*$, choose

$$z = c_3^* = \left(1 + \frac{1}{2\mu}\right)^{-1} \frac{y}{2}. \quad (11.35)$$

Since $s_2^j = 0$, we have that $c_2 \equiv s_1$. To ensure that $c_2 = c_2^*$, choose

$$s_1 = c_2^* = \left(1 + \frac{1}{2\mu}\right)^{-1} \frac{y}{2}. \quad (11.36)$$

The choice of c_2^*, c_3^* ensures that $c_1 = c_1^*$ will satisfy the intertemporal budget constraint. Hence, in the presence of illiquid assets, self 1 can implement the commitment solution. We leave it to the reader to show that this result is unchanged if the solution to (11.34) is $s_2^j > 0$. With a relatively high value of $\gamma = 5$ and $y = \$1000$, $\beta = 0.6$, $\hat{\beta} = 0.8$, it turns out that the optimal consumption levels are $c_1 = 388.8$ and $c_2 = c_3 = 305.6$, which is closer to the consumption profile of an individual with time consistent preferences (see Table 11.1).

We now use the model above to illustrate how one might explain a range of puzzles in macroeconomics.

1. **Why does consumption track income so closely?** In our stylized three period model, the individual has income only during the first period, hence, the income profile is $(y, 0, 0)$. From Table 11.1, the time consistent individual engages in perfect consumption smoothing over the three periods. However, for any of the other three types of present-biased individuals, consumption tracks income more closely relative to the time consistent individual. This feature survives modeling over a longer horizon where income is received over several periods.
 2. **Why do individuals undersave for retirement?** Time consistent individuals do not undersave for retirement. However, the retirement plans of any of the other types can be scuppered by the present bias of one of the future selves who may splurge on current consumption. For instance, under commitment, (11.30) gives desired second period savings, s_2^* , which, from (11.32), equal desired third period consumption c_3^* . However, in the absence of commitment and illiquid assets, second period saving, $s_2^j(s_1) = c_3^j$ given in (11.25), is decided by self 2. Given the present bias of self 2, c_3^j falls short of c_3^* (see Table 11.1). So, in general, individuals with a present bias will not save adequately for their retirement. These issues are considered in a richer framework in Section 11.4 below.
- Brown et al. (2009) explore two possible reasons for undersavings. (i) Bounded rationality (individuals simply lack the necessary sophistication to formulate optimal dynamic plans), and (ii) present-biased preferences. They find that while initially subjects' decisions are not close to optimal decisions due to bounded rationality, individuals learn quickly. However, when *visceral influences* are introduced (in this case, thirst), the behavior of individuals is

consistent with hyperbolic discounting.⁵ The parameter β in hyperbolic discounting models is estimated to be 0.6–0.7.

3. **Why is there a sharp drop in consumption at retirement?** In our three-period model, with the income profile $(y, 0, 0)$, the individual can be interpreted as working for the first period of his life and retired for the next two.⁶ It is apparent from Table 11.1 that for an individual with time consistent preferences, there is no drop in consumption at retirement. However, for all other types of individuals, there is a drop in consumption from the first period onwards. Evidence suggests that the drop in consumption at retirement can be fairly significant. Based on US data, Bernheim et al., (1997) report that the bottom wealth quartile suffers a 30% drop in consumption at retirement. Kotlikoff et al. (1982) find that in the absence of social security and private pensions, consumption in old age would, on average, be about 40% lower.
4. **Why do individuals hold illiquid assets and credit card debt simultaneously?** Illiquid asset can discipline one's future selves only if the future selves find it difficult to borrow against future wealth. Using field data from the Philippines, Ashraf et al. (2006) show that there is substantial demand for illiquid assets as a commitment device, and that such actions enhance savings.⁷ In our three-period model, suppose that self 1 has invested in illiquid assets, but a credit card company unexpectedly gives self 2 an opportunity to borrow in period 2. Self 2 is likely to accept this opportunity if her optimal choice is constrained by the investment in illiquid assets undertaken by self 1. In this instance, the expansion of financial markets may worsen the self-control problems for an individual.
5. **Why have national savings rates been declining?** Countries in the developed world have been experiencing a decline in the savings rate since the 1970s. This period has also coincided with an unprecedented expansion in the credit market. Easy availability of credit on reasonable terms puts a constraint on the ability of current selves to control actions such as consumption splurges of their future selves. This may lead to a reduction in savings (Laibson, 1997).
6. **Why is the marginal propensity to consume asset specific?** Thaler (1990) argues that consumers have different marginal propensities to consume (MPC) from different accounts for different assets. For instance, evidence suggests that the MPC from an unexpected job related bonus is close to unity, while the MPC from an unexpected increase in the value of an equity portfolio is close to zero. In our stylized three period model, we have not attempted to explain the mechanisms that give rise to variations in MPC. A possible explanation might run as follows. The current self tries to restrict the actions of the future selves by choosing to invest in illiquid assets that bind the choices of the future selves. Suppose that in (11.34), $s_2^j(s_1, z) = 0$, i.e., self 2 is liquidity constrained on account of the action taken by self 1. If self 2 now unexpectedly receives a bonus on the job, then she will consume it immediately because the choice of self 1 has restricted her liquidity. However, an unexpected appreciation of the illiquid asset, in the example, will benefit only self 3, without effecting the marginal propensity to consume of self 2.

⁵ For the effects of visceral influences on human choices and actions, see Part 6.

⁶ The alternative assumption of working for the first two periods, and retiring for the third period can be easily accommodated in the model.

⁷ On the demand for commitment devices for retirement savings in US, see Benartzi and Thaler (2004).

11.3.4 Euler equations in a general life-cycle problem

In this section, we derive the Euler equation in a more general life-cycle model, under exponential and hyperbolic discounting.

THE EULER EQUATION UNDER EXPONENTIAL DISCOUNTING

Consider an individual who uses the EDU model and lives for T periods. His date 0 utility function under EDU is

$$U_0(c_0, c_1, \dots, c_T) = E_0 \sum_{t=0}^T \delta^t u(c_t),$$

where E_0 is the expectation operator, conditional on the information set at $t = 0$, and $\delta \in [0, 1]$ is the discount factor. u is a strictly increasing, and concave, instantaneous utility function. $c_t \in R_+$ is consumption at time t . In any time period t , the income of the individual, y_t , is stochastic. The budget constraint in period t is

$$c_t + s_t = y_t + Rs_{t-1} \equiv W_t; t = 1, 2, \dots, T. \quad (11.37)$$

In (11.37), s_t is savings in period t and Rs_{t-1} is the financial income at time t arising on account of savings made in one-period maturity bonds at time $t - 1$. R is the time-invariant gross interest rate on savings. The total income from all sources in period t is denoted by W_t . The intertemporal budget constraint is given by

$$\sum_{t=0}^T R^{-t} c_t \leq \sum_{t=0}^T R^{-t} y_t \equiv W, \quad (11.38)$$

where W is the present discounted value of lifetime income. Since we assume local non-satiation of u , hence, (11.38) binds at the optimal solution. Letting ν be the Lagrangian multiplier on the constraint, the individual's optimization problem is given by

$$(c_0^*, c_1^*, \dots, c_T^*) \in \arg \max_{c_t \in R_+} E_0 \left[\sum_{t=0}^T \delta^t u(c_t) + \nu \sum_{t=0}^T R^{-t} (y_t - c_t) \right],$$

where c_t^* , $t = 0, 1, \dots, T$, is the optimal consumption in period t . The first order condition with respect to c_t for an interior solution is⁸

$$\delta^t E_0 u'(c_t) - \nu R^{-t} = 0; 0 \leq t \leq T. \quad (11.39)$$

Using (11.39), for any two consecutive dates, $j, j + 1$, $0 \leq j < T$ we get

$$E_0 u'(c_j) = R \delta E_0 u'(c_{j+1}). \quad (11.40)$$

⁸ The imposition of the Inada conditions and the finiteness of the budget constraint typically ensure an interior solution in these models.

In particular, for $j = 0$, the current date, we get

$$u'(c_0) = RE_0 \delta u'(c_1). \quad (11.41)$$

(11.40) gives the Euler equation in the EDU model. A slight rearrangement of (11.40) gives the familiar condition of equality between the marginal rate of substitution and the marginal rate of transformation: $\frac{E_0 u'(c_j)}{\delta E_0 u'(c_{j+1})} = R$. The Euler equation can also easily be derived using an arbitrage argument. The LHS of (11.40) is the change in current utility when current consumption is reduced by a dollar; this is the marginal cost. Over one period, the saved dollar is worth R dollars and it is weighted by the discounted marginal utility of consumption, $\delta u'(c_{j+1})$, in the next period; this is the marginal benefit.

THE EULER EQUATION UNDER HYPERBOLIC DISCOUNTING AND SOPHISTICATED MULTIPLE SELVES

We now draw on Laibson's (1998) treatment of the Euler equations in the presence of sophisticated multiple selves of an individual who uses hyperbolic discounting. Assume that the individual is a sophisticate (see (11.11)), hence, $\beta = \hat{\beta} < 1$. Consider the hyperbolic preferences stated in (11.8), and let $T \rightarrow \infty$. The problem is to maximize (11.8) by choosing an optimal consumption profile, subject to the budget constraint given in (11.38). We give a heuristic derivation of the *behavioral Euler equation* below.

Consider the consumption-savings choice of self 0. Suppose that self 0 reduces current consumption by one unit. This alters current utility by $u'(c_0)$; this is the marginal cost of the decision. However, the extra unit saved by self 0 creates a ripple effect on future instantaneous utilities that is felt by all future selves; the aggregate of this ripple effect is the marginal benefit. Self 0 reallocates income in this manner till the marginal costs and marginal benefits are equated. We first state the relevant arbitrage condition in (11.42), and then give a heuristic derivation.

$$u'(c_0) = \beta \left[\delta RE_0 u'(c_1) + \delta^2 R^2 \sum_{i=0}^{\infty} \delta^i R^i E_0 \left[\frac{\partial c_{2+i}}{\partial W_{2+i}} \prod_{j=0}^{i-1} \left(1 - \frac{\partial c_{1+j}}{\partial W_{1+j}} \right) \right] u'(c_{2+i}) \right]. \quad (11.42)$$

In any period t , $\frac{\partial c_t}{\partial W_t}$ is the marginal propensity to consume, so $1 - \frac{\partial c_t}{\partial W_t}$ is the marginal propensity to save. When self 0 saves an extra dollar, the marginal benefit, on account of the effect on self 1 is

$$\beta \delta RE_0 u'(c_1); \quad (11.43)$$

this is analogous to the RHS of (11.41) under EDU, but under hyperbolic discounting there is an extra parameter β that captures the present bias of the individual. This is the first term in the brackets on the RHS of (11.42). Self 1, however, does not consume the entire dollar received from self 0. Of that extra dollar, $1 - \frac{\partial c_1}{\partial W_1}$ is saved for self 2. The term corresponding to self 2 on the RHS of (11.42) is

$$\beta \delta^2 R^2 E_0 \frac{\partial c_2}{\partial W_2} \left(1 - \frac{\partial c_1}{\partial W_1} \right) u'(c_2). \quad (11.44)$$

To understand (11.44), consumption of self 2 increases by $\frac{\partial c_2}{\partial W_2} \left(1 - \frac{\partial c_1}{\partial W_1}\right)$, and this is weighted by her marginal utility of consumption $u'(c_2)$. Since this term arises in period 2, in order to convert it to time 0 units, we need to multiply by $\delta^2 R^2$ to account for (i) discounting over two periods (the term δ^2), and (ii) the return on the one-period financial instrument over two periods (the term R^2).

Of the original dollar saved by self 0, a fraction $\left(1 - \frac{\partial c_1}{\partial W_1}\right) \left(1 - \frac{\partial c_2}{\partial W_2}\right)$ goes to self 3. Hence, we can construct the present discounted value of the marginal benefit (to self 0), in utility terms, on account of self 3 as

$$\beta \delta^3 R^3 E_0 \frac{\partial c_3}{\partial W_3} \left(1 - \frac{\partial c_1}{\partial W_1}\right) \left(1 - \frac{\partial c_2}{\partial W_2}\right) u'(c_3). \quad (11.45)$$

The explanation of (11.45) is parallel to that of (11.44).

We can construct the marginal returns for all future selves in this manner. Adding together the resulting terms such as (11.43), (11.44), (11.45) one obtains the composite present discounted value of marginal benefit of a dollar saved by self 0; this is simply the RHS of (11.42).

Moving (11.42) forward in time by one period, while maintaining the information set at time 0, we get

$$u'(c_1) = \beta \left[\delta R E_0 u'(c_2) + \delta^2 R^2 \sum_{i=0}^{\infty} \delta^i R^i E_0 \left[\frac{\partial c_{3+i}}{\partial W_{3+i}} \prod_{j=0}^{i-1} \left(1 - \frac{\partial c_{2+j}}{\partial W_{2+j}}\right) \right] u'(c_{3+i}) \right]. \quad (11.46)$$

Multiply both sides of (11.46) by $\delta R \left(1 - \frac{\partial c_1}{\partial W_1}\right)$ and subtract from (11.42) to get

$$u'(c_0) = RE_0 \delta \left[1 - (1 - \beta) \frac{\partial c_1}{\partial W_1} \right] u'(c_1). \quad (11.47)$$

(11.47) gives the *behavioral Euler equation* under hyperbolic discounting. Notice that with $\beta = 1$, (11.47) reduces to the Euler equation under EDU given in (11.41). Defining

$$\tilde{\delta}_1 = \delta \left[1 - (1 - \beta) \frac{\partial c_1}{\partial W_1} \right], \quad (11.48)$$

as the *effective discount factor* under hyperbolic discounting, we can express the Euler equation under hyperbolic discounting in a form that is similar to (11.41)

$$u'(c_0) = RE_0 \tilde{\delta}_1 u'(c_1). \quad (11.49)$$

In general, we could have set the starting date to any arbitrary positive $t < T$. In this case, the Euler equation in (11.49) can be written as

$$u'(c_t) = RE_t \tilde{\delta}_{t+1} u'(c_{t+1}) \text{ where } \tilde{\delta}_{t+1} = \delta \left[1 - (1 - \beta) \frac{\partial c_{t+1}}{\partial W_{t+1}} \right]. \quad (11.50)$$

CRR preferences have the following property that considerably simplifies the Euler equation. The optimal consumption in any period, t , c_t , is a constant fraction of W , the lifetime present

discounted value of income defined in (11.38). This fraction is given by $\omega_t = \omega_t(\beta, \delta, R) \in (0, 1)$, so that $c_t = \omega_t W = \omega_{j=t} \sum_{j=t}^T R^{j-t} y_j$. Hence, the marginal propensity to consume out of lifetime income is constant. Furthermore, using $y_j = W_j - R s_{j-1}$ (see (11.37)), we can write

$$c_t = \omega_t \sum_{j=t}^T R^{j-t} (W_j - R s_{j-1}). \quad (11.51)$$

Using (11.51) we can compute

$$\frac{\partial c_t}{\partial W_t} = \omega_t. \quad (11.52)$$

Substituting (11.52) in (11.50), for CRRA preferences, the Euler equation under hyperbolic discounting is given by

$$u'(c_t) = R\delta E_t [1 - (1 - \beta) \omega_{t+1}] u'(c_{t+1}), \quad (11.53)$$

where ω_{t+1} is given by moving forward (11.52) by one period. We will now use (11.53) to illustrate how hyperbolic discounting can explain several anomalies of the life-cycle model under the assumption of EDU.

11.3.5 Missing precautionary savings effects

Individuals engage in *precautionary savings* if they respond to uncertainty in future consumption by saving more in the current period. Let us first derive a tractable expression for the Euler equation (11.41) under the EDU model in the following special case. Suppose that preferences are of the CRRA form and the log of consumption is normally distributed, i.e., $\ln c_t \sim N(\mu, \sigma^2)$. Rewriting (11.41) for CRRA preferences we get

$$c_0^{-\gamma} = R\delta E_0 [c_1^{-\gamma}]. \quad (11.54)$$

Since the exponential function is the inverse of the log function, we have

$$E_0 [e^{-\gamma \ln c_1}] = E_0 [c_1^{-\gamma}]. \quad (11.55)$$

Hence, using (11.55) we get⁹

$$E_0 [e^{-\gamma \ln c_1}] = E_0 [c_1^{-\gamma}] = e^{-\gamma \mu + \frac{1}{2} \gamma^2 \sigma^2}, \quad (11.56)$$

where $\mu = E_0 [\ln c_1]$ is the unconditional mean of $\ln c_t$ and σ^2 is the unconditional variance. Substituting (11.56) in (11.54) we get

$$c_0^{-\gamma} = R\delta e^{-\gamma E_0 [\ln c_1] + \frac{1}{2} \gamma^2 \sigma^2}. \quad (11.57)$$

⁹ We use a standard result in statistics that if $x \sim N(\mu, \sigma^2)$ then $E[e^{-\rho x}] = e^{-\rho(\mu - \frac{\rho}{2}\sigma^2)}$.

Taking logs on both sides of (11.57) and dividing through by $-\gamma$ we get

$$\ln c_0 = \left(\frac{1}{-\gamma} \right) [\ln R + \ln \delta] + E_0 [\ln c_1] - \frac{1}{2} \gamma \sigma^2. \quad (11.58)$$

Defining $\Delta E_0 [\ln c_1] = E_0 [\ln c_1] - \ln c_0$ and simplifying (11.58) we get

$$\begin{aligned} \Delta E_0 [\ln c_1] &= \frac{1}{\gamma} [\ln R + \ln \delta] + \frac{1}{2} \gamma \sigma^2. \\ \Rightarrow \Delta \ln c_1 &= \frac{1}{\gamma} [\ln R + \ln \delta] + \frac{1}{2} \gamma \sigma^2 + \epsilon_1, \end{aligned} \quad (11.59)$$

where ϵ_1 is a random term that cannot be predicted at time $t = 0$ when the decision is made. When equations of the form (11.59) are estimated, the estimated coefficient of σ^2 is found to be very small. So high consumption variability is not associated, in the data, with high consumption growth; for instance Browning and Lusardi (1996) and Lusardi (1998). Hence, the precautionary motive seems extremely small, or absent in the data.

These results seem consistent with the hyperbolic model. Intuitively, the current bias will prevent the individual from undertaking adequate precautionary saving. Laibson (1998) points out that a high variability in consumption growth is normally associated with a high value of the one period ahead marginal propensity to consume, i.e., when σ^2 is high, ω_1 is high. Consider the Euler equation under hyperbolic discounting in (11.53) for $t = 0$. A high value of ω_1 reduces the effective discount rate and brings c_0 and c_1 closer, reducing the slope of the optimal consumption profile. This offsets the precautionary savings effect under hyperbolic discounting relative to the EDU model, which is consistent with the evidence (Laibson, 1998).

11.3.6 Relation between intertemporal substitution and risk

Let us focus on the case of full certainty. The *elasticity of intertemporal substitution of consumption* (EIS) between two consecutive time periods is the percentage change in the ratio of consumption that results from a given percentage change in the relative price of consumption, along the optimal path. In the intertemporal context, the price ratio is simply the gross interest rate, hence, in order to compute the EIS, we need to find $\partial \ln (c_{t+1}/c_t) / \partial \ln R$. For CRRA preferences, and in the absence of uncertainty, (11.54) can be rewritten for any two consecutive time periods as

$$\begin{aligned} c_t^{-\gamma} &= R \delta c_{t+1}^{-\gamma}. \\ \Rightarrow \ln \frac{c_{t+1}}{c_t} &= \frac{1}{\gamma} [\ln R + \ln \delta], \end{aligned}$$

hence,

$$\frac{\partial \ln (c_{t+1}/c_t)}{\partial \ln R} = \frac{1}{\gamma}. \quad (11.60)$$

Under EDU, this sets a fairly strong restriction on the relation between EIS and γ ; each is the inverse of the other. This is not supported by the empirical evidence (Hall, 1988). The general view in the empirical literature appears to be that (Laibson, 1998):

$$\frac{\partial \ln (c_{t+1}/c_t)}{\partial \ln R} < \frac{1}{\gamma}. \quad (11.61)$$

The hyperbolic discounting model can potentially account for (11.61). Writing the Euler equation under hyperbolic discounting, (11.53), under certainty and CRRA preferences, for any two consecutive time periods $t, t + 1$ we get

$$\begin{aligned} c_t^{-\gamma} &= R\delta [1 - (1 - \beta)\omega_{t+1}] c_{t+1}^{-\gamma}. \\ \Rightarrow \ln \frac{c_{t+1}}{c_t} &= \frac{1}{\gamma} [\ln R + \ln \delta + \ln [1 - (1 - \beta)\omega_{t+1}]]. \end{aligned} \quad (11.62)$$

Differentiating (11.62) with respect to $\ln R$ on both sides we get

$$EIS = \frac{\partial \ln (c_{t+1}/c_t)}{\partial \ln R} = \frac{1}{\gamma} - \frac{(1 - \beta)}{\gamma [1 - (1 - \beta)\omega_{t+1}]} \frac{\partial \omega_{t+1}}{\partial \ln R}. \quad (11.63)$$

If $\gamma > 1$, as suggested by several empirical studies (Laibson, 1998), then $\frac{\partial \omega_{t+1}}{\partial \ln R} > 0$. The intuition is as follows. As is well known, interest rate changes have opposing income and substitution effects, hence, the effect on consumption is ambiguous. However, when $\gamma > 1$, the income effect overweighs the substitution effect and so an increase in R increases consumption in period $t + 1$, hence, $\frac{\partial \omega_{t+1}}{\partial \ln R} > 0$. But this implies that $EIS < \frac{1}{\gamma}$, which is in accord with the empirical evidence.

11.3.7 Patience heterogeneity: covariation with wealth and age

Relatively young consumers expect rising income profiles in the future, so they might have high marginal propensity to consume (MPC). Consumers who are liquidity constrained might also have a high MPC. Conversely, old consumers and those who are not liquidity constrained are likely to have low MPC. Hence, the effective discount factor in hyperbolic models, see (11.48) and (11.53), varies over an individual's life and is likely to be high when individuals are old and have greater financial wealth. These results are consistent with the experimental evidence, see Green et al. (1999), but are difficult to reconcile with the EDU model.

11.4 Endogenous retirement decisions

In a model of multiple selves, retirement is a decision made by one's future selves. Current selves, however, have an important stake in that decision because the retirement decision affects the future profile of income, so, it must influence the amount of savings that current selves need to make for the future. What actions can current selves take to influence the retirement decisions of future selves? When are these actions effective? What is the role of labor market policy in the presence of such concerns? We now consider these issues in the three period model of Diamond and Köszegi (2003).

Denote the three periods of an individual's lifetime as periods 1, 2, 3. Each period corresponds to a distinct self of the individual; self $t = 1, 2, 3$ lives in period t . The individual has two kinds of decisions to make. The *savings decision*, i.e., how much to consume/save, and the *retirement decision*, i.e., when to retire?

It is mandatory for self 1 to work. Self 1 inelastically supplies one unit of labor and earns a wage, $y > 0$. To make the retirement decision tractable, we assume that only self 2 makes the retirement decision. Self 1 must always work, and self 3 must always be retired. Self 2 can either inelastically supply a unit of labor and earn wage income, y , or retire, in which case the only source of income is the savings made by self 1, s_1 . There is a fixed cost $e > 0$ to self 2 from working.¹⁰ For simplicity, assume (β, δ) preferences, $0 < \beta < 1$. Assume also that self 1 is *sophisticated*, i.e., has full awareness of the self-control problems of the future selves (see (11.11)).¹¹ We assume that the utility function is of the CRRA form.

$$u(c) = \frac{1}{1-\rho} c^{1-\rho}; \quad \rho > 0, \rho \neq 1,$$

where $c \geq 0$ is real-valued consumption. For CRRA preferences, $u' > 0$ and $u'' < 0$. The next lemma states a useful result.

Lemma 11.2 *Consider the maximization problem*

$$\text{Max}_{(c_1, c_2)} u(c_1) + \lambda u(c_2), \quad \lambda > 0,$$

subject to

$$c_1 + \frac{1}{R} c_2 = W,$$

where $R > 0$ and $W > 0$. When u takes the CRRA form, then there exists $\omega(R, \lambda) : \mathbb{R}_+^2 \rightarrow [0, 1]$ such that the optimal solution is $c_1^* = \omega(R, \lambda)W$. Furthermore, $\frac{\partial \omega}{\partial \lambda} < 0$.

The preferences of self 1 are given by

$$U_1 = \begin{cases} u(c_1) + \beta \delta [u(c_2) - e] + \beta \delta^2 u(c_3) & \text{if self 2 works,} \\ u(c_1) + \beta \delta u(c_2) + \beta \delta^2 u(c_3) & \text{if self 2 retires.} \end{cases} \quad (11.64)$$

As compared to self 2, self 1 cares relatively more about self 3. This is so because the discount factor for self 1 over the two time periods 2, 3 is $\frac{\beta \delta^2}{\beta \delta} = \delta$, while the discount factor of self 2 over time periods 2, 3 is $\beta \delta < \delta$. Hence, self 1 may prefer that self 2 does not retire. However, because self 2 puts relatively lower weight on the utility of self 3, he might be inclined to retire.

Can self 1 take any actions that may induce self 2 to not retire? One possibility is for self 1 to save a “sufficiently low” amount that induces self 2 to continue working. However, saving too little is also costly for self 1 because it reduces the income of self 3. If these costs outweigh the potential benefits, then self 1 does not wish to influence the retirement decision of self 2, through reduced savings. In this case, self 1 is forced to save “too much,” so that some of the savings are passed on to self 3.

The budget constraint of self 1 is given by

$$c_1 + s_1 = y \equiv W_1. \quad (11.65)$$

¹⁰ Including a fixed cost of working for self 1 is not important because we assume that he works regardless.

¹¹ Diamond and Koszegi (2003) consider, in addition, the case of partially naive agents.

The solution to this dynamic game of perfect information is by backward induction. The only source of income for self 3 is the savings made by self 2, s_2 . Savings earn a gross return R , hence, period 3 wealth is $W_3 = Rs_2$. Since $u' > 0$, and there are no bequests, self 3 consumes all available wealth, thus, his utility is given by

$$U_3 = u(Rs_2).$$

Self 2 has two possible choices to make, work or retire; we use superscripts w (work) and r (retire) on the relevant variables to denote these two decisions. In making these decisions, self 2 takes as given the savings, s_1 , made by self 1. Thus, we may write the utility function of self 2 as

$$\begin{aligned} U_2^w(c_2, c_3 | s_1) &= u(c_2) - e + \beta \delta u(c_3) & \text{if self 2 works,} \\ U_2^r(c_2, c_3 | s_1) &= u(c_2) + \beta \delta u(c_3) & \text{if self 2 retires.} \end{aligned} \quad (11.66)$$

The budget constraint of self 2, and the third period consumption, c_3 , under the two decisions is

$$\begin{aligned} c_2 + s_2 &\leq y + Rs_1 \equiv W_2^w & \text{and } c_3 = Rs_2 & \text{if self 2 works,} \\ c_2 + s_2 &\leq Rs_1 \equiv W_2^r & \text{and } c_3 = Rs_2 & \text{if self 2 retires.} \end{aligned} \quad (11.67)$$

Since $u' > 0$, the budget constraints bind. From the perspective of self 2, we may alternatively write these budget constraints in an intertemporal form as

$$c_2 + \frac{1}{R}c_3 = W_2^i, i = w, r. \quad (11.68)$$

where W_2^w, W_2^r are defined in (11.67).

Using Lemma 11.2 we know that under CRRA preferences, the optimal consumption of self 2 is given by

$$c_2^i = \omega_2(R, \beta \delta) W_2^i, i = w, r. \quad (11.69)$$

Denote the optimal level of savings of self 2 by $s_2^w(s_1)$ when he works, and by $s_2^r(s_1)$ when he retires. From (11.69), $s_2^i(s_1) = (1 - \omega_2(R, \beta \delta)) W_2^i, i = w, r$. The corresponding consumption levels of self 3 are given by $c_3^i = Rs_2^i(s_1), i = w, r$. The consumption levels, $c_2^w, c_3^w, c_2^r, c_3^r$ are all functions of the savings choice made by self 1, s_1 . Substituting these optimal levels of consumption in (11.66), we get the indirect utility of self 2 under the two decisions.

$$\begin{aligned} V_2^w(s_1) &= u(c_2^w) - e + \beta \delta u(c_3^w) & \text{if self 2 works,} \\ V_2^r(s_1) &= u(c_2^r) + \beta \delta u(c_3^r) & \text{if self 2 retires.} \end{aligned} \quad (11.70)$$

Self 2 prefers to work rather than retire if $\Delta V_2(s_1) = V_2^w(s_1) - V_2^r(s_1) \geq 0$, or

$$\Delta V_2(s_1) = [u(c_2^w) - e - u(c_2^r)] + \beta \delta [u(c_3^w) - u(c_3^r)] \geq 0. \quad (11.71)$$

In order to make the problem interesting we assume that

$$\Delta V_2(0) > 0, \quad (11.72)$$

thus, if self 1 leaves no income for self 2, then self 2 prefers to work. We also assume that there is some lower bound on the cost of effort, e , which ensures that¹²

$$\Delta V_2(y) < 0, \quad (11.73)$$

i.e., if self 2 inherits the entire income of self 1, he chooses to retire.

Differentiating $\Delta V_2(s_1)$ with respect to s_1 , and using (11.67), (11.69), we get

$$\Delta V'_2(s_1) = R\omega_2 [u'(c_2^w) - u'(c_2^r)] + \beta\delta R(1 - \omega_2) [u'(c_3^w) - u'(c_3^r)] < 0. \quad (11.74)$$

We use two facts to sign (11.74). First, for CRRA preferences, $\lim_{c \rightarrow 0} u'(c) = \infty$, hence, the first period savings choice of self 1, $s_1 \in [0, y]$. For any fixed $s_1 > 0$, (11.67) implies that $W_2^w(s_1) > W_2^r(s_1)$, thus, for CRRA preferences, $c_2^w > c_2^r$ and $c_3^w > c_3^r$. Second, for CRRA preferences, the instantaneous utility function is strictly increasing and strictly concave, so $u'(c_2^w) < u'(c_2^r)$ and $u'(c_3^w) < u'(c_3^r)$. Hence, $\Delta V'_2(s_1) < 0$. Furthermore, $\Delta V_2(s_1)$ is a continuous function over $[0, y]$. From (11.72), (11.73), and the continuity of ΔV_2 , there must exist some critical level of savings $s_1 = s^*$ such that for $s_1 < s^*$, $\Delta V_2 > 0$ (self 2 works) and for $s_1 > s^*$, $\Delta V_2 < 0$ (self 2 retires). At $s_1 = s^*$ we have that self 2 is indifferent between working and retiring. We use the tie-breaking rule that in this case, self 2 chooses to work. We summarize these results for later reference in Lemma 11.3 below, which shows how the savings decision of self 1 influences the retirement decision of self 2.

Lemma 11.3 *Self 2 works if $s_1 \leq s^*$ and retires if $s_1 > s^*$, where $\Delta V_2(s^*) = 0$. Furthermore, $s^* > 0$.*

The final stage of the backward induction process is to find the optimizing choice of self 1. Self 1 is aware that the optimal consumption values for periods 2 and 3, are either (c_2^w, c_3^w) , or (c_2^r, c_3^r) . However, self 1 temporally precedes self 2, hence, under hyperbolic discounting, he differs in the relative weight placed on future utilities. Using (11.64), self 1 evaluates the utilities in (11.70) as follows.

$$\begin{aligned} V_1^w(s_1) &= \beta\delta (u(c_2^w) - e) + \beta\delta^2 u(c_3^w) & \text{if self 2 works,} \\ V_1^r(s_1) &= \beta\delta u(c_2^r) + \beta\delta^2 u(c_3^r) & \text{if self 2 retires.} \end{aligned}$$

Hence, self 1 prefers self 2 to work, rather than retire, if $\Delta V_1(s_1) = V_1^w(s_1) - V_1^r(s_1) \geq 0$, or

$$\Delta V_1(s_1) = [u(c_2^w) - e - u(c_2^r)] + \delta [u(c_3^w) - u(c_3^r)] \geq 0. \quad (11.75)$$

Notice that (11.75) is similar to (11.71), except for the different discount rates used to discount the outcomes for period 3. Since, $0 < \beta < 1$, and $u(c_3^w) - u(c_3^r) > 0$, a comparison of (11.71) and (11.75) reveals that

$$\Delta V_1(s_1) > \Delta V_2(s_1) \text{ for all } s_1 \in (0, y). \quad (11.76)$$

¹² The lower bound on effort, $e = e_L$ is given by

$$[u(\omega_2 y(1 + R)) - u(\omega_2 yR)] + \beta\delta [u((1 - \omega_2)y(1 + R)) - u((1 - \omega_2)yR^2)] \leq e_L.$$

Let $s_1 = s^{**}$ be the savings level such that $\Delta V_1(s^{**}) = 0$; the existence of such a s^{**} can be shown in a manner similar to the existence of s^* , above. As in (11.72) and (11.73), we assume that $\Delta V_1(0) > 0$ and $\Delta V_1(y) < 0$.

Lemma 11.4 *Suppose that $\Delta V_1(0) > 0$ and $\Delta V_1(y) < 0$. The savings level, $s_1 = s^{**}$, at which self 1 is indifferent between the work/retire decision of self 2, is greater than the corresponding value of $s_1 = s^*$ at which self 2 is indifferent between the two decisions, i.e., $s^{**} > s^*$. Given our tie-breaking convention, self 1 prefers self 2 to work for any $s_1 \leq s^{**}$ and retire for any $s_1 > s^{**}$.*

Proof: $\Delta V_1(s_1)$ is a continuous function over $[0, y]$, $\Delta V_1'(s_1) < 0$, $\Delta V_1(0) > 0$ and $\Delta V_1(y) < 0$. Given (11.76), at $s_1 = s^*$ we have $\Delta V_1(s^*) > \Delta V_2(s^*)$. Hence, it must be the case that $s^{**} > s^*$.

Using Lemma 11.4, we summarize the difference in decisions between selves 1 and 2 in Lemma 11.5.

Lemma 11.5 *For any level of saving by self 1, $s_1 : 0 \leq s_1 \leq s^*$ both selves 1 and 2 prefer self 2 to work rather than retire. For $s^* < s_1 \leq s^{**}$ self 2 prefers to retire, but self 1 prefers self 2 to work. Finally, for $s_1 > s^{**}$ both selves 1 and 2 would prefer self 2 to retire.*

From Lemma 11.5, it is the region $s^* < s_1 \leq s^{**}$ that creates a conflict of interest between the two selves.

Suppose that self 1 does not have a commitment device to bind self 2 to either work, or retire. We then need to find the optimal savings of self 1 that serve as an indirect control. We solve the problem in two steps. We shall denote the utility of self 1 when self 2 works by $U_1^w(s_1)$. If self 2 retires, the utility of self 1 is denoted by $U_1^r(s_1)$. Denote the optimal levels of savings by self 1 over the interval $[0, y]$ by s_1^w and s_1^r , respectively.

For $0 \leq s_1 \leq s^*$, self 2 works, giving self 1 a continuation payoff of $\beta\delta u(c_2^w) + \beta\delta^2 u(c_3^w)$, hence, in this region, the optimization problem of self 1 is

$$s_1^{w*} \in \arg \max U_1^w(s_1) = u(y_1 - s_1) + \beta\delta [u(c_2^w) - e] + \beta\delta^2 u(c_3^w); 0 \leq s_1 \leq s^*. \quad (11.77)$$

For any $s_1 > s^*$, self 2 retires and the continuation payoff of self 1 is $\beta\delta u(c_2^r) + \beta\delta^2 u(c_3^r)$, hence, in this region, the optimization problem of self 1 is

$$s_1^{r*} \in \arg \max U_1^r(s_1) = u(y_1 - s_1) + \beta\delta u(c_2^r) + \beta\delta^2 u(c_3^r); s_1 > s^*. \quad (11.78)$$

The optimal savings choice of self 1 is given by

$$\begin{cases} s_1^{w*} & \text{if } U_1^w(s_1^{w*}) \geq U_1^r(s_1^{r*}), \\ s_1^{r*} & \text{if } U_1^w(s_1^{w*}) < U_1^r(s_1^{r*}). \end{cases} \quad (11.79)$$

We illustrate the equilibrium, heuristically, by using Figure 11.1. Each of the panels in Figure 11.1 plots hypothetical shapes of U_1^w and U_1^r over the unconstrained interval $[0, y]$; these curves reach their maximum values at s_1^w and s_1^r , respectively. However, the curve U_1^w applies only to the range $[0, s^*]$, while the curve U_1^r applies only to the range $(s^*, y]$; see (11.77) and (11.78). Over the interval $[0, s^*]$, for the particular curves drawn in Figure 11.1, $U_1^w(s_1)$ reaches its maximum at the boundary point, s^* . In Panel A of Figure 11.1, $U_1^w(s^*) > U_1^r(s_1^r)$, hence, self 1 optimally saves an amount s^* , so self 2 chooses to work. By contrast, in Panel B of Figure 11.1, $U_1^w(s^*) < U_1^r(s_1^r)$, so self 1 optimally saves an amount $s_1^r > s^*$, which induces self 2 to retire.

Figure 11.1 Diagrammatic illustration of the equilibrium in the Diamond-Köszegi model.

In Panel A of Figure 11.1, self 1 optimally undersaves ($s^* < s_1^w$) to force self 2 to work. This is termed as *strategic undersaving*. In Panel B of Figure 11.1, on the other hand, $s_1^w < s_1^r$, so self 1 oversaves. This is termed as *resigned oversaving*. In this case, self 1 knows that it is too costly to prevent self 2 from retirement, so resigns to saving an extra amount for the benefit of self 3.

We can also use Figure 11.1 to illustrate the effects of employment legislation such as minimum retirement age. Suppose that the original employment legislation is that one must work in period 2. However, a new legislation repeals the original legislation, so that the individual is now free to choose when to retire. What are the effects on savings and retirement?

Let us first consider the equilibrium savings and retirement decisions under the original legislation which binds self 2 to work regardless of the actions of self 1. The relevant curve in each panel is now the $U_1^w(s_1)$ curve. Self 1 optimally chooses the level of savings s_1^w and self 2 works. Under the new legislation, self 2 works only if it is optimal for him, so the equilibrium is as described in the absence of any employment legislation. Hence, in Panel A of Figure 11.1 the optimal savings are reduced from s_1^w to s^* and there is no change in the retirement decision. By contrast, in Panel B of Figure 11.1 the new savings are higher under the new legislation ($s_1^r > s_1^w$) and self 2 retires while under the older legislation he was required to work.

11.5 Procrastination and preproperation

Suppose that an individual must undertake a *single* task, or activity, *once* over T periods. In each period, the individual must decide whether to undertake or postpone the activity, conditional on not having undertaken the activity in the past. Once the activity is undertaken, the individual has no further action to take in any period in the future. Denote by $v_t \geq 0$, and $c_t \geq 0$, respectively, the reward and the cost of the activity in period t . Thus, the reward and the cost schedules are given, respectively, by $v = (v_1, v_2, \dots, v_T)$ and $c = (c_1, c_2, \dots, c_T)$.

One can imagine T selves, one for each period, that can undertake the activity. The self in any period t cannot bind the action of any future self in period τ , where $t < \tau \leq T$. Each self has quasi-hyperbolic (β, δ) preferences with $\delta = 1$, i.e., $(\beta, 1)$ preferences. In determining whether a future self will carry out the activity, the beliefs of each self are that any future self has $(\hat{\beta}, 1)$

preferences. Depending on the relation between β and $\hat{\beta}$, these beliefs can be of three possible types, given in (11.10), (11.11), and (11.13), i.e., time consistent, sophisticates, and naifs (we exclude partial naifs here).

The main question that we ask is: In which time period will each of the three types of individuals undertake the action? Do the answers depend on the temporal pattern of rewards and costs? If so, how? We follow O'Donoghue and Rabin (1999b) in exploring these issues further.

We denote by $U_t(\tau)$, the utility of self t if the activity is undertaken in some time period $\tau \geq t$. To illustrate alternative temporal patterns of rewards and costs, we distinguish between the following two main cases; results turn out to be very different for these cases.

1. **Immediate costs:** Suppose that self τ undertakes the activity. The case of *immediate cost* occurs if costs are incurred in period τ , but the reward is received in some future period. Examples include the following. Cleaning one's car, or garage, organizing one's desk, writing a paper, looking for a job, studying for exams, mowing one's lawn, and quitting an addiction such as smoking.

With $(\beta, 1)$ preferences, all future periods are weighted equally, so it is not necessary to specify the exact future period in which the reward is received. The intertemporal utility $U_t(\tau)$ is, therefore, given by

$$U_t(\tau) = \begin{cases} \beta v_t - c_t & \text{if } \tau = t, \\ \beta (v_t - c_t) & \text{if } \tau > t. \end{cases} \quad (11.80)$$

2. **Immediate rewards:** The case of *immediate rewards* occurs if rewards are received immediately, but costs are incurred in some future period. Examples include going away on vacation, watching a late night movie, taking a day off, and splurging on credit card debt. Under $(\beta, 1)$ preferences, the exact future period in which the cost is incurred is not important. Suppose that self τ undertakes the activity. The intertemporal utility of self t , $U_t(\tau)$, is given by

$$U_t(\tau) = \begin{cases} v_t - \beta c_t & \text{if } \tau = t \\ \beta (v_t - c_t) & \text{if } \tau > t. \end{cases} \quad (11.81)$$

The natural equilibrium concept in these problems is a slight modification of subgame perfection. One may term the strategies followed in such an equilibrium as *perception-perfect* strategies; see O'Donoghue and Rabin (1999b). These strategies require that individuals maximize the current payoff given their beliefs about how their future selves will behave. An individual's strategy is a complete plan of action for each of the T selves. Denote a strategy by $s^i = (s_1^i, s_2^i, \dots, s_T^i)$, where s_t^i is the action of self t , and the type of the player is indexed by $i = c, s, n$ for, respectively, time consistent, sophisticates, and naifs (see (11.10), (11.11), and (11.13)). Any s_t^i can take only two possible values in the set $\{Y, N\}$, where Y denotes "undertake activity in period t " and N denotes "do not undertake the activity in period t ."

Definition 11.16 A "perception-perfect strategy" for a type $i = c, n$ (respectively, time consistent, and naif) player is a strategy $s^i = (s_1^i, s_2^i, \dots, s_T^i)$ that satisfies $\forall t < T, s_t^i = Y$, if and only if, $U_t(t) > U_t(\tau)$ for all $\tau > t$. To rule out situations where the activity might never be undertaken, we assume that it is always optimal for the action to be taken in the last period, i.e.,

$$s_T^i = Y. \quad (11.82)$$

The definition of a perception-perfect strategy for time consistent and naifs is identical, although they lie at the two polar extremes in terms of their self-awareness. The reason is that a naif in any period believes that all future selves will behave like time consistent individuals.

Definition 11.17 A perception-perfect strategy for a sophisticate is a strategy $\mathbf{s}^s = (s_1^s, s_2^s, \dots, s_T^s)$ that satisfies $\forall t < T, s_t^s = Y$, if and only if, $U_t(t) > U_t(\underline{\tau})$ where $\underline{\tau} = \min_{\tau > t} \{\tau \mid s_\tau^s = Y\}$.

A sophisticate (Definition 11.17) knows that future selves will have identical self-control problems. So there might be more than a few future selves that actually succumb to temptation. The current self only needs to know the earliest future self that will succumb, because the activity is undertaken only once. By contrast, time consistent and naifs (Definition 11.16) imagine that all future selves have no self-control problems, so the plans that they make are time consistent. Hence, they only need to know if it is optimal to do it now, or later. In equilibrium, the current selves of time consistent will find that their beliefs come out to be true, but naifs often find that their beliefs do not. The examples below will further clarify the definitions.

The method of solution is by backward induction. We first determine the optimal action of self T ; then, the optimal action of self $T - 1$, conditional on the type-contingent beliefs of $T - 1$, and so on. To illustrate the equilibrium in the model, we give the following two examples, motivated by O'Donoghue and Rabin (1999b); each considers a four period model. In each example, we assume $(\beta, 1)$ preferences for individuals who follow quasi-hyperbolic discounting.

11.5.1 The case of immediate costs

Suppose that an individual wishes to reallocate her portfolio of assets that is currently suboptimal. If the individual optimally reallocates the portfolio, her reward is $\bar{v}$, in the following period. Under $(\beta, 1)$ preferences it does not matter which future period the reward $\bar{v}$ is received in. Let $\bar{v} > 26$, $T = 4$, and $\beta = 1/2$. The cost of not reallocating the portfolio optimally increases over time, perhaps on account of the cumulative returns forgone every period. Suppose that the cost schedule is given by

$$\mathbf{c} = (3, 5, 8, 13). \quad (11.83)$$

If self t undertakes the reallocation, she incurs an immediate cost c_t , and receives the reward $\bar{v}$ in the next period. Hence, under $(\beta, 1)$ preferences, her utility is

$$U_t(t) = \beta \bar{v} - c_t = \frac{\bar{v}}{2} - c_t. \quad (11.84)$$

Using (11.83), (11.84), the utility of the period 4 self from undertaking the action is

$$U_4(4) = \frac{\bar{v}}{2} - 13 > 0 \Leftrightarrow \bar{v} > 26, \quad (11.85)$$

which is true. Using (11.83), and (11.84), the lifetime utility of each of the selves from the portfolio reallocation is

$$U_1(1) = \frac{\bar{v}}{2} - 3; U_2(2) = \frac{\bar{v}}{2} - 5; U_3(3) = \frac{\bar{v}}{2} - 8; U_4(4) = \frac{\bar{v}}{2} - 13. \quad (11.86)$$

Let us now look at the decision made by each of the selves, conditional on their beliefs about the self-control problems of the future selves. Recall that $U_t(\tau)$ is the utility of self t , if the activity is undertaken in period $\tau \geq t$.

1. **Time consistent** ($\beta = \hat{\beta} = 1$): From Definition 11.16, these individuals undertake the activity in the period which gives the highest current payoff. Here,

$$U_1(1) = \bar{v} - 3; U_2(2) = \bar{v} - 5; U_3(3) = \bar{v} - 8; U_4(4) = \bar{v} - 13, \quad (11.87)$$

In period 1, the cost is the lowest, so the activity is undertaken immediately. One can check that a perception-perfect strategy is (Y, Y, Y, Y) because $U_t(t) > U_t(\tau)$ for all t , and for all $\tau > t$.

2. **Sophisticates** ($\beta = \hat{\beta} < 1$): We now use Definition 11.17 to analyze the decision of sophisticates. From (11.85), self 4 must choose Y (i.e., reallocate the portfolio). Anticipating correctly this decision, self 3 will choose N (i.e., not reallocate the portfolio) because

$$U_3(4) > U_3(3) \Leftrightarrow \beta(\bar{v} - c_4) > \beta\bar{v} - c_3 \Leftrightarrow 6.5 < 8. \quad (11.88)$$

Anticipating correctly the decisions of the subsequent selves, $\{N, Y\}$, self 2 will choose Y because

$$U_2(4) < U_2(2) \Leftrightarrow \beta(\bar{v} - c_4) < \beta\bar{v} - c_2 \Leftrightarrow 5 < 6.5. \quad (11.89)$$

Self 1 anticipates correctly the decisions of the subsequent selves to be $\{Y, N, Y\}$. Thus, his choice is between doing it now, or leaving it to be done by self 2 (the earliest self who will choose Y , in accordance with Definition 11.17). Therefore, self 1 chooses N because

$$U_1(2) > U_1(1) \Leftrightarrow \beta(\bar{v} - c_2) > \beta\bar{v} - c_1 \Leftrightarrow 2.5 < 3. \quad (11.90)$$

Hence, for sophisticates, the *perception-perfect strategy profile* of the four selves is $\{N, Y, N, Y\}$. The portfolio is reallocated in period 2, one period later than the time consistent.

3. **Naifs** ($\beta < \hat{\beta} = 1$): Naifs believe, incorrectly, that all their future selves are time consistent, and, thus, have no self-control problems. In particular, self t believes, incorrectly, that self $t + 1$ is a time consistent and will choose Y (see (11.87)). A simple calculation shows that the naifs in periods 1 through 3 will all choose N because

$$U_t(t) < U_t(t+1) \Leftrightarrow \beta\bar{v} - c_t < \beta(\bar{v} - c_{t+1}); t = 1, 2, 3. \quad (11.91)$$

Hence, naifs will do the task only in period 4 (see (11.85)).

In the case of immediate costs, therefore, lack of self-awareness about one's own future selves (typified most strongly for naifs) will result in greater procrastination. The reason is that lack of self-awareness leads one to underestimate procrastination in one's future selves. Sophisticates, on the other hand, have perfect foresight about the future, and they anticipate, correctly, that their future selves will procrastinate. Hence, being more aware of the self-control problems of their

future selves, the costs of procrastinating in the current period are higher. This mitigates their propensity to procrastinate; an idea originally recognized by Strotz (1956) and Akerlof (1991).

11.5.2 The case of immediate rewards

Suppose that $T = 4$, and $\beta = 1/2$. An investor faces a sequence of projects whose current value is given by the net reward schedule $\mathbf{v} = (3, 5, 8, 13)$. We assume that the rewards are net of the costs, so the cost schedule is $\mathbf{c} = (0, 0, 0, 0)$. The investment can be undertaken only once. The utility of any self is given in (11.81).

We examine below the investment behavior of time consistents, sophisticates, and naifs, using Definitions 11.16, 11.17. Condition (11.82), which requires that self 4 must always find it profitable to undertake the activity, is satisfied, because the net reward in period 4 is strictly positive.

1. **Time consistents** ($\beta = \hat{\beta} = 1$): Such a type will choose Y in the time period that maximizes the current net reward. For each of the first three selves in periods $t = 1, 2, 3$, we have $v_t < v_4$ (or $U_t(t) < U_t(4)$), hence, the project is undertaken in period 4 (Definition 11.16). Thus, the decision taken by the four successive selves is $\{N, N, N, Y\}$; this is also the perception-perfect strategy. Time consistents optimally procrastinate to the last period.
2. **Sophisticates** ($\beta = \hat{\beta} < 1$): The solution can be found by backward induction as follows. Self 4 will choose Y . Self 3 will undertake the investment because $8 > 13/2$. Anticipating this, selves 2 and 1 will also, recursively, choose Y because, respectively, $5 > 8/2$ and $3 > 5/2$. Hence, the *perception-perfect strategy profile* of the sophisticates is $\{Y, Y, Y, Y\}$. Using Definition 11.17, in equilibrium, a sophisticate will undertake the investment in period 1. Notice that the sophisticate *preproperates* too much when rewards are immediate. Such an individual correctly foresees that each of the future selves will have a self-control problem, and not leave it to the last period, where the net payoff is the highest.
3. **Naifs** ($\beta < \hat{\beta} = 1$): In this case, any self t believes, incorrectly, that self $t + 1$ is time consistent. Hence, selves 1, 2, 3 believe that self 4 will actually undertake the investment, and maximize the net rewards from the activity. It is easily checked that selves 1 and 2 will choose N because, respectively, $3 < 6.5$ and $5 < 6.5$. However, self 3 will choose Y because $8 > 6.5$, thus, the beliefs of selves 1 and 2 are incorrect. The perception-perfect strategy profile of the naifs is $\{N, N, Y, Y\}$, hence, naifs will undertake the investment in period 3.

Unlike the case of immediate costs, lack of self-awareness leads now to a better outcome. Naifs do much better than sophisticates because the latter know that their immediate future selves will give in to temptation, and so each self gives in to temptation as well. In general, relative to the decision of the time consistent types, lack of self-awareness leads one to preproperate, i.e., undertake an activity too quickly when they should, from the perspective of a social planner, actually wait. These results are not specific to the two examples considered here.

One can make these points in more general one activity models; the following two propositions summarize the results. Denote by τ^i , $i = c, s, n$, the time period when it is optimal for a type i individual to undertake the activity. The first proposition shows that for immediate costs, naifs procrastinate more than time consistents, while for immediate rewards, naifs preproperate relative to the time consistents

Proposition 11.19 Consider $(\beta, 1)$ preferences, $0 < \beta < 1$, and time $t \in \{1, 2, \dots, T\}$. The reward and the cost schedules are given, respectively, by $\mathbf{v} = (v_1, v_2, \dots, v_T)$, and $\mathbf{c} = (c_1, c_2, \dots, c_T)$. In the case of immediate costs, the lifetime utility, $U_t(\tau)$, is given in (11.80),

and in the case of immediate rewards, it is given by (11.81). The definitions of time consistent and naif individuals are given, respectively, in (11.10) and (11.13).

- (a) For the case of immediate costs, time consistent complete the task no later than the naifs.
- (b) For the case of immediate rewards, naifs complete the task no later than the time consistent.

Proof: (a) We need to show that if the naifs do it in any period, the time consistent do it too. Consider any time period t . Let t' be the time period where $(v_\tau - c_\tau)$ is maximized for all $\tau > t$. Naifs believe that all their future selves are time consistent. Since $\delta = 1$, they believe that the activity will be undertaken in period t' . Naifs will undertake the activity in period t only if the current reward from undertaking it under immediate costs, $\beta v_t - c_t$, is greater than the utility from having it undertaken it at time t' , $\beta (v_{t'} - c_{t'})$, or

$$v_t - \beta^{-1}c_t \geq v_{t'} - c_{t'}. \quad (11.92)$$

If (11.92) holds for $0 < \beta < 1$, then it also holds for $\beta = 1$, hence, time consistent individuals ($\beta = 1$) will also do it.

(b) Consider the case of immediate rewards. Here we need to show that if time consistent undertake the activity, then naifs undertake it as well. Consider any time period t , and let t' be as in part (a). Time consistent do it if

$$v_t - c_t \geq v_{t'} - c_{t'}. \quad (11.93)$$

Naifs do it in period t if $v_t - \beta c_t \geq \beta (v_{t'} - c_{t'})$, or

$$\beta^{-1}v_t - c_t \geq v_{t'} - c_{t'}. \quad (11.94)$$

If (11.93) holds, then (11.94) holds too, hence, naifs do it as well. ■

We now compare the behavior of sophisticates and naifs for the general case.

Proposition 11.20 Consider $(\beta, 1)$ preferences, $0 < \beta < 1$, and time $1, 2, \dots, T$. The reward and the cost schedules are given, respectively, by $v = (v_1, v_2, \dots, v_T)$, and $c = (c_1, c_2, \dots, c_T)$. In the case of immediate costs, the lifetime utility, $U_t(\tau)$, is given in (11.80), and in the case of immediate rewards, it is given by (11.81). The definitions of sophisticated and naif individuals are given, respectively, in (11.11) and (11.13). For the case of immediate costs and immediate rewards, sophisticates complete the task no later than naifs.

Proof: We need to show here that if naifs undertake an activity in any time period, then so must the sophisticates. From the definition of perception-perfect strategies (see Definition 11.16), naifs do it in period t rather than in any future period if

$$U_t(t) > U_t(\tau) \forall \tau > t. \quad (11.95)$$

Sophisticates do it in period t rather than in any future period if (see Definition 11.17),

$$U_t(t) > U_t(\underline{\tau}) \text{ where } \underline{\tau} = \min_{\tau > t} \{ \tau \mid s_\tau^i = Y \}. \quad (11.96)$$

(11.95) implies that doing the activity in period t must dominate doing it for any future period. In particular it must also then dominate doing it from any subset of the set of future periods. But this implies that (11.96) holds, so the result follows immediately. ■

11.5.3 A brief note on welfare comparisons

Given any two distinct strategies for any of the types, which of these strategies lead to higher welfare for the individual? The Pareto dominance criterion implies that a Pareto dominant strategy must give higher welfare for all selves of the same individual. This is a fairly strong requirement. O'Donoghue and Rabin (1999b) suggest using a weaker efficiency criterion, which is the maximization of *long-run utility*, W_0 , from the perspective of some ex-ante period 0 that precedes period 1.

$$W_0^i(U_1^i, U_2^i, \dots, U_T^i) = \sum_{t=1}^{t=T} \delta^t U_t^i, 0 < \delta < 1, \quad (11.97)$$

where the superscript i denotes the type of the player, such as time consistent, sophisticate, and naïf.

11.5.4 Some other features of present bias

Individuals who have time consistent preferences do not violate two properties, namely, *dominance*, and *independence of irrelevant alternatives*. First, we define these terms. Suppose that there exists some period τ with $v_\tau > 0$, and $c_\tau = 0$. In the context of the one-activity model, an individual violates “dominance” if she performs the activity in some period $\tilde{\tau} \neq \tau$ with $c_{\tilde{\tau}} > 0$ and $v_{\tilde{\tau}} = 0$.

Definition 11.18 (*Dominance*): An intertemporal strategy¹³ dominates another if it gives at least the same payoff in all periods, and a strictly greater payoff in at least one period.

The independence of irrelevant options implies the following. Suppose option a_k is chosen out of a set of options $A = \{a_1, a_2, \dots, a_n\}$, then it would still be chosen out of the set A/a_j where $k \neq j$. For the one-activity model, this leads to the following definition.

Definition 11.19 Suppose that $\mathbf{v} = (v_1, v_2, \dots, v_T)$ and $\mathbf{c} = (c_1, c_2, \dots, c_T)$ give the intertemporal pattern of rewards and costs over time periods $1, 2, \dots, T$. Let the individual choose to undertake the activity in period τ . Then the individual's behavior is “independent of irrelevant alternatives” if she still chooses to undertake the activity in period τ once the rewards and costs for some period $\tilde{\tau} \neq \tau$ are omitted.

Proposition 11.21 (O'Donoghue and Rabin, 1999b): Consider the single activity model. Let individuals have (β, δ) preferences. The following results hold for sophisticated and naïve individuals:

1. There exist payoff and cost vectors $\mathbf{v}, \mathbf{c}$, and assumptions about immediacy (i.e., immediate costs, or immediate benefits) such that an individual with (β, δ) preferences will violate dominance.

¹³ An intertemporal strategy in the one-activity model is a sequence $\{s_t\}_{t=1}^T$ where $s_t \in \{Y, N\}$.

2. There exist payoff and cost vectors v, c , and assumptions about immediacy (i.e., immediate costs, or immediate benefits) such that an individual with (β, δ) preferences will violate independence of irrelevant alternatives.

We leave the proof of Proposition 11.21 as an exercise, but use the following two examples to illustrate it.

Example 11.18 (O'Donoghue and Rabin, 1999b): Consider the case of “immediate rewards.” The utility function is, therefore, given by (11.81). Suppose $T = 3$, $v = (0, 5, 1)$, and $c = (1, 8, 0)$. Suppose that $\beta = 1/2$. Using Definition 11.18, undertaking the activity in period 1 is dominated by doing it in period 3. Consider first a sophisticated individual. If each self were to undertake the activity when it is their turn to make the decision, then, using (11.81), the respective payoffs are

$$U_3(3) = 1 > 0; U_2(2) = 5 - \frac{8}{2} = 1 > 0; U_1(1) = 0 - \frac{1}{2} = -\frac{1}{2} < 0. \quad (11.98)$$

We now use backward induction to solve for the perception-perfect equilibrium. Self 3 undertakes the activity because $U_3(3) > 0$. Self 2 will also undertake the activity because

$$U_2(2) > U_2(3) \Leftrightarrow 1 > \frac{1}{2}. \quad (11.99)$$

Self 1 is sophisticated, so he knows that the earliest future time at which the activity will occur is at time $t = 2$. Thus, he also undertakes the activity because

$$U_1(1) > U_1(2) \Leftrightarrow -\frac{1}{2} > \frac{1}{2}(5 - 8) \Leftrightarrow -\frac{1}{2} > -\frac{3}{2}. \quad (11.100)$$

The perception-perfect strategy profile for the sophisticates is $(s_1^s, s_2^s, s_3^s) = (Y, Y, Y)$. Thus, self 1 undertakes the action in period 1, even though it is dominated by undertaking the activity in period 3 (check that $U_1(1) < U_1(3)$). This action violates dominance. The reason is that self 1 guesses, correctly, that self 2 will undertake the activity (on account of his present bias). If we were to truncate the payoff and cost vectors to remove period 2, then self 1 will leave the activity to be undertaken by self 3. This violates the independence of irrelevant alternatives.

Example 11.19 (O'Donoghue and Rabin, 1999b): Consider now the case of “immediate costs.” Thus, the utility function is given by (11.80). Suppose that individuals are naive (see (11.13)), and $\beta = 1/2$. Let $T = 3$, $v = (1, 8, 0)$, and $c = (0, 5, 1)$. Using Definition 11.18, undertaking the activity in period 3 is dominated by doing it in period 1. If each self were to undertake the activity when it is their turn to make the decision, then the respective payoffs are

$$U_3(3) = \frac{1}{2}(0) - 1 = -1 < 0; U_2(2) = \frac{8}{2} - 5 = -1 < 0; U_1(1) = \frac{1}{2} - 0 = \frac{1}{2} > 0. \quad (11.101)$$

A naive individual believes, incorrectly, that all future selves are time consistent ($\hat{\beta} = 1$). Hence, self 1 believes (incorrectly) that self 2 will undertake the activity because $U_2(2) = 8 - 5 = 3 > 0$. For self 1, $U_1(1) < U_1(2)$ because $\frac{1}{2} < \frac{3}{2}$. Hence, self 1 will not undertake the activity. Self 2 would rather leave the activity to be undertaken by the period 3 self (because $-1 < -\frac{1}{2}$). Because the activity must be undertaken once, it is undertaken by self 3, which is a dominated action.

O'Donoghue and Rabin (1999a) consider the possibility of moral hazard issues in a principal-agent setting. Suppose that the cost realization of an agent, who uses hyperbolic discounting, is privately known to the agent. The principal only knows the distribution of the agent's costs. What if the principal were to observe a delay in completing the task? The delay could have been caused by procrastination on the part of the agent, or it could have been an efficient response to a high cost realization. Hence, if the principal imposed penalties on task completion that are too strict, then procrastination could be reduced, but at the cost of undertaking the task when costs are inefficiently high. O'Donoghue and Rabin (1999a) explore this trade-off under different assumptions on the level of sophistication of the agent. Under certain conditions, the optimal incentive scheme is for delay to be punished leniently early on, but more severely upon the passing of some deadline date.

11.6 Interdependence, multiple activities, and competition

We have considered procrastination and preproperation within the context of a one-activity model and a single individual. How do the results alter when there are multiple individuals and multiple activities (possibly sequential)? We follow Brocas and Carillo (2001) in dealing with these questions.

Suppose that projects are of a sequential nature, i.e., they have a time dimension associated with successive, interlinked, stages. Then, a delay in the current period increases future costs because if a prerequisite stage is not followed, then the completion of subsequent stages may be affected. This increases the cost of delay, and reduces procrastination. Similar arguments might be able to explain why some individuals accept an overload of work. Such acceptance can perhaps be viewed as a commitment device to ensure that delay on account of procrastination is reduced.

Inducing competition among agents through incentive contracts in which the *winner takes all*, can also be an important anti-delay device. If agent A procrastinates, and agent B does not, then the likelihood that agent A gets any reward is reduced. This increases the cost of delay. Furthermore, competition between two agents can also be viewed as a coordination game. One agent could be willing to delay a project, provided the other does too. Thus, one might get multiple equilibria where projects are either completed too soon, or too late, depending on the beliefs. We formalize some of these ideas in this section.

Consider two researchers with (β, δ) preferences who wish to undertake a separate project. If any project is undertaken in period t , then there is an immediate cost c , and a future benefit b in period $t + 1$. There are multiple selves of the same individual in different periods, and we refer to the self in period t as self t . We consider two possibilities.

(1) Each researcher undertakes a single project, and the two projects are *independent*. Thus, the payoff to a researcher from a project does not depend on the completion of the project by the other researcher.

(2) The two projects undertaken by the two researchers are *dependent*. In particular, the researcher who completes the project earlier is declared the winner, and receives all the benefits.

Proposition 11.22 (*Independent Projects*) Consider a situation where each researcher can undertake independent and identical projects. If

$$c \in (\underline{c}, \bar{c}), \text{ where } \underline{c} = \beta\delta b \frac{1-\delta}{1-\beta\delta}, \text{ and } \bar{c} = \beta\delta b, \quad (11.102)$$

then, at each date, each researcher completes the project with a probability $\lambda^* \in (0, 1)$, where

$$\lambda^* = \frac{1 - \delta}{\delta(1 - \beta)} \left(\frac{\beta\delta b}{c} - 1 \right) \in (0, 1). \quad (11.103)$$

λ^* is increasing in β, b , and decreasing in c .

Proof: Self t with (β, δ) preferences prefers doing the activity now rather than never if

$$-c + \beta\delta b > 0 \Leftrightarrow c < \bar{c} = \beta\delta b. \quad (11.104)$$

Self t prefers the activity to be done at date $t + 1$ rather than at t if

$$-c + \beta\delta b < \beta\delta(-c + \delta b) \Leftrightarrow c > \underline{c} = \beta\delta b \frac{1 - \delta}{1 - \beta\delta}. \quad (11.105)$$

Suppose that (11.104), (11.105) simultaneously hold, i.e., $c \in (\underline{c}, \bar{c})$. We consider the time-invariant probability λ of undertaking the project at date t . From (11.104), (11.105) neither of $\lambda = 0$ or $\lambda = 1$ is an equilibrium. In equilibrium, self t knows that all future selves undertake the project with probability λ , hence, self t is indifferent between doing, and not-doing the project if

$$-c + \beta\delta b = [\beta\delta(-c + \delta b)] [\lambda + (1 - \lambda)\lambda\delta + (1 - \lambda)^2\lambda\delta^2 + \dots]. \quad (11.106)$$

Equation (11.106) holds when $\lambda = \lambda^*$, given in (11.103). The comparative statics follow by straightforward differentiation of (11.103). ■

The intuition behind Proposition 11.22 is as follows. From (11.104), the current self of a researcher desires that the project be completed, but from (11.105) he wants to procrastinate. Hence, the optimal solution is an intermediate solution in that he completes the project with some probability. The comparative static results show that if the researcher puts greater weight on future outcomes (high β), or if future benefits, b , are high, then he procrastinates less. An increase in current costs, c , has the converse impact.

We now consider the case of *competition* among the researchers in the following sense. The two researchers undertake the projects separately, and the winner-takes-all, i.e., the first to complete the project gets the entire future benefit, b . If both complete the project at the same time, then both reap the benefit, b .

Proposition 11.23 (Interdependent projects; Brocas and Carillo, 2001) *Under competition between the two researchers in a winner takes all contest:*

- (i) If $c \in [\underline{c}, c^*]$, then both researchers complete the project in period 1 with probability 1, where

$$c^* = \frac{\beta\delta^2 b}{(1 - \beta)(2 - \delta - 2\sqrt{1 - \delta}) + \delta}. \quad (11.107)$$

- (ii) If $c \in [c^*, \bar{c}]$, then the probability that the project is completed each period is given by $p \in [\mu, 1]$, where $\mu > \lambda^*$, λ^* is defined in (11.103), and $\underline{c}, \bar{c}$ are defined in (11.102).

When the costs are low enough (below c^*), then both researchers undertake the project immediately. Since the incentive to procrastinate is low for any researcher in this case, the other

researcher realizes that he will miss out on the prize completely if he procrastinates. This works mutually to ensure early completion of the project. When costs are in the intermediate range, procrastination turns into a coordination problem. Each researcher is willing to procrastinate, provided the other does too. But this depends on mutual beliefs, so, not surprisingly, there is a multitude of equilibria. All symmetric equilibria then yield the same expected payoff to each agent. Introducing competition among the researchers induces earlier completion of the projects, relative to the case of independent projects because of the contractually increased costs of procrastination.

11.7 Optimal sin taxes

Sin goods are goods whose consumption by any temporal self of an individual creates a negative externality for future selves. Time consistent selves take full account of the effects of current consumption on future utility. However, under hyperbolic preferences, the multiple selves are biased towards the present, and do not take full account of the negative externality that they create for future selves. Hence, there is a role for corrective *Pigouvian taxes* to assist in the internalization of a harmful externality. We explore these issues in a simplified version of the model provided in O'Donoghue and Rabin (2006).

Consider two goods, a *composite good*, and a *sin good* (e.g., potato chips). At time t , the consumption of the composite good is z_t , and the consumption of the sin good is x_t . Markets are competitive, and the marginal cost of each good is normalized to unity. Hence, the price per unit of each good is also unity. The instantaneous utility of self t in any period takes the separable quasilinear form, given by

$$u_t = v(x_t) - h(x_{t-1}) + z_t, \quad (11.108)$$

where,

$$v' > 0, v'' < 0, h' > 0, h'' > 0. \quad (11.109)$$

Individuals derive utility from both, x_t and z_t , but they also derive disutility from the past consumption of the sin good, x_{t-1} , that is encapsulated in the *habit function*, h . The quasilinear form guarantees that all income effects in any period are absorbed by z_t , and x_t is sensitive only to the substitution effect. No borrowing or saving is allowed.

The intertemporal preferences take the $(\beta, 1)$ form. In particular, for self $t = 1, 2, \dots, T - 1$, these preferences are given by

$$U_t = u_t + \beta \sum_{\tau=t+1}^T u_{\tau}; \quad 0 < \beta < 1. \quad (11.110)$$

The time-invariant fiscal policy of the government in any period is given by the tuple (θ, α) , where $\theta \in [0, 1]$ is the per unit consumption tax on the sin good, and α is a lump-sum transfer given by the government to the taxpayer. The taxpayer's income in each period is time invariant, and denoted by I . Since savings or borrowings are disallowed, the budget constraint of the individual requires that in each period, expenditure is bounded above by income, i.e.,

$$(1 + \theta) x_t + z_t \leq I + \alpha. \quad (11.111)$$

Substitute (11.108) in (11.110), and isolate terms corresponding to the choice variables of self t . We can then rewrite (11.110) as

$$U_t = u^P(x_t, z_t) + \beta \sum_{\tau=t+2}^T u_\tau + (\beta v(x_{t+1}) + \beta z_{t+1} - h(x_{t-1})), \quad (11.112)$$

where

$$u^P(x_t, z_t) = v(x_t) - \beta h(x_t) + z_t. \quad (11.113)$$

The first term in (11.112), shown in (11.113) as the *private utility* of self t , lists all the terms that are influenced by the choices of self t . The initial level of x_0 is exogenously given.

Using (11.111) to (11.113), we can treat the decision problem of the individual as a sequence of time t problems, where $t = 1, 2, 3, \dots, T-1$. In (11.113), $\beta < 1$ is the source of self-control problems. For $\beta = 1$, there are no self-control problems, and we get the *social utility* of self t ,

$$u^S(x_t, z_t) = v(x_t) - h(x_t) + z_t. \quad (11.114)$$

Using (11.109), u^P and u^S are strictly concave in x . Using the terminology in Kahneman (1994), the distinction between (11.113) and (11.114) is analogous to that between *decision utility* and *experienced utility*.¹⁴ Since the decision problem at time t is independent of any other time period, we will, henceforth, drop time subscripts.

11.7.1 First best allocation

The first best allocation maximizes (11.114), subject to the *resource constraint*, which obtains by eliminating distortionary policy instruments (i.e., set $\theta = \alpha = 0$ in (11.111)). Thus, the resource constraint is given by

$$x + z \leq I. \quad (11.115)$$

Since marginal utility of the composite good is strictly increasing, the resource constraint binds. Substituting the resource constraint into (11.114), the unconstrained first best problem is

$$x^S = \arg \max u^S(x, z(x)) = v(x) - h(x) + (I - x), 0 \leq x \leq I. \quad (11.116)$$

Since u^S is strictly concave in x , and $x \in [0, I]$, the solution is unique. Assuming an interior solution, the first best solution is given implicitly by

$$v'(x^S) - h'(x^S) = 1, \text{ and } z^S = I - x^S. \quad (11.117)$$

11.7.2 Privately optimal choice

The privately optimal choice of the individual at time t is found by substituting (11.111) in (11.113). The unconstrained problem of the individual is

¹⁴ Decision utility is concerned with choices made by an individual while experienced utility encapsulates the individual's ex-post welfare.

$$x^P \in \arg \max u^P = v(x) - \beta h(x) + (I + \alpha - (1 + \theta)x), 0 \leq x \leq \frac{I + \alpha}{1 + \theta}.$$

u^P is strictly concave in x , and x belongs to a compact interval, so the solution is unique. Assuming an interior solution, the unique, privately optimal solution is given implicitly by¹⁵

$$v'(x^P) - \beta h'(x^P) = 1 + \theta, \text{ and } z^P = I + \alpha - (1 + \theta)x^P. \quad (11.118)$$

Let the solution to (11.118) be given by $x^P(\theta, \beta)$ and $z^P(\theta, \alpha, \beta) = I + \alpha - (1 + \theta)x^P(\theta, \beta)$. It follows by implicit differentiation that

$$\frac{\partial x^P}{\partial \theta} < 0; \quad \frac{\partial x^P}{\partial \beta} < 0. \quad (11.119)$$

A reduction in the degree of impatience (an increase in β) reduces consumption of the sin good. A higher value of β allows the individual to internalize better the negative effect of habit formation on the self in the next period. With quasilinear preferences, there are no income effects on x . Hence, the substitution effect implies that consumption of the sin good is decreasing in its price, $1 + \theta$.

The use of Pigouvian taxes to counter overconsumption on account of self-control problems has also been considered in Gruber and Köszegi (2001). In actual practice, cigarette taxes are alleged to be regressive with respect to income. Gruber and Köszegi (2004) point to a countervailing factor. The tax elasticity of consumption of cigarettes is higher for poorer individuals, hence, such taxes allow poorer individuals with present bias to engage in relatively better self-control, partially offsetting the negative effects of a regressive tax.

11.7.3 Implementation of the first best

We can choose the tax rate, θ , in such a way that the first best is implemented in private markets; this is the Pigouvian tax solution. Choose $\theta = (1 - \beta)h'(x)$, and substitute in (11.118) to get $v'(x) - \beta h'(x) = 1 + (1 - \beta)h'(x)$. Simplifying we get,

$$v'(x) - h'(x) = 1,$$

which, using (11.117), holds, uniquely, for $x = x^S$. Hence, appropriately designed sin taxes are able to implement the first best.

11.7.4 Population heterogeneity

Suppose that the only source of heterogeneity in the population is the extent of the self-control problem given by the magnitude of $1 - \beta$. As β increases towards 1 the self-control problem diminishes (for $\beta = 1$ we are back in an EDU framework, where optimal plans are time consistent). Suppose that the distribution function of β is given by $F(\beta)$, and the support of the density is given by $[\underline{\beta}, \bar{\beta}]$. We refer to an individual with $(\beta, 1)$ preferences as a β -individual. The demand

¹⁵ A sufficient condition for an interior solution is $v'(0) - \beta h'(0) > 1 + \theta$.

for the sin good by an individual is given by $x^P(\theta, \beta)$, so that the aggregate per capita, or average demand, $X(\theta)$, is given by

$$X(\theta) = E_F [x^P(\theta, \beta)] = \int_{\underline{\beta}}^{\bar{\beta}} x^P(\theta, \beta) dF(\beta),$$

where E_F is the expectation operator with respect to the distribution of β . The average tax proceeds are returned to each consumer as a lump-sum transfer, $\alpha(\theta)$, hence,

$$\alpha(\theta) = \theta X(\theta). \quad (11.120)$$

Given quasilinear preferences, income effects on account of α are fully absorbed into the demand for the composite good, z . We are now primarily interested in the comparative static effects of the policy parameters, θ, α . Hence, we suppress β , and summarize the privately optimal bundle of goods demanded by the consumer as $(x^P(\theta), z^P(\theta, \alpha))$.

We are interested in a welfare analysis below. Hence, we use the social utility u^S in (11.114), rather than the private utility u^P in (11.113). Substituting the consumption bundle $(x^P(\theta), z^P(\theta, \alpha))$ in (11.114), gives the indirect (social) utility function of a β -individual, $u^S(x^P(\theta), z^P(\theta, \alpha) | \beta)$. Substituting α from (11.120) gives u^S as a function only of θ , conditional on a value of β , i.e., $u^S(x^P(\theta), z^P(\theta, \alpha(\theta)) | \beta)$. The utilitarian social welfare function of society that gives equal weight to the social utility of any β -individual is then given by

$$W(\theta) = E_F [u^S(x^P(\theta), z^P(\theta, \alpha(\theta)) | \beta)], \theta \in [0, 1]. \quad (11.121)$$

Substituting (11.114), (11.115) in (11.121), we can rewrite social welfare as

$$W(\theta) = E_F [v(x^P(\theta)) - h(x^P(\theta)) - x^P(\theta) + I | \beta] \equiv E_F [\omega(\theta) + I | \beta], \quad (11.122)$$

where

$$\omega(\theta) \equiv v(x^P(\theta)) - h(x^P(\theta)) - x^P(\theta) \quad (11.123)$$

is maximized at $x^P(\theta) = x^S(\theta)$ (see (11.116), (11.117)).

We now show that in the absence of self-control problems ($\beta = 1$) there are no sin taxes. However, if at least some individuals have self-control problems, then the optimal tax, θ , on the sin good is strictly positive. A positive sin tax reduces the harmful externality that current selves cause on future selves through a higher current consumption of the sin good.

Proposition 11.24 *Under alternative assumptions on β , the optimal sin taxes are as follows.*

- (a) *If all consumers have $\beta = 1$, then the optimal tax $\theta^* = 0$.*
- (b) *If all consumers have $0 < \beta \leq 1$, and some individuals have $\beta < 1$, then the optimal tax $\theta^* > 0$.*

Proof: Implicitly differentiating (11.123), $\frac{\partial \omega}{\partial \theta} = \frac{\partial \omega}{\partial x} \frac{\partial x^P}{\partial \theta} = [v'(x^P(\theta)) - h'(x^P(\theta)) - 1] \frac{\partial x^P}{\partial \theta}$. Using (11.118) we can rewrite this as

$$\frac{\partial \omega}{\partial \theta} = [\theta - (1 - \beta) h'(x^P(\theta))] \frac{\partial x^P}{\partial \theta}. \quad (11.124)$$

(a) Suppose first that all consumers have $\beta = 1$. Then, from (11.124), $\frac{\partial \omega}{\partial \theta} = \theta \frac{\partial x^P}{\partial \theta}$. Hence, differentiating (11.122) we get

$$W'(\theta) = E_F \left[\frac{\partial \omega}{\partial \theta} \right] = \theta E_F \left[\frac{\partial x^P}{\partial \theta} \right]. \quad (11.125)$$

$W(\theta)$ is continuous over the compact interval $[0, 1]$. Using (11.119), $\frac{\partial x^P}{\partial \theta} < 0$, so $W'(\theta) = 0$ for $\theta = 0$, and $W'(\theta) < 0$ for $\theta > 0$. Thus, the optimal tax $\theta^* = 0$.

(b) Suppose that $\beta \leq 1$ for all consumers, and $\beta < 1$ for some consumers. For all consumers such that $\beta = 1$ we have

$$\beta = 1 : \left(\frac{\partial \omega}{\partial \theta} \right)_{\beta=1} = \frac{\partial \omega}{\partial x} \frac{\partial x^P}{\partial \theta} = \theta \frac{\partial x^P}{\partial \theta}. \quad (11.126)$$

Using (11.124), for all consumers such that $\beta < 1$,

$$\beta < 1 : \left(\frac{\partial \omega}{\partial \theta} \right)_{\beta < 1} = \frac{\partial \omega}{\partial x} \frac{\partial x^P}{\partial \theta} = [\theta - (1 - \beta) h'(x^P(\theta))] \frac{\partial x^P}{\partial \theta}. \quad (11.127)$$

$W(\theta)$ is a continuous function over a compact interval $[0, 1]$. When $\theta = 0$, $\left(\frac{\partial \omega}{\partial \theta} \right)_{\beta=1} = 0$, but $\left(\frac{\partial \omega}{\partial \theta} \right)_{\beta < 1} > 0$ ($h' > 0$ and $\frac{\partial x^P}{\partial \theta} < 0$), thus, we have $W'(0) > 0$. At $\theta = 1$, a simple calculation shows that $W'(1) < 0$. Hence, at any local maximum, we must have $\theta^* > 0$. There is no guarantee, unless we make further assumptions, that this equilibrium is unique. ■

How does the optimal sin tax vary with the extent of self-control problems within the population. Suppose that we have two distributions of β , $F(\beta)$ and $G(\beta)$, such that $F(\beta) \leq G(\beta)$, hence, F first order stochastically dominates G . The extent of the self-control problem is given by the magnitude of $1 - \beta$. Under distribution G , there is a relatively greater proportion of the population with lower values of β . Hence, distribution G is worse (relative to F) from the point of self-control problems.

Under certain conditions, O'Donoghue and Rabin (2006) show that the optimal tax is higher under distribution G . The intuition is that the negative externality created for one's future selves is higher under distribution G , hence, the consumption of the sin goods needs to be curbed to a greater extent. Insofar as higher taxes reduce the negative externality on future selves, they provide a commitment device to an individual who cares about lifetime consumption. Such an individual might actually be more happy after the imposition of sin taxes. Gruber and Mulainathan (2005) verify this insight by showing a positive link between excise taxes on cigarettes and self-reported measures of happiness of smokers from the US and Canada. No such link is found between other kinds of taxes and self-reported measures of happiness of smokers.

Further issues of Pareto optimal sin taxes and the distributional impact of β on optimal sin taxes are taken up in one of the exercises below.

11.8 Investment and leisure goods

Let us focus attention on only two kinds of goods, *investment goods* and *leisure goods*. Consumption of investment goods incurs current costs, and generates future benefits, e.g., attendance at

a health club. Leisure goods, on the other hand, are associated with current benefits, but future costs, e.g., credit card borrowing. Suppose that individuals exhibit hyperbolic preferences, and are either *sophisticated*, or *naive*. Sellers of investment and leisure goods are assumed to maximize profits. We are interested in the optimal behavior of firms for investment and leisure goods when they know that consumers use hyperbolic preferences. We now consider this question in the context of the model by DellaVigna and Malmendier (2004).

11.8.1 Investment goods

Suppose that there are three time periods, described below.

1. Period 0 (Participation decision): A monopolistic firm can sell one unit of output to a consumer. It offers a two part tariff (L, p) to a consumer, where L is a lump-sum fee, and p is the price per unit of the good. The consumer can either accept or reject. If the consumer rejects the contract in period 0, then firms make zero profits, and the consumer gets some reservation utility $\bar{u}$ in period 1. The consumer knows that her future cost, c , of consuming the good is drawn from some density $f(c)$; the corresponding distribution function is $F(c)$. For instance, if the good is a health club membership, then the cost, c , could include items such as costs of commuting to the health club, rearranging one's schedule with a partner/child, and missing favorite live television programs.
2. Period 1 (Current costs): At the beginning of period 1, the consumer learns her cost of consuming the good. If the consumer accepts the contract in period 0, then she has to pay the lump-sum cost, L in period 1. Now, she decides whether to consume the one unit, or not. If the consumer does not consume, after accepting the contract, then she gets a payoff equal to $-L$. If the consumer chooses instead to consume, then costs in period 1 equal $-L - c - p$.
3. Period 2 (Future benefits): If the consumer consumes the good in period 1, then she derives a benefit $b > 0$ in period 2, and if she does not consume in period 1, she derives zero benefits from the good in period 2.

THE CONSUMER'S PROBLEM

We assume that each period, $t = 0, 1, 2$, corresponds to a different self of the consumer. The risk neutral consumer has (β, δ) preferences, so the preferences of self 0 are given by

$$u_0 + \beta\delta u_1 + \beta\delta^2 u_2, \quad (11.128)$$

where u_t is the instantaneous utility function of self t . The standard case of time consistent preferences arises by setting $\beta = 1$. Such a consumer is referred to as an *exponential consumer*. Self 0 expects self 1 to have the preferences

$$u_1 + \hat{\beta}\delta u_2, \quad (11.129)$$

where $\hat{\beta}$ is the predicted value of β . A *sophisticated* self knows that $\beta = \hat{\beta} < 1$, a *naive* self thinks that $\beta < \hat{\beta} = 1$, and a partial-naif believes that $\beta < \hat{\beta} < 1$. We may consider $\hat{\beta} - \beta \geq 0$ to be a measure of *consumer overconfidence*. Thus, individuals who follow EDU, and sophisticated selves, have no overconfidence, while partial naifs and naifs have strictly positive overconfidence.

We now work out the consumer's decisions in successive periods.

1. Period 0: Using (11.128), the lifetime utility of self 0 who pays the lump-sum payment, L , and chooses to consume in period 1 is

$$0 + \beta\delta(-p - c - L) + \beta\delta^2b = \beta\delta(\delta b - p - c - L). \quad (11.130)$$

By contrast, the lifetime utility from incurring the lump-sum payment, L , but choosing not to consume is

$$0 + \beta\delta(-L) + 0 = -\beta\delta L. \quad (11.131)$$

From (11.130), (11.131), self 0 would like to consume if

$$c \leq \delta b - p. \quad (11.132)$$

Self 0 does not know the realization of cost, c . But he does know that if the subsequent realization of cost is no higher than $\delta b - p$, then she will consume. Given that the distribution function for cost is given by $F(c)$, the following result is obvious.

Lemma 11.6 *In period 0, the probability that the consumer will consume in the future is $F(\delta b - p)$. If the firm charges a higher price, p , then the probability that the consumer will consume is lower.*

2. Period 1: Self 0 believes that the utility of self 1 is given by (11.129). So she believes that the lifetime utility of self 1 from consuming is $(-p - c - L) + \hat{\beta}\delta b$, and the utility from not consuming is $-L$. Hence, self 0 believes that self 1 will consume if

$$c \leq \hat{\beta}\delta b - p. \quad (11.133)$$

Thus, self 0 believes that the probability of consumption in period 1 is

$$F(\hat{\beta}\delta b - p). \quad (11.134)$$

Lemma 11.7 *(Overconfidence) A measure of self 0's overconfidence is given by the difference between the forecasted and the actual consumption probabilities, i.e., $F(\hat{\beta}\delta b - p) - F(\beta\delta b - p)$, which is always non-negative because $\beta \leq \hat{\beta}$. For EDU decision makers, $\beta = \hat{\beta} = 1$, and for sophisticated selves $\beta = \hat{\beta} < 1$, so there is no overconfidence. Naifs ($\beta < \hat{\beta} = 1$) have the greatest degree of overconfidence, followed by partial-naifs ($\beta < \hat{\beta} < 1$).*

The lifetime expected utility of self 0 who accepts the contract is given by

$$\beta\delta(-L) + F(\hat{\beta}\delta b - p)(\beta\delta(-p - c) + \beta\delta^2b). \quad (11.135)$$

The first term gives the present value, in period 0, of the lump-sum payment, L . With probability $F(\hat{\beta}\delta b - p)$, consumption takes place in period 1, which generates, in present value terms, a period 1 cost of $\beta\delta(-p - c)$, and a period 2 benefit of $\beta\delta^2b$. Self 0 has some reservation utility $\bar{u} \geq 0$ that materializes in period 1, so she will accept the contract if

$$\beta\delta \left[-L + \int_{-\infty}^{\hat{\beta}\delta b - p} (\delta b - p - c)f(c)dc \right] \geq \bar{u}. \quad (11.136)$$

The LHS of (11.136) is just a restatement of the expression in (11.135). We shall refer to (11.136) as the *consumer's participation constraint*.

THE FIRM'S PROBLEM

The monopolist firm makes a take it or leave it offer, (L, p) , to the consumer in period 0 by incurring some set up cost $K \geq 0$. If the contract is accepted, the firm receives a lump-sum fee, L , in period 1. If the consumer decides to exercise the right to consume the one unit in period 1, then the firm receives a price, p , and incurs a marginal cost of production, $\alpha > 0$. The firm can borrow and lend at an interest rate of $r > 0$, and its discount factor is given by $\frac{1}{1+r} = \delta$. The firm knows, at $t = 0$, the distribution of the consumer's cost, $F(c)$. The expected profit of the firm, from the consumption of the good, subject to the consumer's participation in period 0, is

$$\Pi(p) = \delta [L - K + F(\beta\delta b - p)(p - \alpha)]. \quad (11.137)$$

The firm receives all payments in period 1, hence, all payoffs are discounted by the discount factor, δ . If the contract is signed, the firm receives a lump-sum payment, net of the setup costs. With probability $F(\beta\delta b - p)$, consumption takes place, and the firm receives the per unit price, p , net of its marginal cost of production, α . In writing (11.137), we make the strong assumption that firms know the true value of β for the consumer, thus, we replace $\hat{\beta}$ by β .

The firm maximizes its expected profit in (11.137), subject to the participation constraint of the consumer in (11.136). The participation constraint binds in equilibrium because the firm can always improve expected profits by increasing L . Substituting L from the binding participation constraint into (11.137) we get

$$\Pi(p) = \int_{-\infty}^{\beta\delta b - p} (\delta b - \alpha - c)f(c)dc + \int_{\beta\delta b - p}^{\hat{\beta}\delta b - p} (\delta b - p - c)f(c)dc - K - \bar{u}. \quad (11.138)$$

The firm chooses its price, p , in order to maximize $\Pi(p)$ given in (11.138). L is chosen residually to ensure that the participation constraint of the consumer binds. The first term on the RHS of (11.138) is the expected social surplus (sum of firm's profits, and the consumer's utility). The second term in (11.138) is the fictitious consumer surplus that results from underestimating one's future self-control problems. From Lemma 11.7, we know that the second term equals zero for exponential and sophisticated consumers, but it is strictly positive for partial-naifs and naifs.

Applying Leibniz's rule¹⁶ we can write the first order condition for the firm's profit maximization problem as

$$p^* - \alpha = -(1 - \hat{\beta})\delta b \frac{f(\hat{\beta}\delta b - p^*)}{f(\beta\delta b - p^*)} - \frac{F(\hat{\beta}\delta b - p^*) - F(\beta\delta b - p^*)}{f(\beta\delta b - p^*)}, \quad (11.139)$$

where p^* is the optimal price; we assume that a unique interior solution exists.

¹⁶ Leibniz's rule is given as follows. For a function, g , whose partial derivatives exist, and are continuous, we have

$$\frac{d}{dx} \int_{a(x)}^{b(x)} g(x, t)dt = g(b(x), t)b'(x) - g(a(x), t)a'(x) + \int_{a(x)}^{b(x)} \frac{d}{dx} g(x, t)dt,$$

assuming the derivatives $a'(x)$ and $b'(x)$ exist.

For exponential consumers, $\beta = \hat{\beta} = 1$. Substituting in (11.139), we get the traditional optimality condition that price equals marginal cost, $p^* = \alpha$. This ensures that the consumer undertakes the consumption decision only when $c \leq \delta b - p^* \Leftrightarrow \delta b - c - \alpha \geq 0$, i.e., when the net surplus is positive.

When $\beta < 1$, the following possibilities arise. For sophisticates, $\beta = \hat{\beta} < 1$, hence, the RHS of (11.139) equals $-(1 - \beta)\delta b < 0$, thus, $p^* < \alpha$, i.e., price is lower than marginal cost. A simple calculation shows that for $\beta < 1$ and for partial-naifs or for naive consumers, the RHS of (11.139) is also negative, so $p^* < \alpha$. The lump-sum payment, L , is set to ensure that the participation constraint binds. From (11.136), there is an inverse relation between the lump-sum payment, L and the price, p .

What is the intuition for the $p^* < \alpha$ result? Two distinct rationales (depending on whether we have a sophisticate or a naive consumer) can be given.

1. **Commitment rationale:** Individuals who are aware that their future selves have present bias know that their period 1 selves are less likely to consume the good. This is because period 1 costs are more salient to them relative to the period 2 benefit. The reduction in price (below marginal cost) increases the probability that they will consume in period 1 (see Lemma 11.6). This is captured by the first term on the RHS in (11.139). In effect, the sophisticate consumer is willing to pay a larger lump-sum cost, L , in return for a commitment device from the firm (lower price per unit of usage) that enhances future consumption.
2. **Consumer overconfidence:** A partially or fully naive consumer overestimates (in period 0) consumption in period 1 (see Lemma 11.7). Thus, the firm offers the consumer a discount on the per unit price, p , but a higher lump-sum payment, L (to ensure that the participation constraint binds). However, because the consumer will eventually consume less than anticipated, her ex-post welfare is lower with a contract that offers a price discount, but a higher lump-sum fee. In turn, the firm's profits are higher under this misperception of the consumer. One of the problems at the end of Part 3 formalizes this issue. The consumer overconfidence effect is directly proportional to the overconfidence of the consumer (see the second term in (11.139) and Lemma 11.7), which reflects the overestimation of future consumption.

11.8.2 Leisure goods

Leisure goods, such as credit cards, are characterized by current benefits and future costs. A slight reinterpretation of the investment goods model allows us to incorporate leisure goods. In the case of leisure goods, in period 2, reinterpret $b < 0$ as the future cost, while in period 1, reinterpret $c < 0$ as the current benefit (or negative cost). Hence, the distribution $F(c)$ is over a negative domain. Let us now reinterpret the two terms on the RHS of (11.139). The first term is positive (because $b < 0$). The second term is also positive because the overconfidence term $F(\hat{\beta}\delta b - p^*) - F(\beta\delta b - p^*) < 0$. Hence, the RHS is positive, and we are led to the result that $p^* > \alpha$, i.e., for leisure goods, price is greater than marginal cost.

The intuition is as follows. Unless she is naive, the consumer knows that she has self-control problems in the future, so she knows that she will overconsume in the future. The optimal $p^* > \alpha$ allows the firm to offer a commitment strategy to the consumer to reduce future consumption. However, insofar as future self-control problems are underestimated by consumers, they present a profit opportunity for the firm.

For exponential consumers, $\beta = \hat{\beta} = 1$, so, from (11.139), $p^* = \alpha$, as in the case of investment goods. Such consumers know that they have no self-control problems, and they are correct in these expectations, so there is no need to give them an incentive to underconsume. Exactly the same pricing outcome obtains for $b = 0$. In this case, there is no future temptation in period 1; this aligns the incentives of self 0 and self 1.

11.8.3 *Empirical results*

The main implication of current-biased preferences is that for investment goods, price is below marginal cost, while the converse is true for leisure goods.

To test the prediction for investment goods, DellaVigna and Malmendier (2004) examined the data from health clubs in the Boston area. Their final sample included 67 companies, which together own 97 clubs. They find that three main types of contracts were offered.

- (i) A monthly contract with a lump-sum start-up fee of \$129, and an average (across clubs) monthly fee of \$55.
- (ii) An annual contract with a start-up fee of \$64, and an average annual fee of \$625. These contracts do not allow a pay-per-visit feature.
- (iii) A pay-per-visit contract was also offered with average fee per visit of about \$11.

The pay-per-visit contracts are least prevalent, and only 2 out of the 67 companies offer them. The most common contracts offer a monthly fee, followed by those that offer an annual fee. On average, health clubs price their attendance at least \$3–\$6 below marginal cost, which is consistent with the predictions of the hyperbolic discounting model.¹⁷

Interestingly, in the 1950s, health clubs mainly offered the pay-per-visit contract. By the 1970's, such contracts had largely disappeared. One possible interpretation is that firms have learned gradually, over time, to offer contracts that maximize their profits. If consumers underestimate their future self-control problems, then they anticipate visiting the health clubs far more than they actually will. Hence, they are willing to trade off higher lump-sum fees in return for lower per-visit-fees of fixed monthly/annual costs. Firms benefit by receiving the higher lump-sum fees, and a lower than expected health club usage.

The second implication of the analysis is that for leisure goods, price exceeds marginal cost. To test this, DellaVigna and Malmendier (2004) examine evidence from credit card companies. They find that the interest rate on outstanding balances charged by credit card companies exceeds the prime rate by as much as 10%, thus, supporting the predictions of theory.

11.9 Other applications of hyperbolic discounting

In this section, we give a very brief and condensed treatment of some of the other evidence on hyperbolic discounting; the interested reader is encouraged to pursue the original sources mentioned below. Glaeser et al. (2003) provide a novel explanation for why Americans have become increasingly obese. They argue that, for technological reasons, the time delay between the onset of the desire to have food, and the actual consumption of food has gone down. For individuals who use hyperbolic discounting, small time delays matter greatly, on account of the desire for

¹⁷ The authors show that their data rules out other potential explanations, such as price discrimination and transaction costs.

immediate gratification. So, in the presence of the culture of instant meals, individuals tend to consume a greater amount relative to their long-term interests.

In the EDU model, consumers should perfectly smooth consumption over different pay periods. However, consistent with hyperbolic discounting, a *payday effect* is observed. Consumption declines between successive paydays. Huffman and Barenstein (2004) find an 18% decline in consumption spending between the first week of the monthly pay period and the last. Similar declines in consumption over successive payday periods are found by Shapiro (2005) for recipients of food stamp payments and Stephens (2003) for social security recipients.

Paserman (2008) and DellaVigna and Paserman (2005) exploit the distinctive features of the job search process (immediate costs and delayed benefits) to distinguish between the exponential and the hyperbolic model. There are two distinct sorts of costs in the job search process. In the first category are immediate and direct costs such as finding information about vacancies, writing résumés, making contact with employers, and attending interviews. The second set of costs arise from comparing the long-term benefits and costs of accepting a job, and deciding if to continue to search. The first set of costs might be particularly onerous to job seekers who use hyperbolic discounting (which makes current costs more salient relative to exponential discounting). Thus, there could be suboptimal job search, which seems to be borne by the evidence. It follows that a longer spell of unemployment might not just be due to pure luck, but also due to inefficient job search choices made by present-biased individuals. Thus, labor market policy that promotes job search is potentially welfare improving. Using field data, Paserman (2008) finds a significant degree of present bias for low and medium wage workers.

A related problem is one of accepting the *default option* when searching for alternatives that involve current costs, but future benefits. Choi et al. (2004) find support for this idea in the context of acceptance of the default option for the 401(k) retirement savings plan in the US. Individuals might procrastinate and not search for a better or cheaper alternative, hence, they may simply accept the default option set by their employers. This, of course, has immediate implications for the role of public policy in ensuring sensible default options.¹⁸

An important problem in labor economics is the long-term dependence on welfare payments by welfare recipients. One possible explanation for the long-term take-up of such programs is that recipients of welfare, on account of their current bias, might not spend enough time searching for a job. Hence, if their choice set is constrained, for instance, by legislating time bound welfare programs, then such a policy could provide these individuals with a commitment device to quit welfare and go back to work. Fang and Silverman (2009) find evidence of such present bias among single mothers with children that prevented them from going to work. However, in Fang and Silverman (2004) they find that the actual design of these time bound welfare programs prevented single mothers from becoming better off.

Using field evidence, Ariely and Wertenbroch (2002) examine the effect of deadlines on completion of class assignments. In their experiments, executive-education students have to write three assignments. In the first treatment, students can choose their own deadlines, and in the second, evenly spaced deadlines are exogenously imposed on the students. If students have a bias towards the present, then deadlines may ensure that they complete tasks on time. It turns out that there is a demand for deadlines. In the first treatment, instead of choosing to submit the assignments at the end, students use self-imposed deadlines. This is consistent with the idea that many students prefer to use deadlines as a commitment device. However, self-imposed deadlines are

¹⁸ See Benartzi and Thaler (2004) for examples of sensible default policy choices. See Part 8 of the book for a more detailed discussion of these issues.

not successful in preventing delay to the same extent as exogenously imposed deadlines. Hence, students in the first treatment are possibly partially naive in that they underestimate their future self-control problems and do not impose an efficient set of deadlines on themselves.

Wertenbroch (1998) considers why smokers purchase single packs of cigarettes when they could get quantity discounts on larger packs? One explanation is that there is a commitment value to restricting oneself to a smaller number of cigarettes. Furthermore, he finds that consumers are willing to pay a price premium to restrict themselves to smaller packages of their favorite chocolate chip cookies or potato chips.

Ausubel (1999) looks at variations in the response of customers, over a period of 21 months, to a change in the pre-teaser and post-teaser rates of interest offered by a credit card company. The control group were offered a 6.9% annual interest rate for the first six months, and a rate of 16% thereafter. The pre-teaser treatment group was presented with the altered figures of 4.9% for the first six months, and 16% thereafter. The post-teaser treatment offered 6.9% for the first six months, and 14% thereafter. Clearly, the interest rates offered in the post-teaser treatment should be at least as attractive as those in the pre-teaser treatment. However, contrary to this intuition, the increase in the take-up rate for the pre-teaser treatment was 2.5 times that for the post-teaser treatment. Ausubel's interpretation is that individuals exhibit a degree of naiveté. They think that their future selves will behave more in line with the standard textbook models, and will borrow more responsibly in the future. Hence, they do not find the post-teaser treatment to be an attractive one. But individuals seem to mispredict, and ex-post would have been better off, on average, accepting the post-teaser treatment instead. See also Shui and Ausubel (2004) for an extension to a dynamic stochastic model that replicates quantitative features of the real-world data. They estimate that the present bias parameter of hyperbolic discounting is $\beta = 0.8$.

Standard public economics provides the basis to tax cigarette consumption. Smokers create externalities for non-smokers, so the tax induces them to internalize the external costs that they impose on society. Gruber and Köszegi (2001) argue that this analysis does not take account of the internal costs that smokers impose on themselves. On account of a present bias, the current consumption of cigarettes by smokers is far greater than what their own patient long-run self would desire. Hence, if the optimal cigarette tax were to take account of this additional cost, then it would be even higher, relative to current magnitudes; see Section 11.7, above, for a theoretical model.

Duflo et al. (2011) find that 97% of farmers in Kenya intend to use fertilizers in the following season, but only 37% actually end up using fertilizers; this is sometimes known as the *intention-action divide*. They apply a *stochastic version of hyperbolic preferences* to the issue of the take-up of fertilizer use. They allow a fraction of the farmers to have stochastically varying degrees of impatience in a $(\beta, 1)$ model. For instance, farmers could have two levels of impatience, β_L, β_H , with respective probabilities $1 - p, p$ such that $\beta_L < \beta_H \leq 1$. However, the current selves of farmers could be naive, and overestimate the value of p (i.e., believe that in the future there is a greater likelihood that they will be more patient).

There is a small, fixed, cost of purchasing fertilizers. Due to present-biased preferences, farmers may be put off by this fixed cost, and not purchase the fertilizer. They may think, incorrectly, that because their future selves have a high value of β , they are less likely to procrastinate in buying fertilizer. In the event, all future selves may not buy the fertilizer despite it being optimal to buy from an ex-ante perspective. A subsidy on the price of the fertilizer may be optimal under these circumstances. In the actual intervention, home delivery of fertilizers that eliminates travel costs improves fertilizer use by 70%.

The success of the Grameen Bank in Bangladesh in extending microcredit (small-scale loans) has typically been explained in terms of traditional agency theory. It has been argued that the terms of the contract (e.g., group lending) increase the incentives of borrowers to repay and take fewer risks. Bauer et al. (2012) provide an alternative explanation based on present-biased preferences. They conjecture that individuals with self-control problems may find it particularly attractive to borrow from microcredit institutions for the following two reasons.

First, loan officers hold group meetings with borrowers. Hence, borrowers who do not repay are, in effect, publicly named and shamed. Second, the repayments involve immediate weekly repayments of the loan amount even before the investment bears fruit. Thus, borrowers must dip into their current income every week to start repaying. Both features are very attractive to a current self who believes that future selves may have self-control problems. In order to test this conjecture, the authors conduct lab experiments in the field. The discount rates from a random sample of 573 villagers from 18 villages in India are elicited. The main finding is that, as conjectured, subjects who exhibit present-biased preferences in the lab are also more likely to select microcredit institutions to borrow money. However, this result holds only for women, a finding that is similar for the case of the Philippines by Ashraf et al. (2006).

Exercises for Part 3

1. Prove Corollary 1.
2. (Manzini and Mariotti, 2007) Suppose that the utility function is given by $u(z, \tau) = \delta^\tau z^\alpha$, $0 < \alpha < 1$; z, τ is an outcome–time pair, and δ is a discount factor. Consider two alternative prizes $z, z' : z < z'$. Suppose that a, b are the compensations required by the decision maker to delay the respective rewards, z, z' , by one time period. Show that EDU implies that $\frac{z}{z+a} = \frac{z'}{z'+b}$, while the magnitude effect implies that $\frac{z'}{z'+b} < \frac{z}{z+a}$.
3. Show that the magnitude effect is not explained by hyperbolic discounting.
4. (Manzini and Mariotti, 2007) Suppose that we have a time interval $[0, \tau_3]$ that we split into three subintervals $[0, \tau_1], [\tau_1, \tau_2], [\tau_2, \tau_3]$. Suppose that the observed pattern of choice is cyclic, i.e., $(z_2, \tau_2) \succ (z_3, \tau_3) \succ (z_1, \tau_1) \succ (z_2, \tau_2)$, where (z_i, τ_i) denotes a prize of z_i received at the end of the interval $[\tau_{i-1}, \tau_i]$. Suppose also that in comparing two outcome–time pairs, the decision maker splits aggregate time into subintervals such that the common subintervals cancel out. So, for instance, $(z_2, \tau_2) \succ (z_3, \tau_3)$ implies $u(z_2)\delta_0^{\tau_2} > u(z_3)\delta_0^{\tau_2}\delta_{\tau_2}^{\tau_3}$; where δ_t^τ is the discount factor over a time interval $[t, \tau]$, $t \leq \tau$. Show that the observed cyclic choice is consistent with subadditive discounting.
5. (al-Nowaihi and Dhami, 2008a) Consider the interval discount function in Definition 10.3. Show that a continuous discount function, $D(r, t)$, is continuous in t .
6. (al-Nowaihi and Dhami, 2008a) Consider the interval discount function in Definition 10.3.
 - (a) (Time sensitivity): Let D be a continuous discount function. Suppose $r \geq 0$. If $0 < x \leq y$, or if $y \leq x < 0$, then show that $v(x) = v(y)D(r, t)$ for some $t \in [r, \infty)$.
 - (b) (Existence of present values): Let D be a discount function (continuous, or otherwise). Let $r \leq t$. Let $y \geq 0$ ($y \leq 0$). Then, show for some x , $0 \leq x \leq y$ ($y \leq x \leq 0$), $v(x) = v(y)D(r, t)$.
7. (al-Nowaihi and Dhami, 2009) Show that the following classes of popular utility functions are incompatible with increasing elasticity of the value function which is required to explain the magnitude effect (see Proposition 10.3).
 - (a) Constant relative risk aversion (CRRA), given by

$$v(x) = \frac{x^{1-\gamma}}{1-\gamma}, 0 < \gamma < 1.$$

- (b) Hyperbolic absolute risk aversion (HARA), given by

$$v(x) = \frac{\gamma}{1-\gamma} \left[\left(\mu + \frac{\theta x}{\gamma} \right)^{1-\gamma} - \mu^{1-\gamma} \right], \theta > 0, \mu > 0, 0 < \gamma < 1, x \geq 0.$$

- (c) Constant absolute risk aversion (CARA), given by

$$v(x) = 1 - e^{-\theta x}, \theta > 0, x \geq 0.$$

- (d) Logarithmic functions, given by

$$v(x) = \ln(1 + \theta x), \theta > 0, x \geq 0.$$

(e) Quadratic functions, given by

$$v(x) = \frac{1}{2}\mu^2 - \frac{1}{2}(\mu - \theta x)^2, \theta > 0, 0 \leq x < \frac{\mu}{\theta}.$$

(Hint: Show that for members of the CRRA class of value functions, $\epsilon_v(x) = \frac{xv'(x)}{v(x)}$ is constant. For members of the HARA, CARA, logarithmic, and quadratic classes of functions, $\epsilon_v(x)$ is declining. Hence, conclude that none of these families is compatible with Proposition 10.3.).

8. Prove Proposition 10.4.
9. (al-Nowaihi and Dhami, 2008a) For the SIE utility function in (10.10), derive expressions for $\rho_A = -\frac{v''(x)}{v'(x)}$, and $\rho_R = -\frac{xv''(x)}{v'(x)}$. Show that $\rho_A > 0$ and $\rho_R > 0$ for $x > 0$ and $\rho_A < 0$ and $\rho_R < 0$ for $x < 0$.
10. Prove Proposition 10.8.
11. Prove Lemma 10.1.
12. Prove Proposition 10.9
13. (Saito, 2011) Consider the model of Saito (2011) discussed in section 10.3.3. Preferences are said to be *temporally unbiased* if for $x, y \in X, d, d', s, t \in \mathbb{R}_+$

$$(x, t) \succeq_d (y, s) \Leftrightarrow (x, t) \succeq_{d'} (y, s).$$

Show that $\succeq^r$ satisfies the independence axiom of expected utility if, and only if, $\succeq_d$ is temporally unbiased.

14. (al-Nowaihi and Dhami, 2014) Prove Propositions 10.11, 10.12.
15. (al-Nowaihi and Dhami, 2014) Derive the values for the delay, speedup, and generating functions shown in Table 10.2.
16. (al-Nowaihi and Dhami, 2014) Prove Proposition 10.13.
17. (al-Nowaihi and Dhami, 2014) Prove Proposition 10.14.
18. (al-Nowaihi and Dhami, 2014) Prove Proposition 10.15.
19. (al-Nowaihi and Dhami, 2008a) Consider Thaler's apples example (Example 9.1). Take the reference point to be the status quo, i.e., no apple. Use the prospect theory utility function with $\lambda = 2.25, \gamma = 0.88$ (see Part 1 for a definition of this function). Consider two discount functions: the LP-discount function, and the RS-discount function (see Table 10.1). Choose the parameters: $\alpha = \beta = \tau = \rho = 1$.
 - (a) Show numerically that both discount functions explain Thaler's example.
 - (b) Show numerically that the LP-discount function exhibits declining impatience, but the RS-discount function exhibits constant impatience.
 - (c) Show numerically that the LP-discount function is additive, but the RS-discount function is subadditive.
 - (d) What can you conclude about the relative channels through which the two discount functions explain Thaler's example?
20. Prove Proposition 11.18.
21. Prove Proposition 11.21.
22. Using present-biased preferences explain the following phenomena.
 - (a) In the UK, there has been a massive growth of pawnbrokers on the high streets of cities offering loans at astronomical interest rates.

(b) Many Americans buy furniture on a rent-to-own plan that costs, over its lifetime, three times more than directly buying the furniture.

(c) There has been recent spurt in the growth of *payday loans*. These are loans that are borrowed between one payday, and the next payday, using the next paycheck as collateral. According to O'Donoghue and Rabin (2007), there is an 18% interest rate over a month, or typically over two weeks on these loans (what is the implied annual interest rate?). In a typical transaction, a person borrows \$300, and pays back \$354 when the next paycheck arrives in a month/two weeks time. It is estimated that in 2002, 8.5% of Americans took out such loans.

23. (Kaur et al., 2015) Kaur et al. designed an intervention in an Indian data-entry company that took the form of a “negative bonus” scheme. Under this scheme, workers were paid normal piece rate if they met *self-chosen* data entry targets, but penalized if they did not. The take-up of the scheme was voluntary. About 35% of workers chose to set non-zero targets. The negative bonus contracts increased output by an amount that was equivalent to the effect of increasing their piece rate by 33%, or that which would be achieved by a worker with a year's further education. How might we explain these results? Can you think of other domains of employer–employee relations where such policies might work, e.g., in the domain of worker absenteeism?
24. How do you explain the reasoning behind the following quote from Datta and Mulainathan (2014)? “Clocky is an alarm clock that makes it easier to stick to plans to wake up early. When you hit its snooze button, Clocky jumps off the nightstand and rolls into a corner. When it goes off again, you have no choice, but to get up. Similarly, a non-profit organization called StickK allows people to stake their own money on things they are trying to get themselves to do, such as give up smoking. Their funds are only returned to them if they are certified as having met their goal by a third party. So far, nearly 150,000 “commitment contracts” have been taken out on www.StickK.com.”
25. (Diamond and Köszegi, 2003) Consider the model of retirement under hyperbolic discounting presented in Section 11.4. Imagine the following policy intervention. Suppose that the original employment legislation was compulsory retirement in period 2. What happens if this law is now repealed, and retirement in period 2 is a voluntary decision?
26. DellaVigna and Malmendier (2006) examine contracts signed by clients at health clubs. Among those who sign a monthly contract, the average cost per visit is \$17 over six months. If these individuals had instead chosen to pay per visit they would have paid \$10 per visit. Furthermore, the monthly contract has an automatic renewal feature such that the contract can only be canceled if the individual visits the health club to cancel the contract, or cancels by mail. There is a lag of about 2.29 months on average in canceling the contract since the last visit to the club. There is also a positive correlation between the cancellation lag in the monthly contract, and the average price paid per visit. Can these findings be explained under exponential discounting? How can we use insights from models of present-biased preferences to explain these findings?
27. (O'Donoghue and Rabin, 2007) Suppose that there is a single activity that an individual must undertake once during a 7 day period. The pattern of rewards, v , and costs c , is given in Table 3.E1.

The two possible cases are *immediate costs* (costs incurred now, rewards in the next period), and *immediate rewards* (rewards incurred now, costs in the next period). The utility functions corresponding to these two cases are given in 11.80, and 11.81.

Table 3.E1 Pattern of rewards and costs over seven days

Completion day	1	2	3	4	5	6	7
Rewards	5	9	17	33	33	33	33
Costs	5	5	5	5	9	17	33
Net benefit	0	4	12	28	24	16	0

Source: O'Donoghue and Rabin (2007).

- (a) Which day will an individual who uses exponential discounting choose to complete the activity in the two cases of immediate costs and immediate rewards?
- (b) Consider an individual who has $(\beta, \delta) = (0.5, 1)$ preferences.
- (b1) In the case of immediate costs, prove the following. (i) Naifs procrastinate till day 7. (ii) Sophisticates perform the activity on day 5.
- (b2) In the case of immediate rewards, prove the following. (i) Naifs complete the activity on day 3. (ii) Sophisticates perform the activity on day 1.
- (b3) Compare the behavior of naifs with exponential discounters. For the case of immediate costs, naifs do the activity relatively later than exponential discounters, and for the case of immediate rewards, the converse happens. Why?
- (c) Suppose that individuals were asked, prior to day 1, when they would commit to do an activity. Show that all types of individuals (exponentials, sophisticates, naifs) will prefer to commit to day 4 in both cases (immediate costs and immediate rewards). Would all types of individuals see value in taking up the opportunity to commit if commitment can be made at some cost? Would there be circumstances where giving an incentive to the individual to make a commitment may not be optimal?
28. Consider the problem of a social planner who wishes to choose the consumption profile $c_0, c_1, \dots, c_T$ to maximize

$$U_0(c_0, c_1, \dots, c_T) = \log(c_0) + \beta \sum_{t=1}^T \delta^t \log(c_t), \quad 0 < \beta \leq 1,$$

where $0 < T \leq \infty$, subject to the budget constraint

$$c_t + k_{t+1} = k_t^\alpha, \quad 0 < \alpha < 1, \quad (3E.1)$$

where k_t is the capital stock, and the production function is given by $y(k_t) = k_t^\alpha$. The initial level of capital, k_0 , is given.

- (a) Derive the optimal solution when $\beta = 1$. Is the solution time consistent?
- (b) Now let $\beta < 1$. Show that the optimal solution is given by

$$k_1 = \phi k_0^\alpha, \text{ and } k_{t+1} = \alpha \delta k_t^\alpha, \quad t \geq 1,$$

where ϕ is a scalar that depends on α, β, δ .

- (c) What is the steady state capital stock when $\beta = 1$, and $\beta < 1$? How does the steady state depend on the impatience parameter, β ?
- (d) In your answer to part (b), suppose that $(\beta, \delta) = (0.5, 0.975)$, and $\alpha = 0.5$. Find, numerically, the optimal values of the capital stock, $k_1^*, k_2^*, k_3^*, k_4^*$. Now consider the solution

to the problem of the individual from the perspective of time $t = 1$, $U_1(c_1, \dots, c_T)$, subject to the constraint in (3E.1), and given the new initial capital stock k_1^* . Find, numerically, the new optimal values $k_2^{**}, k_3^{**}, k_4^{**}$. Compare the values k_2^*, k_3^*, k_4^* with the values $k_2^{**}, k_3^{**}, k_4^{**}$ from the perspective of time consistency of optimal plans.

29. Consider a quasi-hyperbolic model of discounting where $(\beta, \delta) = (0.5, 1)$. Consider a special case of immediate costs in which time is discrete, $0, 1, 2, \dots$, the reward schedule from some project is $\mathbf{v} = (0, 0, \dots, 0)$, and the time t cost of doing the project at t is $(1.5)^t$. The project must be completed by some deadline time T .
- At which date will a naif complete the project?
 - At which date will a sophisticate complete the project? Does your answer depend on whether the deadline T is odd or even?
 - Now consider a partial naif who expects the impatience parameter of the future selves to be $\hat{\beta}$. Show that if $\hat{\beta} < 2/3$, then the project is completed in period $t = 0$. When is the project completed if $\hat{\beta} > 2/3$?
30. (O'Donoghue and Rabin, 2007) Suppose that a student has to read a total of P pages in T days. Let p_t be the number of pages read on day $t = 1, 2, \dots, T$. The student wishes to choose the optimal sequence $\{p_1, p_2, \dots, p_T\}$, such that $\sum_{t=1}^T p_t = P$. It takes h hours to read p pages, and the reading technology is given by $h_t = p_t^\alpha$, $\alpha > 1$. Reading is onerous, hence, the disutility from spending h hours on reading at time t is given by $u_t = -h_t$. Let Eve be an exponential discounter with $\delta = 1$, and let Neil be a naive individual with $(\beta, 1)$ preferences such that $\beta < 1$.
- For Eve, what is the optimal sequence of pages to read $\{p_1^E, p_2^E, \dots, p_T^E\}$?
 - Let $\mu = \beta^{\frac{1}{\alpha-1}}$. Show that on day 1, Neil optimally reads p_1^N pages, where

$$p_1^N = \frac{\mu}{T-1+\mu},$$

and on any day $t > 1$ he optimally reads p_t^N pages where

$$p_t^N = \left(\prod_{k=1}^{t-1} \frac{T-k}{T-k+\mu} \right) \frac{\mu}{T-t+\mu}.$$

(c) Suppose that $P = T = 30$ and $\alpha = 2$. Determine, numerically, the optimal hours put in by Eve and Neil on each day. What is the total number of hours put in by each individual over the 30 days. Who puts in more hours in the aggregate over the 30 days, and why? Give the intuition behind Neil's optimally chosen hours for the first three days.

(d) Suppose that a teacher wishes for Neil to study more efficiently. The teacher comes up with a requirement that one page must be read every day. What is the outcome? What insight does such an intervention give us about the nature of optimal interventions?

31. (O'Donoghue and Rabin, 2007) Consider a model of harmful habit formation. At any time t , the individual derives utility from the consumption, x_t , of a harmful good (e.g., cigarettes, unhealthy meals, alcohol), and disutility from the level of consumption at time $t-1$, x_{t-1} , which captures the role of habit formation. The unit price at time t of the harmful good is $p_t = 1$, for all t . The utility function at time t is given by

$$u_t = \begin{cases} 15 \ln(1 + x_t) - x_t & \text{if } x_{t-1} = 0 \\ 20 \ln(1 + x_t) - x_t - (20 + 10 \ln(1 + x_{t-1})) & \text{if } x_{t-1} > 0. \end{cases}$$

The utility function incorporates, in a reduced form, the following features. (a) Consumption of the harmful good reduces composite consumption (hence $p_t x_t \equiv x_t$ is subtracted from the RHS). (b) If there is no addiction, $x_{t-1} = 0$, then the marginal utility from consumption is relatively lower, as compared to the case of addiction, $x_{t-1} > 0$. The last term in u_t when $x_{t-1} > 0$, reflects the harmful effects of addiction on current utility. Consider two individuals. Eve is an exponential discounter with $\delta = 1$, and Neil is a naive quasi-hyperbolic discounter with $\beta = 0.8$ and $\delta \approx 1$.

- (a) Suppose that we consider steady state behavior in which one is either addicted, or unaddicted. Will Eve choose to be addicted, or unaddicted? Would your result change if Eve had started off being addicted in her youth (off the steady state). What can you conclude about the role of history in this case?
 - (b) Does Neil prefer the addicted steady state, or the unaddicted steady state?
 - (c) Consider now the role of history for Neil who is not making a choice between quitting now, or never. Rather he is making a choice between quitting now, or tomorrow.
 - (c1) Suppose that Neil starts off being unaddicted. Then does he choose to consume the harmful good?
 - (c2) Suppose that Neil starts off being addicted. Then does he choose to consume the harmful good?
 - (d) Why does history play different roles for Eve and Neil?
32. (Brocas and Carillo, 2001; Carillo and Dewatripont, 2008) Suppose that an individual with multiple selves, one for each period, lives for three time periods $t = 0, 1, 2$. He has a choice to perform tasks only in period $t = 1$. He can perform τ tasks such that $\tau = 0, 1, 2$. Each task is identical and involves an immediate effort cost e , and a one-period delayed reward that has a value equal to 1. The individual has $(\beta, 1)$ preferences and $e \in (\beta, 1)$.
- (a) Show that self 0 prefers self 1 to perform $\tau = 2$ tasks in preference to $\tau = 1$ tasks which in turn is preferred to $\tau = 0$ tasks. Also show that self 1 prefers just the opposite, i.e., no tasks to one task to two tasks.
 - (b) Now suppose that self 0 can make a promise, at some cost, to a third party about the number of tasks that self 1 will perform. Promises have the feature that breaking a promise is costly. Denote by $[x, y]$ the completion of $\tau = x$ tasks when self 0 promises that y tasks will be completed (so $x = 0, 1, 2$, and $y = 0, 1, 2$). Falling short of one task (i.e., $[1, 2]$, or $[0, 1]$) has cost c_1 , while falling short of two tasks (i.e., $[0, 2]$) has cost c_2 such that $c_2 > c_1$.
 - (b1) Suppose that $c_1 < e - \beta$, and $c_2 - c_1 < e - \beta$. Show in this case that self 0 optimally decides not to make any promises.
 - (b2) Suppose that $c_1 < e - \beta$, and $c_2 - c_1 > e - \beta$. Show in this case that self 1 will fall short of one task for any promise, but self 0 prefers $[1, 2]$ to $[0, 1]$. What condition is required for self 0 to prefer $[1, 2]$ to making no promises at all?
 - (b3) Suppose that $c_1 > e - \beta$, and $c_2 < 2(e - \beta)$. Show in this case that self 1 fulfills one promise, but breaks two promises. The period 0 self, thus, prefers a mild commitment to be honored rather than a stiff one be broken.
 - (b4) Suppose that $c_1 > e - \beta$, and $c_2 > 2(e - \beta)$. Show that in this case, all promises are honored, and the equilibrium outcome is $[2, 2]$.
33. Consider a three period model of consumption. A separate self lives in each period. The utility function of self 1 is given by

$$U_1(c_1, c_2, c_3) = \log(c_1) + \beta \log(c_2) + \beta^2 \log(c_3).$$

The budget constraint of the consumer at time t is given by

$$c_t + A_{t+1} = A_t + y_t,$$

where, at time t , A_t is the level of assets, and y_t is the labor income. The initial level of assets is $A_1 = 1$. The labor income at times 1, 2, and 3 is $y_1 = 0$, $y_2 \in \left[1, \frac{1}{\beta}\right]$, and $y_3 = 1$. At each time t , the consumer faces liquidity constraints, so $c_t \leq A_t$. Suppose that the individual is a sophisticate. Derive the optimal path of consumption. Does consumption track income too closely relative to the neoclassical model where $\beta = 1$?

34. (DellaVigna and Malmendier, 2004) Consider the model of DellaVigna and Malmendier (2004) outlined in Section 11.8.
- (a) (Perfect competition) Suppose that instead of a monopolist firm, contracts are offered in period 0 by perfectly competitive firms. Assume that increased competition only affects the utility $\bar{u}$ of the consumer in the alternative activity, and raises it. Show that the solution p^* is unaffected. What, if any, are the effects on the lump-sum fee, L .
- (b) (Welfare issues) Substitute L from the binding participation constraint and p^* from (11.139) to obtain the indirect utility function of the consumer, and the profit function of the firm. Show that profits are increasing in the degree of naiveté $\hat{\beta} - \beta$ of the consumer. Also show that partially naive consumers have lower indirect utility relative to sophisticated consumers.
35. (O'Donoghue and Rabin, 2006): Consider the model of sin taxes in Section 11.7.
- (a) Suppose we have two distributions of β , $F(\beta)$, and $G(\beta)$, such that $F(\beta) \leq G(\beta)$ for all β , and $F(\beta) < G(\beta)$ for at least one value of β . Hence, F first order stochastically dominates G . Let θ^F and θ^G be the optimal taxes under the distributions, $F(\beta)$ and $G(\beta)$, respectively. Show that if $\frac{\partial}{\partial \beta} \left(\frac{\partial \omega(\theta)}{\partial \theta} \right) < 0$ (where $\omega(\theta)$ is defined in the text in (11.123)), then $\theta^F > \theta^G$.
- (b) Keeping the notation as in Section 11.7, suppose that the long-run utility of a β -individual is given by

$$L(\theta) = [(v(x^P(\theta)) - c(x^P(\theta)) - x^P(\theta)) + (I + \alpha(\theta) - \theta x^P(\theta)) | \beta].$$

Denote by $\mathcal{B}$ the compact support of the distribution of β . Then a tax θ_1 is *Pareto-superior* to a tax θ_2 if $L(\theta_1) > L(\theta_2)$ for all $\beta \in \mathcal{B}$. Furthermore, a tax is *Pareto-efficient* if there is no Pareto-superior tax. Suppose now that $\beta \leq 1$ for all consumers, and $\beta < 1$ for some consumers. Further, for all $\beta \in \mathcal{B}$ and for all points in the domain of v ,

$$v''' - \beta c''' \geq \frac{2c''}{c'} (v'' - \beta c'').$$

Show that there exists $\hat{\theta} > 0$ such that all taxes in the open interval $(0, \hat{\theta})$ are Pareto-superior to $\theta = 0$.

36. (Harris and Laibson, 2013) Consider the (β, δ) model of quasi-hyperbolic discounting. Suppose that we extend it to continuous time as follows. For any self born at time, $t = 0$, called self 0, the “present” lasts from period $t_0 = 0$ to $t_1 = 0 + \tau_0$, and the “future” lasts from t_1 to $t = \infty$. The current self has control over the present, and the future selves have control over the future. Self 1 is born at time t_1 . For Self 1 the present period lasts from t_1 to

$t_2 = t_1 + \tau_1$, and the future period from t_2 to ∞ . We can now define future selves recursively. For Self n the present period lasts from t_n to $t_{n+1} = t_n + \tau_n$, and the future lasts from t_{n+1} to ∞ . Each of the terms in the sequence $\tau_0, \tau_1, \tau_2, \dots$ is stochastic, and is drawn from an exponential probability distribution with a hazard rate $\lambda \in [0, \infty)$. Having distinguished between the present and the future periods for any self, discounting over these periods is, in essence, similar to the (β, δ) model. Consider self n born at time t_n . Then the discount function is given by

$$D_n(t) = \begin{cases} \delta^t & \text{if } t \in [t_n, t_n + \tau_n) \\ \beta\delta^t & \text{if } t \in [t_n + \tau_n, \infty). \end{cases} \quad (3E.2)$$

- (a) What are the values of β and λ for which the continuous time hyperbolic function in (3E.2) collapses to the exponential discount function?
- (b) Plot this discount function for a particular realization of $\tau_0 = 3.4$ for self 0.

PART 4

Behavioral Game Theory

INTRODUCTION TO PART 4

In Part 1 we studied the behavior of humans when they engage in non-strategic interaction against nature (game against nature). By contrast, in Part 4 of the book, we consider multiperson strategic decision problems of individuals, firms, or organizations, in which nature is one of the possible players. In these problems, moves by nature, the choices of the players, and their beliefs interact to give rise to individual payoffs. It is assumed that readers are familiar, at a bare minimum, with the material in the appendix on game theory.

Classical game theory plays a hugely influential and important role in economics. It has forced economists to think carefully and formally about the players in their models, their strategies, the sequence of moves, and the payoffs. It has developed plausible equilibrium concepts in different strategic situations. This has allowed it to make precise, testable predictions. It is probably fair to say that the basic machinery of classical game theory underpins most results in modern economics in a mathematically elegant and parsimonious manner.

Part 4 is split into two chapters. Chapter 12 describes the evidence on human choices in strategic situations. The main emphasis is on experimental and field evidence that is designed to test the predictions of various equilibrium concepts in classical game theory. Chapter 13 considers models of behavioral game theory that are motivated by the evidence in Chapter 12. We also consider the relevant evidence on these models. These models range from those that are relatively well-established and backed by reasonably solid evidence to others that are promising, yet need further testing to enable us to make a more informed choice.

Chapter 12 is divided into several sections. Generally, in the early rounds of games and in unfamiliar games, human behavior is often not consistent with the predictions of classical game theory. It typically takes a substantial amount of experience and repeated play of the game before play converges towards the predictions of classical game theory, but this is often not the case in many environments (see also Part 5). Humans engage in many important decisions for only a limited number of times in their lives. For instance, when they choose a university degree, a marriage partner, a house, a consumer durable, or a pension plan. Many decisions made by firms are also of an infrequent nature. These include: capital restructuring, mergers, sunk costs in major machinery and equipment, and the choice of a new product. Even in decisions that are taken frequently, the economic environment is ever-changing and uncertain, bringing about an element of novelty in most decisions. For all these reasons, it is arguably the choices made in the early rounds of an experiment that may be critical in understanding strategic human behavior in many important domains.

We begin in Section 12.2 by looking at the evidence from the simplest games in which a unique Nash equilibrium is found by *iteratively deleting dominated strategies* in a small number of steps. Yet, the outcome in most experiments differs from Nash equilibrium if the number of steps is more than two or three.

In a fundamental result, Nash (1950a) showed that every finite game has at least one *mixed strategy Nash equilibrium* (MSE); Section 12.3 shows that the evidence on the play of equilibrium mixed strategies by individuals is mixed. In the majority of experiments, individual play does not conform to the predictions of an MSE, but the aggregate play is closer to an MSE. However, a fair number of experiments also reject MSE both at the individual and the aggregate levels.

Individuals do play mixed strategies but, typically, not in the proportions that are predicted by an MSE. There is too much serial correlation between strategies over successive rounds. Even when players are given a randomizing device, their play still suffers from serial correlation. There is evidence from professional sport that tennis and soccer players may choose an MSE, but this ability is not portable to other contexts.

In Section 12.4, we consider coordination games that have *multiple equilibria* and the aim is to see if players can coordinate on any of the equilibria. We examine the role of *focal points* and the conflict between focal points and *payoff-salience*. None of the existing selection principles such as *payoff dominance* or *risk dominance* can fully account for the data. Newer, behavioral selection principles, based on loss aversion may be promising. The chosen equilibria are also strongly *history dependent*. *Outside options*, *forward induction*, and *preplay communication* influence the degree of coordination, even in cases where classical game theory predicts that there should be no such effect.

Bargaining games are considered in Section 12.5. We consider the neoclassical theoretical framework and the relevant empirical evidence for *normative* and *positive sequential alternating offers models of bargaining*. We also consider models that do not fit into any of these categories, such as models of *self-serving bias* and *focal points*. The support for classical game theory under full information is relatively weak, and under *one-sided asymmetric information* it is, at best, mixed. The evidence does not appear to be consistent with models where players have purely self-regarding, risk-neutral, homogeneous preferences. However, under *two-sided asymmetric information*, which requires very high cognitive demands from the players, we find surprising support for classical game theory under *sealed bid mechanisms*. We also consider evidence from experiments that attempt to discover the *cognitive process* underlying choices in games using MOUSE-LAB experiments. Unless subjects are trained in the relevant game theoretic concepts, their actual pattern of *searches* and *lookups* is not consistent with the expected pattern from classical game theory.

Section 12.6 examines the evidence from *signaling games*. In several experiments, while play does not conform to the predictions of classical game theory in the early rounds of play, there is greater conformity in later rounds. But, typically, a significant fraction of the players still do not play in accordance with the predictions. A much replicated finding is that there is no support for refinements beyond the Cho–Kreps *intuitive criterion*.

Section 12.7 considers the experimental evidence on *correlated equilibria* in which a choreographer gives recommendations to the players to play particular strategies. In equilibrium, each player finds it in his interest to follow the recommendations, if others do so. When no non-binding preplay communication is allowed, then experimental results show that the recommendations are not followed. This is reversed in the presence of preplay communication. The main result is that the existence of a correlated equilibrium is a necessary, but not a sufficient condition for the recommendations to be followed.

Section 12.8 highlights experimental evidence from games in which the actions of players are either *strategic complements* (SC) or *strategic substitutes* (SS). The evidence suggests that the actions of players in both cases are positively correlated. This is suggestive of reciprocity considerations among players. We also consider the implications of SC and SS for macroeconomics. In the presence of such considerations, nominal rigidity can be explained by behavioral factors such as *money illusion* and *anchoring*.

Section 12.9 explores empirical evidence for a Walrasian competitive equilibrium, where strategic considerations, in the limit, vanish. The main message of this research is that there exists an institution (double auction) and a particular rule for changing prices (the market improvement

rule) that can implement a competitive equilibrium in relatively few rounds of play, even with a small number of players.

The evidence on human strategic choices in Chapter 12 has motivated the development of alternative theoretical models, which are often in better conformity with the empirical evidence as compared to classical game theory. Chapter 13 turns to a consideration of these models. We now outline the plan of this chapter.

A *perfect Bayesian Nash equilibrium* (PBNE) requires two conditions. First, given any history of the game, each player chooses his best reply, conditional on his beliefs at that stage of the game and the subsequent equilibrium strategies of the players. Second, beliefs are formed using Bayes' rule, wherever possible, and actions and beliefs are consistent with each other. The models considered in Chapter 13 relax these conditions individually or jointly.

Section 13.2 is devoted to the *quantal response equilibrium* (QRE). This relaxes the first condition of a PBNE. Players play *noisy best replies*, in the sense that all actions are played with a strictly positive probability but, conditional on the beliefs, the likelihood of playing actions that give a higher expected payoff is also greater. A QRE requires the cognitively demanding condition that players have the correct beliefs about the noisy play of others. An equilibrium requires the consistency of such beliefs with the actions of players, so the second condition of a PBNE holds. A QRE is able to organize much better the evidence from a range of games as compared to a Nash equilibrium.

Section 13.3 relaxes the second feature of a PBNE but keeps the first. Arguably this leads to a less cognitively challenging model. *Level- k models*, and the *cognitive hierarchy models* (CH), are the leading behavioral models in this category. In these models, there is a hierarchy of types among the players. Each type is more cognitively accomplished, relative to the lower types. The two models differ in the distributional assumptions on the lower types. Level- k models assume that each player believes that the other player is of the immediately lower type, while in CH models, a player of any type believes that there is a non-degenerate distribution of lower types. Such models are able to make precise predictions in a large variety of games that are consistent with the evidence. In many of these games, a Nash equilibrium is unable to account for the data; perhaps the *p-beauty contest* is the most popular example.

Section 13.4 describes several applications of level- k and CH models with particular emphasis on coordination games. The *market entry game*, considered in this section, was traditionally held up as a vindication of classical game theory because most experimental evidence was consistent with it (Daniel Kahneman described these results as *magical*). However, it turns out that level- k and CH models are able to account for this evidence equally well.

In classical game theory, players do not derive utility directly from the beliefs about others (*first order beliefs*) or beliefs about the beliefs of others (*second order beliefs*). Yet, human morality, and a range of emotions, such as guilt, and notions of justice, such as perceived fairness, seem to impart direct utility, based on second order beliefs. Since second order beliefs are endogenous, one cannot simply append the psychological payoffs to the material payoffs and use the framework of classical game theory. Rather, this requires new concepts and machinery that is embodied in *psychological game theory*. We consider the relevant equilibrium concepts for both normal form and extensive form games in Section 13.5. We also consider applications that include an explicit modeling of the role of *reciprocity* (see Part 2 of the book for the evidence), and to the role of *guilt* in a range of games.

Section 13.6 is devoted to some of the central ideas in Gintis (2009) that are sufficiently important to merit a section in their own right. He argues that there are no plausible *epistemic foundations* that imply *common knowledge* of rationality in classical game theory. Gintis also ascribes to

social norms and *conventions* the role of a *choreographer* in a *correlated equilibrium* that coordinates human behavior. He also cautions against necessarily interpreting Nash equilibria as social norms because many social norms, such as certain norms of cooperation, are often not Nash equilibria.

Section 13.7 explores a range of other behavioral models of game theory. Each of these models establishes a promising new direction, although the extent of psychological underpinnings of these models, and the evidence for them, varies. Equilibrium concepts based on these models, that we consider, include: *analogy-based equilibrium*, *subjective heterogenous quantal response equilibrium*, *evidential equilibrium*, *cursed equilibrium*, and *noisy introspection*.

The final section, Section 13.8, considers the behavioral economics of auctions. Particular attention is given to *common value auctions* that are characterized by a *winner's curse*. We consider the relevant theoretical explanations and the empirical evidence.

CHAPTER 12

The Evidence on Strategic Human Choice

12.1 Introduction

This chapter documents an extensive, and growing, body of experimental and field evidence that puts to the test the predictions of classical game theory. This evidence has enabled us to develop a better understanding of human behavior in strategic situations, and has guided developments in the emerging field of behavioral game theory that we consider in Chapter 13.

Of particular interest is the class of games which lead to a unique outcome when one iteratively deletes dominated strategies of players. Suppose that the unique outcome of a game can be found by successively deleting dominated strategies in j steps. Then the game is said to be solvable with j steps of iterated deletion of dominated strategies. In classical game theory, j can be any finite number. Section 12.2 tests this prediction for normal form and extensive form games, when $j = 2, 3$. These are some of the simplest games that one could use in order to test the predictions of classical game theory.

The evidence on normal form games with two to three steps of iterated dominance is considered in Sections 12.2.1 and 12.2.2. For $j = 1$, the predictions of classical game theory usually hold. However, when $j = 2$, a majority of the players violate the predictions. One possibility is that as j increases beyond 1, players may have lesser confidence in the rationality of others to engage in iterated deletion of dominated strategies. There are two problems with such a-priori arguments. First, if a player is rational, why does he believe that his opponent is irrational? Second, if opponents are believed to be irrational in such exceedingly simple games, then there are hardly any games where we can invoke common or even mutual knowledge of rationality. This severely restricts the scope of classical game theory. A range of other factors such as *resentment*, *assurance*, and *reciprocity*, may also be important in such games (Beard and Beil, 1994). When $j = 2$, extensive form games and their equivalent normal form representations elicit different behavioral responses. For instance, the frame (extensive or normal) may potentially influence the ability of people to spot dominated strategies (Schotter et al., 1994).

In Section 12.2.3, we consider iterated deletion of dominated strategies in extensive form games of perfect information. A particularly tractable and popular game in this class is the *centipede game*. Depending on the number of nodes in the centipede game, one can test for $j = 1, 2, 3, \dots$ steps of iterated deletion of dominated strategies. For centipede games that involve four to eight alternating moves by players, the evidence is not consistent with the subgame perfect outcome (McKelvey and Palfrey, 1992). In these games, players need more than three steps of iterated

thinking to solve the game, so it is not surprising that the cognitive demands on players are quite high.

One may test iterated dominance using special subject pools that are likely to be familiar with the logic of such reasoning; for instance chess players (Palacios-Huerta and Volij, 2008). In particular, when chess grandmasters play against other grandmasters, the authors report 100% conformity with the backward induction outcome of the centipede game. On the face of it, this is striking support for classical game theory. However, in carefully conducted experiments with professional chess players of high ability, Levitt et al. (2011) showed that 0% of the chess grandmasters conformed with the predictions of classical game theory. Furthermore, their performance was no better than the performance of the students.

In Section 12.2.4, we consider two very simple mechanisms, the Abreu–Matsushima and the Glazer–Perry mechanisms that are dominance solvable, respectively, in simultaneous and sequential games. However, the experimental evidence shows that the performance of these simple mechanisms is unsatisfactory (Sefton and Yavas, 1996; Katok et al., 2002). There is some evidence of learning, but even after several rounds of play, conformity with the predictions of the mechanism is relatively low. These results cast doubt on the implementability of more complex mechanisms.

Nash (1950a) showed that every finite strategic form game has an equilibrium in mixed strategies. Section 12.3 describes experimental evidence on mixed strategy Nash equilibrium (MSE) from a range of experiments. Many of the experimental results in this area are conducted on *zero-sum two-player games*. In these games, an MSE coincides with the maximin and the minimax outcomes,¹ a result that is often exploited in experimental games.

In Section 12.3.1, we first consider early evidence from a two-player zero-sum game in which each player has two strategies (O'Neill, 1987). The overall marginal frequency of play of each strategy is remarkably close to the MSE prediction. However, in an important paper, Brown and Rosenthal (1990) arrived at the opposite result, using exactly the same game. They showed that O'Neill's tests lack power to discriminate among alternative theories. In particular, the observed data in O'Neill (1987) can be explained by a range of plausible behavioral explanations. The statistical tests reject the hypothesis that individual data is identical to the MSE predictions. The current choice of the subjects in experiments is heavily influenced by their past actions as well as the past actions of the opponents. By contrast, theory predicts that over successive rounds, these choices should be independently and identically distributed (iid). There is little evidence of learning by the players.

In the *equilibrium in beliefs* interpretation of MSE, players do not actually play mixed strategies (Binmore, 1991). Rather, each player plays a pure strategy but the proportion of players who play each pure strategy is identical to the predicted MSE. Binmore et al. (2001) apply these ideas to eight different games (including the game in O'Neill, 1987) and allow for the possibility of learning. They find some evidence of convergence. However, the observed frequencies of play, although visually close to the MSE predictions, are statistically different. Section 12.3 then shows that *players do actually play mixed strategies, but not the ones predicted by MSE* (Shachat, 2002). This rejects the equilibrium in beliefs interpretation.

Mookerjee and Sopher (1994) reject MSE not only at the individual level but also at the aggregate level (unlike the findings of O'Neill (1987) and several others). Their verdict on MSE (p. 109) is that “it cannot even be treated as an acceptable as if theory.” Like Brown and Rosenthal (1990), but unlike Binmore et al. (2001), they find no tendency of play to converge to MSE.

¹ That the minimax and maximum outcomes are identical in these games was showed by von Neumann (1928).

Subjects randomize more successfully in game theoretic tasks, relative to decision theoretic tasks (Rapoport and Boebel, 1992; Budescu and Rapoport, 1994). It is likely that game theoretic interaction is more cognitively challenging, making it more difficult to remember past strategies. However, in each case, MSE fails.

Section 12.3.2 considers the evidence for MSE in the context of games with an explicitly economic context. We first consider experiments in a three-firm Hotelling competition model (Collins and Sherstyuk, 2000). The predictions of MSE are violated at the individual level and at the aggregate level. Rapoport and Amaldoss (2000) consider an R&D investment game that has a unique MSE. There is qualified support for the MSE at the aggregate level but rejection of MSE at the individual level. We also examine the related literature that considers similar classes of games.

In order to disentangle the separate effects of the players' desire to play an MSE and their inability to successfully make iid draws from the same distribution, in Section 12.3.3 we introduce a *mixed strategy device*. Such a device elicits the players' desired mixed strategy and then aids in making iid draws from the desired distribution (Bloomfield, 1994; Ochs, 1995; Shachat, 2002). When subjects are provided with a mixed strategy device, their play still does not conform to the predictions of MSE (Shachat, 2002). To be sure, players play mixed strategies, however, their mixtures are quite different from the MSE predictions. This evidence contradicts the *equilibrium in beliefs* interpretation of MSE.

Several papers have explored the ability of professional sports players to detect the play of an MSE. For instance, consider a tennis player randomizing serves to both sides of the opponent. Or a penalty kicker in football, randomizing kicks to both sides of the goalkeeper. One could then test for an implication of MSE by calculating if the win rates of players are identical from serving left or right or kicking to the left or right. In Section 12.3, we discuss the caveats to this line of research. For instance, this research tests for motor skills that are well-honed in human evolution. It is not clear if these results are portable to interesting economic contexts, say, investing in a portfolio of assets or choosing among pension plans. Furthermore, there are other aspects of the problem that are not easy to control for. For instance, in a tennis serve, some of the other relevant dimensions include the amount of topspin, sliced serves, or other bodily deceptions while serving.

In Section 12.3.4, we first report evidence that win rates on tennis serves for professional players are statistically similar for left and right serves (Walker and Wooders, 2001). However, there is serial dependence in the serves of even the top professionals that runs counter to the predictions of MSE. Interestingly, this serial dependence is not discovered by the opponents, who are, therefore, not able to exploit it. In a similar vein, there are statistically identical win rates from kicking to the left or to the right of the goalkeeper in professional soccer games (Palacios-Huerta, 2003). Section 12.3.4 also reports results on the portability of successful randomization experience in sports to other domains. Initial results claimed to have found evidence for such portability (Palacios-Huerta and Volij, 2008). However, this claim has been rejected in several carefully conducted studies (Wooders, 2010; Levitt et al., 2010).

In Section 12.4, we consider multiple equilibria that are ubiquitous in economics. For instance, in New Keynesian macroeconomic models, one of the equilibria is Pareto optimal (say, full employment) but the others are sub optimal (perhaps these involve a degree of unemployment). One of the central insights of this literature is that economic agents may not be able to coordinate on the Pareto optimal equilibrium. Such a situation is said to be one of *coordination failures*.

In game theory, multiple equilibria can arise in several ways. Camerer (2003a, p. 341) suggests a useful classification. In one class of games, all equilibria may have the same payoffs for the players. Consider, e.g., players who simultaneously choose locations to meet up in New York in

Schelling's classic example. In this case, players may use *conventions* or *focal points* to coordinate their actions. In a second class of games, there are asymmetric payoffs in the different equilibria, e.g., the battle of sexes (BoS) game. In this case, pre play communication, or the timing of moves may determine actions. In the third class of games, the equilibria are asymmetric but players are symmetric. An example is the stag-hunt game. Various selection principles such as *payoff dominance* or *risk dominance* may determine the outcome in this case.

In Section 12.4.1, we consider coordination failures in simple coordination games (Cooper et al., 1989). We begin, in Section 12.4.3, with *median action games*. In these games, the payoffs of players depend on their chosen action and on the median action of the group. The experimental evidence shows widespread coordination failures (Van Huyck et al., 1991). Furthermore, none of the selection principles such as payoff dominance or risk dominance are able to fully account for the data in any of the treatments. The equilibria are also strongly *history dependent*.

In choosing among multiple equilibria, one long-standing conjecture, dating back to Schelling (1960), is that people will choose a *focal* or a *salient* equilibrium. The relation between focal points and coordination is considered in Section 12.4.2. Mehta et al. (1994) consider a focal or a salient outcome in a wide variety of situations, such as coordinating on the name of a flower, city, year, color, car manufacturer, and a boy's name. When the payoffs of subjects depend on coordinating their choices with others (relative to making their own preferred choices), choices of players achieve relatively greater coordination, suggesting that *labels* carry important salience or focal information. Furthermore, non-Nash strategy profiles can also serve as focal points even when the game has Nash equilibria (Bosch-Domènech and Vriend, 2013).

In Section 12.4.4, we consider *weak link games*. These games are similar to median action games, except that the median is replaced by the minimum action over all players. For instance, in a sequential multi-stage production process, a slowdown at any stage, delays all subsequent stages. The results here are similar to those in median action games, i.e., widespread coordination failures, and an inability of any of the selection principles to fully organize the data (Van Huyck et al., 1990). The organization of groups as captured, for instance, in permanent versus random pairing of other group members, is a more important determinant of coordination than just the size of groups.

In Section 12.4.6, we consider issues of coordination in a stag-hunt game (Battalio et al., 2001). These authors consider three different kinds of games with identical multiple Nash equilibria. Define the *optimization premium* as the Nash equilibrium payoff minus the payoff from the next best action. The optimization premium does not alter any of the Nash equilibria, however, its size has an important bearing on the extent of coordination failures.

In section 12.4.7, we examine the effect of *outside options* and the role of *forward induction* in the class of two-player coordination games (Cooper et al., 1993). Even when classical game theory predicts that the outside option will have no bite, it alters the outcome to the advantage of the player who has the outside option.² There is also evidence for the role of *forward induction* and for a range of factors related to *timing* and *framing* effects that are not predicted to have any effect in classical game theory.

Section 12.4.8 considers the effect of preplay communication in achieving coordination in two-player games (Cooper et al., 1989, 1992, 1993, 1994). Two forms of communication are studied: One-way communication (1W) and two-way communication (2W). In the former, only one player is allowed to engage in *cheap talk* (sending costless messages) prior to the game, while in

² For instance, the outside option has no bite when the payoffs from the outside option are lower than what one might get from the continuation game.

the latter, both players can engage in cheap talk. In the battle of sexes game, 1W communication fosters coordination on the preferred equilibrium of the player who is allowed to engage in cheap talk. The opposite result is found for coordination games in which there is a conflict between payoff dominance and risk dominance, such as in stag-hunt games. In this case, 2W communication works very well. For instance, if both players can assure each other to play the risk dominant equilibrium through 2W communication, then this acts as an assurance to both players and facilitates coordination.³

Section 12.4.9 explores the powerful *role of history* in influencing the degree of cooperation in the *continental divide game* (Van Huyck et al., 1997). One of two possible equilibria in this case is determined entirely by the accidental choices in the early rounds of the experiment.

Section 12.4.10 considers the role of *financial incentives* such as bonuses in enhancing cooperation (Brandts and Cooper, 2006). We consider a *corporate turnaround game* in which a firm chooses a wage level and a bonus level. A team of workers then simultaneously choose their effort levels. The production technology is such that the minimum effort level in the team determines the final outcome. So, if workers cannot coordinate on a high effort level, the output produced and the bonus received are low. The introduction of a bonus enhances cooperation. However, the mere presence of the bonus, rather than its precise rate seems critical in promoting coordination. Furthermore, groups of players who had *strong leaders* (who make a large effort response to the bonus) do better at coordination.

Most of the literature has typically looked at payoff dominance and risk dominance as selection principles in coordination games. In Section 12.4.11, we consider a new selection principle based on *loss aversion* (Cachon and Camerer, 1996). In a median action game, they find that some of the improved coordination that is typically ascribed to forward induction actually arises on account of loss aversion.

In section 12.4.12, we ask the question if coordination can be “grown” in the lab by gradually increasing group size (Weber, 2006). It is surprisingly difficult to cultivate coordination in the lab. Coordination emerges successfully only under special conditions that include gradual growth of group sizes, successful coordination in small groups, and a knowledge of the history of such coordination.

Section 12.4.13 shows that inter-generational *public advice* under common knowledge can enhance coordination (Chaudhuri et al., 2009). However, private advice and public advice without common knowledge are not effective. Similar results are found by Schotter and Sopher (2003, 2007). Interestingly their findings are suggestive of *punctuated equilibria*, which we shall encounter again in Part 5 when we undertake the study of stochastic social dynamics. In a punctuated equilibrium, one of the coordination equilibria gets established for a few rounds (e.g., as a convention or a norm), only to be replaced by another, and yet emerge once again a few rounds later.

Each of the coordination equilibria is a Nash equilibrium, so players should play their part of the strategy profile, conditional on the other players playing their equilibrium strategy. We ask in Section 12.4.14 if the recommendations of an external arbiter to play a coordinated equilibrium will be followed (Van Huyck et al., 1992). It turns out that the recommendations are only followed if they do not conflict with some other salient principle such as equality of payoffs or payoff dominance.

Section 12.4.15 considers the role of *preplay communication* in the corporate turnaround game (Brandts and Cooper, 2007). They append to the corporate turnaround game a prior stage in

³ Mutual assurance could work, for instance, because humans may have a cost of breaking a promise (see Chapter 7).

which the manager and the workers can communicate with each other. They find that preplay communication significantly enhances coordination. Indeed, the coordination achieved through such communication is higher than that arrived at through purely financial incentives. Effective communication takes a particularly simple form. The manager requests higher effort from the workers, stresses the mutual benefits of doing so, and highlights that workers are well paid!

In Section 12.5 we consider bargaining games. We shall mainly focus on theories of bargaining in the mainstream economics literature.⁴ Within these theories we further restrict attention to those that have been sufficiently empirically tested; thus, we omit the theoretically important class of coalitional theories of bargaining.

Section 12.5.1 considers the *Nash bargaining approach*. Here, one begins with a set of axioms that summarize the desirable features of any bargaining outcome and then derives the unique bargaining outcome that satisfies the relevant axioms (Nash, 1950b). In this approach, there is no bargaining protocol, or rules of bargaining. Hence, tests of this approach are best conducted using *unstructured bargaining* in which parties bargain without explicit rules. Anonymity of subjects in experiments is typically preserved, unless one wishes to explore the implications of face to face bargaining.

We first briefly explain the Nash bargaining approach and the implications of relaxing some of its axioms and then consider the relevant evidence. Early experiments found a strong tendency for equal splits to be implemented (Nydegger and Owen, 1975; Rapoport et al., 1977; Siegel and Fouraker, 1960). However, these studies typically confounded the distinction between the utility and the monetary payoffs of players, as well as the amount of information that players have. The first clinching and satisfactory test of the model was conducted by Roth and Malouf (1979), and it gave support to the Nash bargaining solution. We also explore the role of other factors that are not consistent with any of the main existing normative theories of bargaining. These include the effect of risk attitudes (Murnighan et al., 1988), deadlines (Roth et al., 1988), fairness and relative information possessed by players (Roth and Murnighan, 1982), and sociological factors (Roth et al., 1981).

Section 12.5.2 considers structured models of bargaining in the tradition of Ståhl (1972) and Rubinstein (1982). In these models, there is a definite bargaining protocol, and a set of strict rules of bargaining. Two players (or parties) alternatively make offers and counter offers that can be accepted or rejected by the other player. If an offer is accepted, the game ends. If rejected, the game proceeds to the next round with the other player making a counter offer that can be either accepted or rejected, and so on in successive rounds. In these models, delay is costly. Delay costs may arise due to time discounting reasons, or due to other factors that reduce the size of the pie, such as unproductive strikes, or go-slow tactics in the workplace. Thus, players who have greater patience may be willing to hold out for a better settlement.

We begin by considering non-cooperative bargaining experiments under full information in Section 12.5.2. Early results indicated strong support for the alternative offers bargaining game (Binmore et al., 1985). However, several objections were raised about their experimental protocol. Accounting for these issues either failed to replicate the results (Güth and Tietz, 1988; Neelin et al., 1988) or found significantly weaker support for the theory, as in Ochs and Roth (1989), who also find that the subgame perfect outcome is a poor predictor of experimental data. Ochs

⁴ Other approaches are available in the social sciences. For instance, there is a great deal of literature on *negotiations research* that tends to be taught in business and law schools; see, for instance, Tsay and Bazerman (2009). A set of papers on a rich spectrum of alternative theories of bargaining in the social sciences is collected in Bolton and Croson (2012).

and Roth (1989) also make the surprising discovery, replicated elsewhere (Binmore et al., 1985; Neelin et al., 1988), that when players reject an offer, they often make counteroffers that give them an even lower share of the pie (disadvantageous counteroffers).

Several reasons have been given for the puzzling finding of disadvantageous counteroffers. It could be that players use heuristics that vary in the degree of strategic and fairness considerations, and players may switch between them depending on the context (Güth and Tietz, 1990). Another extremely plausible argument is that the players care not only about their own payoffs, but also their relative payoffs. Thus, players may reject a high offer because they get a relatively low share, yet the disadvantageous counteroffer is more attractive because it gives them a relatively higher share (Bolton, 1991). There is evidence that when such models are nested within a *quantal response equilibrium* framework, they predict well, out of sample (De Bruyn and Bolton, 2008).

We also consider a range of other bargaining issues under full information. The evidence does not seem to indicate experimenter demand effects on the bargaining outcome (Bolton and Zwick, 1995; Bolton et al., 1998). While there is still a substantial departure from the subgame perfect outcome in the presence of outside options (Binmore et al. 1989), there is greater support for the *deal me out solution* relative to the *split the difference solution*.⁵ When the infinite horizon version of the alternating offers bargaining game, as in Rubinstein (1982), is implemented by having a probability of termination of the game at each stage, then the predictions of the relevant theory are violated (Zwick et al., 1992).

Section 12.5.2 considers bargaining under one-sided and two-sided asymmetric information. In the alternating offers bargaining game, results are sensitive to whether parties have asymmetric information about each other or not. Delay is costly, yet one of the parties may be willing to hold out longer, to signal that it is more patient, in the hope of eliciting greater future concessions. Asymmetric information can be one-sided or two-sided. There is a relatively small number of studies on this subject, hence, it would be wise to resist general conclusions, yet there are some intriguing findings.

We first consider a dynamic model of one-sided asymmetric information in which a seller and a buyer bargain over a single unit of an object (Rapoport et al., 1995). The objective is to test the relevant theoretical predictions of this model relating to the time path of prices and the comparative static effects of parameters, such as discount rates (Fudenberg et al., 1985; Gul et al., 1986). The authors draw negative conclusions for the theoretical predictions from their experiments, and find that their subjects follow simple rules of thumb. A second model of one-sided asymmetric information that we consider is a model of strikes in a union–firm setting (Forsythe et al., 1991). While the model is more successful in explaining the results within groups of games where strikes should and should not occur, it is less successful in explaining differences among games in a group. The model also finds it difficult to explain the bargaining allocations among the players based on predictions of Myerson's *random dictator axiom*.

We then move on to two-sided asymmetric information games in which a buyer and a seller each have privately known and uniformly distributed valuations for a single indivisible unit of an object. They bargain under a *sealed-bid bilateral bargaining mechanism* in which players simultaneously submit bids. If the buyer's bid is higher, then trade takes place at the average of the two bids, otherwise both players get zero. Chatterjee and Samuelson (1983) derive the optimal

⁵ These terms are defined in greater detail below. The *split the difference solution* arises from the non-cooperative bargaining models. Essentially, each player gets his disagreement payoff plus a share of the surplus. The *deal me out solution* respects the fact that at each stage, a player will reject any offer below his outside option.

bidding strategies, while restricting to the class of linear bids by both players. Among the class of all Bayesian equilibria, the one in which both players use linear bidding strategies turns out to be the most efficient (Myerson and Satterthwaite, 1983).

On the face of it, these games are the most cognitively challenging of all bargaining games considered in this chapter. Further, given ambiguous support for simpler bargaining games, our prior might be that the data would reject the predictions arising from such games. Amazingly, the finding is just the reverse. We begin with a classical test of the sealed-bid mechanism (Radner and Schotter, 1989). The authors find that the bidding strategies of players are stepwise-linear as predicted. Furthermore, the strategies are different on both sides of the optimal cutoff points in the manner predicted by theory. However, buyers did not shave their bids as much as predicted by the theory.

These results have turned out to be surprisingly robust to changes in experimental protocol, such as random matching of players, more rounds of the experiment, and feedback on the history of the game (Daniel et al., 1998; Valley et al. 2002). Furthermore, the degree of efficiency obtained in the experiments is very high. In the presence of prebid communication, trades take place that are not even predicted to take place in the absence of communication, and the efficiency exceeds the Myerson–Satterthwaite upper bound (Valley et al. 2002). Further, face to face communication is even more conducive to bargaining agreements, relative to written communication only, which in turn is better than no communication at all. It seems that the opportunity to communicate, prior to bidding, allows players to coordinate their expectations and, in a large number of cases, they bid an identical price. Although communication is conducive to bargaining agreements, players are often not fully honest in revealing their private information (sellers overstate costs and buyers overstate valuations). However, players are less likely to lie when communication is face to face.

Section 12.5.3 considers unstructured bargaining that does not fall into any of the other categories considered above. *Self-serving bias* is a leading candidate to explain *bargaining impasse* under full information (Babcock and Loewenstein, 1997). A self-serving bias may occur if players are selective about the facts of the case and about events from their memory, in a manner that serves to underpin their own interests. On account of a self-serving bias, players may confuse between their self-interest and a fair outcome. Hence, they may push too hard for an essentially self-interested outcome, convinced that they are only asking for a fair outcome. This may lead to a bargaining impasse. For instance, we do observe protracted and bitter divorce settlements, and labor union strikes. Such a self-serving bias may also nicely complement and explain some of the earlier bargaining results too. In particular, it alerts us to the fact that asymmetric information is not a necessary condition for a bargaining impasse.

The second theory that we consider in Section 12.5.3 is Schelling's (1960) *tacit coordination* based on payoff-irrelevant cues. In particular, we focus on the empirical study by Isoni et al. (2013). They derive strong support for Schelling's insights, based on stylized, abstract, yet quite simple bargaining games. In these games, players make choices based on spatial cues. The payoffs from these games may be symmetric or asymmetric, yet players find it in their interests to use spatial cues as a coordinating or equilibrium selection device.

Section 12.5.4 considers tests designed to infer the cognitive process of subjects when they play experimental bargaining games. Game theory does not make any direct assumptions about the cognitive processes that underlies strategic choice. Traditionalists might argue that a study of these cognitive processes cannot confirm or reject the predictions of game theory. However, on the flip side, the evidence is so strong and persuasive that it would be undesirable to reject it on a-priori grounds.

Consider Rubinstein's alternative offer bargaining game played by two players over three rounds. The game is easily solved by backward induction. Given the solution concept, one expects players to search backwards. We expect them to first explore the last round data, such as payoffs and actions, then look at the second round data and finally, at the first round data. One may use MOUSELAB software to determine if the pattern of searches and lookups of subjects in experiments is backward, beginning with the third round data (Johnson et al., 2002).⁶ It turns out that most subjects search forward rather than backward. Traditionalists might argue that subjects could search forwards, memorize the data, and then solve the game backwards in their heads. Not only would this be very cognitively costly, evidence shows that when subjects are taught the logic of backward induction, they are more likely to end up searching backward; the outcomes in this case are closer to the predicted outcomes in classical game theory.

Section 12.6 considers the evidence on signaling games. The notion of an equilibrium in signaling games is quite complex and cognitively demanding. Given the evidence from simpler games, reviewed above, a priori it would seem that such equilibria are even less likely to be observed.

In Section 12.6.1, we consider the evidence from simple sender–receiver signaling games (Brandts and Holt, 1992). The only equilibria in these experimental games are pooling equilibria. Of the available pooling equilibria, the authors take as their theoretical prediction, the unique pooling equilibrium that survives the Cho–Kreps *intuitive criterion*. They find that one of the types almost always conformed to the equilibrium predictions. The other type conformed poorly in the early rounds but got better towards the end of the experiment. None of the “unintuitive” equilibria were played. The results are mixed but encouraging for traditional game theory. A well-replicated result is that there is little evidence that the data respects any of the refinements beyond the Cho–Kreps intuitive criterion (Banks et al., 1994).

Section 12.6.2 considers evidence from the *limit entry pricing game* of Milgrom and Roberts (1982) (Cooper et al., 1997b). Under asymmetric information about costs or market demand, firms engage in limit pricing if they restrict their quantity choice relative to the case of full information. By doing so, they attempt to signal bad news to a potential entrant (say, low demand) to induce the entrant to stay out. The payoffs in the experiments are chosen in such a manner that there are both separating and pooling equilibria. In the first few rounds, subjects try to play the full information equilibrium. As subjects gain experience in these games, they move towards a pooling equilibrium. However, convergence is slow. Even in the best sessions, a substantial fraction of the subjects still do not play according to the equilibrium predictions. In treatments that do not have a pooling equilibrium, subjects have a tendency to engage in pooling before a separating equilibrium emerges.

Section 12.6.3 considers models of finitely repeated asymmetric information games. The equilibrium predictions in this class of models (the KWMR model) derive from the results of Kreps and Wilson (1982) and Milgrom and Roberts (1982). Jung et al. (1994) put this model to the test in an entry deterrence game played over several rounds. Up to about round 31, the experimental data does not support the equilibrium predictions and existing incumbents are too accommodating of entry relative to the predictions. However, from rounds 31 onwards there is evidence of *predatory pricing*, i.e., firms take actions to deter entry. However, there are important departures from the predictions of the KWMR model.

Section 12.6.4 considers evidence from models of asymmetric information in corporate finance (Cadsby et al., 1990, 1998). Managers might wish to signal their private information on the prospects of their firm to uninformed investors by sending some costly signal (Myers and Majluf,

⁶ The early, pioneering work is by Camerer et al. (1994).

1984). For instance, managers could signal good prospects by relying more on borrowing relative to equity finance. This may explain, for instance, why firms are sometimes excessively leveraged. When costly signaling is not allowed, experimental play converges to the predictions of the signaling model quite rapidly (Cadsby et al., 1990). Such convergence is quicker when there is a unique equilibrium. When there are multiple equilibria, separating, hybrid, and pooling, then outcomes converge to the pooling equilibrium. In the presence of costly signaling, the findings are less positive for the classical predictions (Cadsby et al., 1998).

Contributions from large donors (leaders) to charities are often found to elicit enhanced contributions from others (followers). One possible explanation is that most donors have asymmetric information about the quality of the charity. The contributions of the leaders convey valuable information about quality. An alternative hypothesis is that players are motivated by “other-regarding preferences.” In this view, the initial leadership contributions elicit positive reciprocity among followers who then contribute more. In section 12.6.5, we consider experiments that distinguish between these two competing hypotheses (Potters et al., 2007). The signaling hypothesis is predicted to have bite in the asymmetric information treatment but not in the full information treatment. Reciprocity turns out to be important because even in the full information treatment, leadership contributions elicit more contributions from followers. However, under asymmetric information, the effect of leadership contributions on the contributions of followers is even more potent, suggesting an additional role for the signaling hypothesis.

Section 12.6.6 looks at the case of *multiple signals* in three classes of games, the prisoner’s dilemma game, the stag-hunt game, and the game of chicken (Duffy and Feltovich, 2002, 2006). In alternative treatments, they allow subjects to either engage in cheap talk, prior to the game, or allow them to observe the history of the game, or allow them to observe if previous cheap talk by players was matched by the intended actions. They find that when cheap talk was predicted to be credible, then the level of cooperation among the players was greater in the cheap talk treatment. In this case, *words spoke louder than actions*. When subjects receive additional information about the past play of opponents, there are two possibilities. One is that past intentions stated through cheap talk were matched by past actions and the subject is revealed to be honest. The other is that subjects are found to be dishonest. If currently stated intentions are identical to past intentions, then the past honesty of players becomes an important determinant of the current response of players. Hence, cooperation is either enhanced or reduced, depending on the level of inferred honesty.

Section 12.7 considers the experimental evidence on *correlated equilibria*. The idea behind a correlated equilibrium is that if all players in a game can condition their play on a commonly observed public signal, then they can improve their payoffs. Think, for instance, of the coordinating role of traffic lights (public signal). It is beneficial for everyone to “go” when the light is green and “stop” when the light is red. The *recommendation* to “go” when the light is green and “stop” when it is red is self-enforcing in the sense that if others are expected to follow the recommendations, then it is in the interests of each player to also follow them.

Cason and Sharma (2007) aim to see if players play a correlated equilibrium in which the payoffs of all players are greater, relative to any of the three Nash equilibria of their game. Subjects in experiments do not always follow the recommendations of a choreographer who recommends each player to play his part of the correlated equilibrium. Recommendations are more likely to be followed when humans play against robot opponents, as compared to human opponents, suggesting that subjects may doubt the rationality of others. When non-binding preplay communication is allowed, then the evidence is consistent with the play of recommended strategies (Moreno and Wooders, 1998). Duffy and Feltovich (2010) try to implement several strategy profiles that give

payoffs higher than, equal to, or lower than the Nash equilibrium payoffs. They find that a recommendation to play a correlated equilibrium moves play in the direction of such an equilibrium, relative to the mixed strategy Nash equilibrium of the game. Correlated equilibrium turns out to be a necessary, but not a sufficient condition for recommendations to be followed.

The concepts of *strategic complements* (SC) and *strategic substitutes* (SS) are fundamental in many areas of economics, such as coordination failures in macroeconomics, and network externalities. The actions of two players are SC if an increase in the action by one player increases the marginal payoff of the action of the other player. By contrast, in the case of SS, the marginal payoffs of players are decreasing in the actions of the opponents. Hence, one would expect the actions of players to be positively correlated in the SC case and negatively correlated in the SS case. Section 12.8 examines evidence from strategic environments characterized by SC and SS.

Section 12.8.1 shows that cooperation among players is higher when actions are SC rather than SS (Potters and Suetens, 2009). Play does not converge to the Nash equilibrium of the stage game. Interestingly, in both cases, SC and SS, the actions of the players are positively correlated. Reciprocity is one possible explanation. When a player takes an action that facilitates, or reduces, joint payoff maximization, the other player reciprocates likewise.

The work of Fehr and Tyran (2008) in Section 12.8.2 has deep and profound consequences for modern macroeconomic theory. They consider a monopolistic competition type model in which firms derive utility from their own price, the price level of others, and the nominal money supply.⁷ Two factors turn out to be important in explaining nominal rigidity; these are *money illusion* and *anchoring*. The strategic environment also turns out to be an important determinant of the extent of nominal rigidity. Prices are more rigid in the SC case relative to the SS case.

Competitive general equilibrium (CE) lies at the heart of modern economic theory. A CE is a vector of prices of all outputs and inputs such that all consumers maximize utility, all firms maximize profits, and all markets clear. The existence of a CE requires several strong assumptions, thus, it is important to experimentally test it. Theoretical treatments of competitive equilibrium require the existence of a fictitious actor, the Walrasian auctioneer, which makes it difficult to falsify the theory. Importantly, in a CE, no trading is allowed at any non-equilibrium price, and all trading immediately takes place when an equilibrium price is discovered by the Walrasian auctioneer. Two approaches have been taken in the literature, and we outline both in Section 12.9; these approaches create different proxies for a Walrasian auctioneer.

The first attempt to experimentally test for a CE was made in a seminal paper by Chamberlin (1948) that we consider in Section 12.9.1. Chamberlin (1948) put Harvard economics students in a room, assigned sellers their private costs and buyers their private valuations, and asked people to freely meet and strike bargains. This implementation of a CE would seem to many as eminently plausible. However, the experimental results reject a CE. In interpreting these results, Chamberlin (1948) questioned the very notion of a CE.

The second approach to testing for a CE was proposed by Smith (1962); we consider this in Section 12.9.2. Smith's innovation was to introduce the institution of a *double auction* and induced value elicitation. In this method, participants in their role as buyers and sellers are assigned privately known values and costs, and make public bids and asks. A critical component of the double auction institution is the *market improvement rule*. In successive rounds, sellers can only adjust their "ask price" downwards and buyers can only "bid" their price upwards until some trade takes place. Smith (1962, 1964) found evidence consistent with a CE. These results have been widely

⁷ This class of models should be familiar to most advanced undergraduate macroeconomics students. See, for instance, section 8.1 in Blanchard and Fischer (1989).

replicated; convergence to a CE is quick even when there are very few market participants, sometimes as few as three. However, Smith (1962, 1964) and Chamberlin (1948) allow for out of equilibrium trading and institutions such as the double auction method that are not a part of the theoretical framework. The Walrasian hypothesis, namely that prices increase more when excess demand is high, is rejected by Smith's experiments.

When the double auction experiment is played out with *zero intelligence robots* and the market improvement rule is imposed on their "bids" and "asks," a CE results in a few rounds with high economic efficiency (Gode and Sunder, 1993); we consider this in Section 12.9.3. In the textbook competitive equilibrium model, the likelihood of a CE being achieved is always greater under full information. Just the opposite result is found in experiments. Introducing full information retards rather than facilitates a CE. Perhaps the main message of the CE experiments is to demonstrate that an institution (double auction, augmented with a market improvement rule) exists that can implement a CE. One may wish to employ this institution on account of the desirable efficiency properties of a CE. While we do observe a similar institution in stock market trading, and in commodity markets, and in a few other selected domains, it is perhaps a puzzle why we do not observe it more widely. These experiments still implement a fairly simple version of a CE. When the setting is enriched by allowing for endogenous quality, then a CE does not obtain, as we showed in the introductory chapter and in Part 2 (Fehr et al., 1998).

12.2 Iterated deletion of dominated strategies

In this section, we consider two classes of games. Normal form games that can be solved by iterated deletion of dominated strategies and extensive form games of perfect information, such as centipede games, that can be solved by backward induction. For pedagogical reasons, it is expedient to defer a consideration of some other games in this category, such as *market entry games* and the *p-beauty contest*, to subsequent sections. The main empirical finding is that, while players are able to engage in a few steps of iterated dominance (usually one or two), higher steps of reasoning are rare.

12.2.1 Failure of two steps of iterated dominance

Beard and Beil (1994) gave one of the simplest, and earliest, demonstrations of the failure of iterated dominance using a game that was motivated by Rosenthal (1981). The baseline game is shown in its extensive form in Figure 12.1. The strategically equivalent normal form representation, with player 1 being the row player, is also shown.⁸ Players 1 and 2 move in sequence and choose an action from their respective strategy sets $\{L, R\}$ and $\{l, r\}$. The payoffs corresponding to each strategy profile are shown at the terminal nodes.

In the extensive form game, the unique outcome arising from backward induction is the strategy pair (R, r) . There is another Nash equilibrium, (L, l) , but it relies on a non-credible threat by player 2 to play his dominated action l , if given the move. Two steps of iterated dominance are needed to achieve the backward induction outcome. Strategy r weakly dominates strategy l . Mutual knowledge of rationality allows player 1 to delete strategy l . Rolling back the game tree, strategy R is the dominant strategy for player 1. Thus, the strategy pair (R, r) is the unique

⁸ By contrast, for a given normal form game there is no guarantee that one can write a unique representation in terms of the extensive form. Many extensive form games can correspond to a given normal form game.

Figure 12.1 The extensive form and the strategically equivalent normal form in the baseline treatment.

prediction of classical game theory. A rejection of the equilibrium prediction may indicate the inability of players to perform two steps of iterated reasoning, or a lack of mutual knowledge of rationality. In the baseline treatment, 66% of subjects in their role as player 1, nevertheless, played L. It is possible that, while player 1s respect dominance, they are not confident that player 2s will also respect dominance.

Suppose that player 1 assigns probability p that player 2 will play r . Denote by q , the actual fraction of player 2s who responded to the play of R with r . Then, assuming subjects are randomly matched, player 1 is predicted to be indifferent among L and R if and only if

$$9.75 = 3(1 - p) + 10p \Leftrightarrow p = 0.97.$$

Thus, if $p > 0.97$, then, clearly player 1 would choose R over L (and L over R when $p < 0.97$). In the experiment, the fraction of player 2s who responded to the play of R by player 1s with the dominant action r , is $q = 0.83$. Since $0.83 < 0.97$ ($\Leftrightarrow q < p$) we cannot necessarily infer that 66% of player 1s who played L were irrational. This, does not, however, explain why 34% of player 1s played R.

Classical game theory typically assumes that people derive utility solely from their payoffs in the payoff matrix. To check for the influence of other factors such as resentment, risk, assurance, and reciprocity, Beard and Beil (1994) employ a range of other treatments that are reported in Table 12.1. We omit the baseline treatment (Treatment 1) that we have already described above. For all treatments in Table 12.1 (Treatments 2–7), $p < q = 1$, so, classical game theory predicts that player 1 should choose R over L. Thus, in the last column of Table 12.1, the predicted numbers in classical game theory are 0.0.

In Treatments 2 and 3, the *reduced risk treatments*, the payoff to player 1 from choosing L is reduced (to 9 and 7 respectively). This reduces the risk to player 1 from choosing R, making it more likely to be the chosen strategy. In Treatment 4, the *greater assurance treatment*, the payoff to player 2 from playing l is reduced. This should increase the confidence of player 1 that player 2 will not choose the dominated strategy, l . In Treatment 5, the *greater resentment treatment*, the payoff of player 2 from the strategy profile (L, l) or (L, r) is increased. Thus, if player 1 were to play R, then player 2 has to forgo a greater payoff, irrespective of her own strategy. Thus, the play of R by player 1 might make player 2 more resentful who, in turn, can then decide to play l instead of r in order to punish player 1. This is expected to increase the incentive of player 1 to play L. In Treatment 6, that combines *lower risk* for player 1 and *greater reciprocity* on the part of player 2, the incentive of player 1 to play L increases on both counts (lower risk and greater reciprocity). Finally, in Treatment 7, players face *higher stakes*. However, players receive their associated payoff with probability 1/6.

Table 12.1 Treatments 2–7.

Treatment	Number of pairs	Payoffs from various strategy combinations			% of Player 1s choosing strategy L
		(L, l) or (L, r)	(R, l)	(R, r)	
2	31	9, 3	3, 4.75	10, 5	0.65
3	25	7, 3	3, 4.75	10, 5	0.20
4	32	7, 3	3, 3	10, 5	0.47
5	21	7, 6	3, 3	10, 5	0.86
6	26	7, 5	5, 9.75	10, 10	0.31
7	30	58.5, 18	18, 29.4	60, 30	0.67

Source: Beard and Beil (1994).

The main finding from Table 12.1 is consistent with the intuition in Rosenthal (1981). Except for Treatments 3 and 6, where the choice of L drops to respectively 20% and 31%, a high proportion of player 1s play L. Since, for Treatments 2–7, $q = 1$ (i.e., player 2s always responded with the action r when player 1 played R), we should expect no play of L. But in half the cases, this prediction is not even supported by a majority of the subjects. One plausible conclusion from these results is that players fail to perform one to two steps of iterated dominance. These results were replicated by Goeree and Holt (2001); see one of the problems at the end of the chapter.

Consider the following two-player two-stage sequential bargaining game in Goeree and Holt (2001) that illustrates the failure of two steps of iterated dominance. The problem is to divide a pie that shrinks in size from \$5 to \$2 from the first to the second stage; this is a proxy for discounting the future. The reservation amount for each player in the experiment is zero. In the first stage, player 1 moves first to propose a split of \$5. If accepted by player 2, the proposed split is implemented and the game ends. If rejected, at the second stage, player 2 can make a counteroffer based on a pie of size \$2. Player 1 can either accept the counteroffer (payoffs being divided as in the counteroffer) or reject, in which case, both players get zero.

This is a dynamic game of perfect information, hence, it can be solved by backward induction. Suppose that the smallest unit of money is a cent and the reservation utility of each player is 0. Applying backward induction, at the second stage, player 2 should propose to keep \$1.99 for himself and offer \$0.01 to player 1. Player 1 should accept this offer because it exceeds the reservation amount. At the first stage, if player 1 offers player 2 a share $\$2 > \$1.99$, then player 2 should immediately accept. Hence, the unique backward induction outcome is for player 1 to keep \$3 and offer \$2 to player 2 at stage 1, which should be immediately accepted. Notice that the equilibrium offer of player 1 is the size of the initial pie minus the amount by which the pie shrinks. Thus, if the pie shrinks from \$5 to \$0.50, then, in equilibrium, player 1 keeps \$4.50 and offers \$0.50 to player 2, which should be immediately accepted.

Goeree and Holt (2001) use six cohorts of ten students each as their subjects in the experiment. In the first game, with a pie that shrinks from \$5 to \$2, the average amount kept by player 1 was \$2.83, not far from the equilibrium prediction of \$3. However, in the second game in which the pie shrinks from \$5 to \$0.50, the average amount kept by player 1 was \$3.38, which is substantially lower than the equilibrium prediction of \$4.50. Furthermore, rejections by player 2s were common. By rejecting the offer of player 1, player 2 can get no more than \$0.50, which is not rational.

The results described above are consistent with the pattern of results in similar games that had already emerged by the early 1990s (Davis and Holt, 1993). One possible explanation for the deviations from the backward induction prediction arises from the possibility that players have “other-regarding preferences.” For instance, if relative payoffs are important, then player 2 may reject a higher offer in the first stage, yet be willing to accept a lower amount at stage 2 because it is relatively more equal; see Goeree and Holt (2000) for a fuller consideration of these issues.

12.2.2 *Framing effects and failure of three steps of iterated dominance*

In classical game theory, one may expect the equilibrium outcomes to be identical if we consider games in extensive form or in their equivalent normal form representation (invariance). Schotter et al. (1994) ask if the two alternative game form representations are associated with different framing effects. For instance, spotting dominance may be relatively easier in one representation rather than the other. Figure 12.2 gives the extensive form representation for a two-player game and the strategically equivalent normal form. Subjects in the experiment are asked to play both representations of the game separately.

The backward induction outcome is (R, r) because strategy l is dominated by r for player 2. Folding back the game tree, strategy R dominates L for player 1. Hence, the equilibrium (R, r) requires two steps of iterated dominance. In the normal form version, 43% of player 1s choose R , while in the extensive form version, 92% choose R . One interpretation is that players have less confidence in the ability of player 2s to respect dominance in the normal form version relative to the extensive form version. Such expectations turn out to be justified. In the normal form version, 80% of player 2s choose the dominant strategy, r , while in the extensive form version, this increases to 98%. Thus, framing effects are critical in actual choice insofar as they may help to spot dominance. Framing effects can also arise from other sources. For instance, if only a verbal statement of the game is given, then people’s mental representation of the game may be neither of the normal or extensive form versions. This has implications for which equilibrium, if any, is likely to arise.

A second objective of Schotter et al. (1994) is to test whether individuals undertake three steps of iterated deletion of dominated strategies. Consider the extensive form game in Figure 12.3 with its strategically equivalent normal form. Eliminating weakly dominated strategies, the normal form game can be solved for the unique strict Nash equilibrium (M, M) . To see this: First eliminate the strictly dominated strategy B for player 1, then the (weakly) dominated strategies

T and B for player 2, then the dominated strategy T for player 1.⁹ Thus, three steps of iterated removal of weakly dominated strategies are required to achieve the Nash equilibrium (M, M). However, only 16% of the row players and 26% of the column players play M. 82% of the row players play T, the safe strategy. The vast majority (96%) of column players do not play their dominated strategy B. However, reasoning to three levels seems beyond most players. Now consider the extensive form game described in the right panel of Figure 12.3. The main difference from the extensive form game of Figure 12.2 is that, following the original move of L by player 2, both players play a simultaneous move battle of sexes game (BoS) in which each player chooses among one of two possible strategies, M and B. There are two subgame perfect outcomes.¹⁰ In the first equilibrium, player 1 plays T and ends the game, so that each player gets a payoff of 4. In the second equilibrium, player 1 plays L and the payoffs are (6, 3) corresponding to the play of (M, M) in the BoS game.

What outcome can we expect by using forward induction arguments? Suppose that instead of playing T, player 1 plays L and player 2 finds that she is unexpectedly given the move. What should player 2 infer? A rational player 1 must only have given up a payoff of 4 in the expectation of receiving a greater payoff, which only happens if both players play (M, M) in the BoS game. Anticipating this, player 2 should play L. The players may then be able to coordinate on the (M, M) outcome in the BoS game rather than the other pure strategy equilibrium in the BoS game given by (B, B). In the experimental data, while 100% of player 1s choose M in the BoS game, only 31% of column players do so. The vast majority of column players, 69%, play B instead. Possibly, correctly forecasting this, 70% of player 1s play T at the first node and end the game. In particular, the solution found by iteratively deleting weakly dominated strategies, (M, M), is played by only a small minority of players.

The play of T by player 1s is consistent with the prediction of subgame perfection. However, it does not necessarily imply that players do use backward induction. The payoff of 4 for player 1 is relatively high compared to the payoff of 0 that he/she could potentially achieve in three out of

⁹ Recall from the appendix on game theory that iterated deletion of weakly dominated strategies may also eliminate some Nash equilibria in the game such as (T, T) and (T, B). However, (M, M) is the only strict Nash equilibrium in this game.

¹⁰ See the appendix on game theory for the BoS game.

the remaining five cases. Player 1, could, for instance, be sufficiently loss averse and cognitively challenged, in which case it is not surprising that he may choose the safe payoff of 4 from playing T. More varied experimental designs are needed before we can say anything more definite.

12.2.3 Centipede games and failure of higher order steps of iterated dominance

Centipede games, introduced originally by Rosenthal (1981), are dynamic games of perfect information that have a finite number of players and strategies. In the typical game, there are two players who make alternating moves. At each move, a player can either play down, D, and end the game or play across, A, and pass on the move to the other player. Payoffs accrue at each terminal node.

Panels (a) and (b) of Figure 12.4 illustrate, respectively, the four-move and six-move games in McKelvey and Palfrey (1992). These games begin with the choice by player 1 from the actions A and D. If player 1 chooses A at any node, then player 2 also gets to make a choice between A and D. The total payoff to the two players doubles as one moves across to the right along successive nodes. For this reason, the Pareto optimal outcome is achieved if the player at the last node chooses A; this achieves respective total payoffs of \$8 and \$32, in the four-move and the six-move games. However, if the game were to end with the first player playing D at the first node, the total payoff to both players equals just \$0.50. Centipede games can be solved by applying backward induction. In each case, the backward induction outcome is for player 1 to play D at the very first move and end the game. This can be a disturbing outcome, even for classical game theorists.¹¹

Panel (a)

Panel (b)

Figure 12.4 Four-move and six-move centipede games.

¹¹ See, for instance, Aumann (1992, 1995). Aumann (1995) showed that the backward induction outcome in which the player at the initial node plays D arises not due to rationality, or mutual knowledge of rationality but due to *common knowledge of rationality*. However, the importance of this result depends on how rationality and

Table 12.2 Conditional probability of choosing action D.

Type of game	P1	P2	P3	P4	P5	P6
4 move	0.07	0.38	0.65	0.75		
4 move (high stakes)	0.15	0.44	0.67	0.69		
6 move	0.01	0.06	0.21	0.53	0.73	0.85

Source: McKelvey and Palfrey (1992).

The rationality requirements for the backward induction equilibrium in the case of the centipede game are even more stringent compared to the other games that we have considered above. For instance, player 1 has to solve for four steps of iterated reasoning in the backward induction outcome in the four-move game. In the six-move game, this number rises to six. Insofar as the evidence generated by simpler games suggests that players fail to successfully iterate over a lower number of steps, it should not come as a surprise that the prediction of backward induction often fails for the centipede games.

McKelvey and Palfrey (1992) ran a total of seven sessions with students. No subject participated in more than one session; in each session, each subject participated in ten games. The first three sessions used the four-move game. The fourth session used a high stakes four-move game and sessions five through seven used the six-move game. The results across all sessions are shown in Table 12.2, where p_i is the probability of playing D at node i , $i = 1, 2, \dots, 6$, conditional on play having reached node i .

The results are as follows. (1) There is very little evidence of the backward induction outcome (i.e., play of D at the first node). Across the three types of games (four-move game, four-move game with high stakes, and the six-move game), the respective percentages of play of D at the first node are 7, 15, and 1. (2) The probability of playing D increases as we move closer towards the last node.¹² (3) Comparing corresponding nodes in the high stakes four-move and the six-move games, there is typically a higher probability of playing D in the four-move game, except for node 2.

Rapoport et al. (2003) ran three-player centipede game experiments; the game is shown in Figure 12.5. This experiment is not simply an extension of the McKelvey and Palfrey experiments to an additional player and much higher stakes (the payoffs are the dollar amounts of payoffs). Rather, there are several differences between the two sets of experiments that could have a bearing on the results. (1) Three players instead of two. All three players move in sequence and each player moves twice over the entire game. (2) The payoffs at the last node from moving across are zero for all players, while in the McKelvey and Palfrey experiments these payoffs are the highest possible in the game. (3) Subjects play the game over 60 rounds as compared to the 10 rounds in the McKelvey and Palfrey experiments. This allows for potentially much greater learning.

The results in Rapoport et al. (2003) are quite different from McKelvey and Palfrey (1992). (1) Averaged across sessions 1–4, about 40% of the play by player 1 at the first node is D. (2) The conditional probability of playing D at node i , p_i , is fairly stable across decision nodes 2 to 8.

common knowledge (or common belief) are defined, and there is disagreement over these concepts. These issues are treated in detail in Dekel and Siniscalchi (2015). I am grateful to Pierpaolo Battigalli for drawing my attention to these issues.

¹² There is only one exception to this finding. This was session 5 with Caltech students in which at the last two nodes, the conditional probability drops from 0.91 to 0.50.

	1	2	3	1	2	3	1	2	3	0
	A	A	A	A	A	A	A	A	A	0

One conjecture for these results is that humans might be more hardwired to cooperate in dyadic relations (two individuals) rather than triadic (three individuals) relations. Another possibility is that there is some form of learning that explains a relatively greater play of D at the first node. There are, however, two possible caveats to the results. First, 60% of the choices still do not strictly conform to the backward induction prediction. Second, 60 rounds of learning in this simple environment might be too large for many kinds of actual human learning, e.g., buying a mortgage or an insurance, marriage, divorce, and buying a pension plan.

Fey et al. (1996) propose a constant-sum variant of the centipede game. Players divide a constant sum of \$3.20 at each node. The division at the first node is strictly equal. However, as one moves across towards the end node, the division becomes increasingly unequal. Thus, if players have "other-regarding preferences," then they should play D much earlier than comparable experiments. In their ten node and six node versions, 45% and 59% of the outcomes were, respectively, consistent with the backward induction outcome suggesting that other-regarding preferences may be a contributory factor.

Nagel and Tang (1988) considered a two-player, twelve-node, centipede game. Players are shown a strategically equivalent normal form game. Many of the results of McKelvey and Palfrey (1992) are replicated. The modal play indicates that players play D about halfway through the game. Only 0.5% of the choices are consistent with the strict backward induction outcome in which player 1 plays D at the first node. There is insufficient evidence to indicate that players converge, over successive rounds, towards the backward induction outcome.

Palacios-Huerta and Volij (2008) ran artefactual field experiments in which professional chess players play the centipede game. In their first experiment, chess players are matched with other chess players. In the second experiment, conducted in the lab, chess players play the centipede game with students and other chess players over multiple rounds under a random rematching design. In the first experiment, when the centipede game is played with chess players, the outcome of 69% of the games is consistent with the backward induction outcome. When chess grandmasters play against other chess players, without exception, they play the backward induction outcome in centipede games perfectly (i.e., choose D at the first node). In the second experiment, in repeated interactions of chess players against chess players, over ten rounds, 70% of the results are consistent with the backward induction outcome. When students play against chess players (respectively, other students) and acted as player 1, then 30% (respectively, 3%) of the games ended with the play of D at the first node. On the face of it, these experiments suggest that the strong refutation of backward induction that arises in experiments, typically conducted on student populations, may not apply to professionals. Indeed, when professionals who possess

Figure 12.6 A six-move centipede game.

Source: Levitt et al. (2011) with permission from the American Economic Association.

skills in backward induction play the centipede game, their performance provides evidence for classical game theory.

In a careful study, Levitt et al. (2011) carry out a replication of the artefactual field experimental design of Palacios-Huerta and Volij (2008) and reach diametrically opposite conclusions. In their experiments, they ask professional chess players to play two games.¹³ (i) A six-move centipede game in which the backward induction outcome is for the player starting the game to play D; see Figure 12.6. (ii) A “race to 100” game in which players sequentially choose numbers between 1–9 in one treatment and 1–10 in another. The numbers chosen in each sequential stage are added and the individual whose choice leads the aggregate sum to be 100 wins a prize, while the opponent gets nothing. This game can be solved by backward induction.¹⁴ The reason for introducing the second game is that it is not at all obvious that common belief in rationality implies backward induction in the centipede game, while such a link is clearer in the race game.¹⁵

The distinguishing feature of these experiments is the very high quality of the subject pool. Among chess players, ranking is based on the following main three-tiered hierarchy: Grandmasters, International Masters, World chess federation (FIDE) and United States chess Federation (USCF) Masters. Two further categories are introduced for chess players who do not have titles, yet they play at a high level. These two categories are based on Elo rating points for players who have, respectively, greater than and less than 2000 points. Each pair of players in the sample of 206 chess players played the following three games in random order: Centipede game, race to 100 in the 1–9 treatment and race to 100 in the 1–10 treatment.¹⁶

The results are as follows. Only 3.9% of the players respect the strict backward induction prescription to play D at the first node. In 45% of the cases, the play reaches the penultimate node (5th node) of the game. Conditional on the play having reached node 5, 37% of the players play A despite this being a dominated action. Two candidates for an explanation of such behavior are cognitive limitations and social preferences.

Table 12.3 shows the proportion of players who chose D at each of the six nodes, conditional on play having reached these nodes. For instance, conditional on play having reached node 4, across all chess players, 35.2% played D. Recall that Palacios-Huerta and Volij (2008)

¹³ Professional chess players were recruited from two international chess tournaments in 2008. Particular attention was focused on recruiting high ranked players.

¹⁴ This is easiest to see in the 1–9 treatment. If the second mover uses backward induction correctly, he will always win the game. For any number suggested by the first mover, the second mover needs to suggest a number that ends in a multiple of 10. So the following sequence will guarantee a win: 10, 20, ..., 90, 100.

¹⁵ For other experimental results on the race game, see Dufwenberg et al. (2010) and Gneezy et al. (2010). These papers also throw light on bounded rationality and learning issues in games.

¹⁶ Earnings were paid in cash, immediately, and privately, following all three games.

< 2000	0.042 (24)	0.103 (29)	0.286 (21)	0.526 (19)	0.700 (10)	0.667 (6)

claim that when chess Grandmasters play other chess players, they play D at the first node in 100% of the cases. However, in Table 12.3 not one of the 16 Grandmasters played D at the first node.

Only 11.11% of the Grandmasters played D at the second node and only 6.7% of the Grandmasters played D at the third node when play reached the third node. A very similar pattern holds for the International Masters who are in the next tier of the rankings. Overall, the results for this dataset decisively debunk the view that highly ranked chess players play the backward induction outcome in centipede games.

In the race to 100 in the 1–9 treatment, 60% of the players play the backward induction outcome. However, players do much worse in the 1–10 treatment; only 12.6% are able to play in accordance with strict backward induction. Players who play best the backward induction outcome in the relatively more difficult race to 100 in the 1–10 treatment are particularly poor at playing the backward induction outcome in the centipede game. Their performance in the centipede game was nearly identical to those who demonstrated little evidence of playing backward induction in the race to 100 in the 1–10 treatment.

Several explanations for the experimental results in the centipede game have been proposed. McKelvey and Palfrey (1992) consider the effect of a slight degree of incomplete information, namely a small probability that any player is altruistic rather than concerned only with own material reward, as in Kreps and Wilson (1982) and Milgrom and Roberts (1982). Altruistic players always play A in the centipede game. If rational players believe that some of their opponents are altruistic, this creates an incentive for them to play A for a while. However, the presence of altruistic players among the subjects in experiments was found to be relatively small (about 7% of the sample). Zauner (1999) provides yet another explanation in which players play with some error. In particular, the individual payoffs are additively and independently perturbed. Assuming a shrinking error rate explains some of the experimental results. Fey et al. (1996) use the *quantal response equilibrium* (QRE) model to explain the increased probabilities of playing D, as one approaches the end node. The *cognitive hierarchy* (CH) model can explain the difference

between the two-player and three-player games.¹⁷ A range of learning models has also been used to explain the results of the centipede game.¹⁸ These models are discussed later.

12.2.4 Evidence from mechanism design problems that are dominance solvable

In this section, we describe two simple mechanisms that rely on iterated deletion of dominated strategies in simultaneous and sequential play. These mechanisms are due to Abreu and Matsushima (1992) and Glazer and Perry (1996). We then examine empirical tests of these mechanisms due to Sefton and Yavas (1996) and Katok et al. (2002). Consider the following two-player game from Glazer and Rosenthal (1992) in which each player has two possible strategies, A and B.

	A	B
A	100, 100	0, 0
B	0, 0	200, 200

The game has two Nash equilibria (A, A) and (B, B). The equilibrium (B, B) is payoff dominant and risk-dominant, so it would seem to be salient.¹⁹ Suppose, that a social planner wishes to implement the Pareto-inferior outcome (A, A) instead. One possible story behind the choice of the social planner is the following. The row player is a shopping mall and the column player is a representative consumer. Strategies A and B are simply locations, say, the suburbs and the city center, respectively. Consumers and shopping malls would like to locate in the city center because of its auxiliary benefits.

A social planner might, however, be worried about the congestion created from such a move. From a social point of view, therefore, it may be preferable for the shopping mall to be located in the suburbs (choice A). The choice (A, A) gives lower private payoffs, of a 100 each, but it gives higher social payoffs that are internalized by the social planner but not by the players (hence, not shown in the payoff matrix). Abreu and Matsushima (1992) and Glazer and Perry (1996) propose two alternative mechanisms to implement the social planner's choice.

The idea in both mechanisms is to play the strategic-form stage game shown above over T time periods, and introduce a small fine f , if action B is played. Let us denote the row and column players, respectively, by players 1 and 2. Let x_{1t} and x_{2t} be, respectively, the strategy sets of the row and the column players at time $1 \leq t \leq T$. We focus on strictly dominated strategies, which, by definition, are pure strategies, so each player makes a binary choice (A or B). Denote the choices of A and B, respectively, by 0 and 1 so that $x_{1t} = \{0, 1\}$ and $x_{2t} = \{0, 1\}$.

In the stage game, shown above, each player gets a strictly positive payoff only if the strategies of both players match.²⁰ If $x_{1t} = x_{2t} = 0$, then the payoff at time $t \in \{1, 2, \dots, T\}$ to each player is $\frac{100}{T}$, and if $x_{1t} = x_{2t} = 1$, then each gets a payoff of $\frac{200}{T}$. If $x_{1t} \neq x_{2t}$, then each player gets a payoff of zero. Thus, the aggregate payoff to any player, $j = 1, 2$, over the T time periods is given by

¹⁷ See also Kawagoe and Takizawa (2012) who formalize this idea more fully.

¹⁸ These include reinforcement models of learning (Nagel and Tang, 1988), adaptive models of learning (Rapoport et al., 2003), and evolutionary models of learning (Ponti, 2000).

¹⁹ This is confirmed in pilot experiments of Sefton and Yavas (1996), where 92% choose B in a game with similar payoffs. See the game theory appendix for the definition of payoff dominance and risk dominance.

²⁰ The justification is that perhaps a coordinated effort is required for the project to be successful, as in the example of the shopping mall and the consumers, above

$$\pi_j = \sum_{t=1}^T \left[\left(x_{1t}x_{2t} \frac{200}{T} + (1 - x_{1t})(1 - x_{2t}) \frac{100}{T} \right) - x_{jt}f\phi_{jt} \right]. \quad (12.1)$$

The first term inside the square brackets is the payoff at any time t , as described above. The second term is the fine paid at time t . The variable ϕ_{jt} in (12.1) takes two possible values, 0 or 1. When $\phi_{jt} = 1$, the fine term is switched on, so that a fine is incurred from a particular choice of action (to be specified) and when $\phi_{jt} = 0$, it is switched off, so that no fine is incurred by any choice of action. We explain the term ϕ_{jt} in more detail below, following a fuller description of the two mechanisms. The main difference between the two mechanisms is that in the Abreu–Matsushima mechanism, the entire profile of actions by the two players is chosen simultaneously at the beginning, while in the Glazer–Perry mechanism, actions are chosen in sequence.

THE ABREU–MATSUSHIMA MECHANISM

Each player simultaneously submits the sequence of choices $\{x_{1t}\}_{t=1}^T$ and $\{x_{2t}\}_{t=1}^T$ where $1 \leq t \leq T$. The first player to play B according to the submitted choice pays a one-off fine, f . If both players make a choice of B in the same period, they both pay the fine. For the Abreu–Matsushima mechanism, ϕ_{jt} in (12.1) can be defined recursively. It is switched on till time t when someone first plays B (i.e., $x_{jt} = 1$) and pays the fine, but for all subsequent periods, i.e., $t + 1, \dots, T$, it is switched off.

Example 12.1 Suppose that $T = 10$ and $f = 30$. The strategies for the two players are given as follows. For player 1, $x_{1t} = B$ for all $1 \leq t \leq 10$. For player 2, $x_{21} = A$ and $x_{2t} = B$ for all $2 \leq t \leq 10$. The choices of both players are different for $t = 1$ but match for time periods $2 \leq t \leq 10$. Thus, the payoff in the first term in the square brackets in (12.1) for each player is $9 \times \frac{200}{10} = 180$. Since player 1 is the first player to play B, he also pays a fine $f = 30$, thus, the respective payoffs of player 1 and 2 are 150 and 180.

We now state the main result under the Abreu–Matsushima mechanism.

Proposition 12.1 Suppose that $f > \frac{200}{T}$ and players have common knowledge of rationality. The unique strategies of both players that survive iterated deletion of strictly dominated strategies are $x_{1t}^* = x_{2t}^* = 0$ for all $1 \leq t \leq T$.

Proof: Fix any strategy profile of player 2, $\{x_{2t}\}_{t=1}^T$. We first show that for player 1, the strategy profile $y_{11} = (0, x_{12}, \dots, x_{1T})$ strictly dominates $y'_{11} = (1, x_{12}, \dots, x_{1T})$. Since the actions under y_{11} and y'_{11} are identical for $2 \leq t \leq T$, the continuation payoffs from the two strategies, following the first period choices, are also identical. Thus, we simply need to show that the current payoff at $t = 1$ from playing $x_{11} = 0$ (choice A) strictly dominates that from playing $x_{11} = 1$ (choice B).

There are two possibilities, depending on the choice of the first period action of player 2. (a) $x_{21} = 1$. In this case, the current payoff to player 1 from playing $x_{11} = 0$ is 0, while the payoff from playing $x_{11} = 1$ is $\frac{200}{T} - f < 0$. (b) $x_{21} = 0$. In this case, the current payoff to player 1 from playing $x_{11} = 0$ is $\frac{100}{T} > 0$, while the payoff from playing $x_{11} = 1$ is $-f < 0$. Thus, y_{11} strictly dominates y'_{11} and the play of $x_{11} = 0$ is a best response of player 1 in period 1 to any strategy of the opponent.

A similar calculation also holds for player 2. Due to common knowledge of rationality, player 1 believes, correctly, that $x_{21} = 0$. Thus, the strategies $x_{11} = 1$ and $x_{21} = 1$ are deleted at the first step of the iterated deletion process and the play of $x_{11}^* = 0$ and $x_{21}^* = 0$ is a best response of each player in period 1 to any strategy of the opponent.

In the next stage, we consider the decisions from time $t = 2$ onwards. Hold fixed the strategy of player 2 at $\{x_{2t}\}_{t=2}^T$ and consider two strategy profiles for player 1: $y_{12} = (0, 0, x_{13}, \dots, x_{1T})$ and $y'_{12} = (0, 1, x_{13}, \dots, x_{1T})$. Proceeding as above, a simple calculation shows that y_{12} strictly dominates y'_{12} . Using common knowledge of rationality we can conclude that the strategies $x_{12} = 1$ and $x_{22} = 1$ are deleted at the second step of the iterated deletion process. Thus, the play of $x_{12}^* = 0$ and $x_{22}^* = 0$ is a best response of each player in period 2 to any strategy of the opponent.

Continue with this recursive process of iterated deletion of strictly dominated strategies to conclude that the unique outcome is $x_{1t}^* = x_{2t}^* = 0$ for all $1 \leq t \leq T$. ■

THE GLAZER-PERRY MECHANISM

Unlike the Abreu–Matsushima mechanism, in the Glazer–Perry mechanism, players move sequentially. In each period, player 1 makes his choice x_{1t} , which is observed by player 2 who then makes his choice x_{2t} . Thus, the sequence of choices over the T time periods is given by: $x_{11} \rightarrow x_{21}; x_{12} \rightarrow x_{22}; \dots; x_{1T} \rightarrow x_{2T}$. The player who is the “last” to choose B incurs a fine, f ; the sequential nature of moves ensures that only one player incurs the fine.

Example 12.2 Suppose that $T = 10$ and $f = 30$. The strategies for the two players are given as follows. For player 1, $x_{1t} = B$ for all $1 \leq t \leq 10$. For player 2, for all $1 \leq t \leq 9$ and $x_{210} = A$. The choices of both players match for time periods $1 \leq t \leq 9$ and are different for $t = 10$. Thus, the payoff in the first term in the square brackets in (12.1) for each player is $9 \times \frac{200}{10} = 180$. Since player 1 is the last player to play B he also pays a fine $f = 30$, thus, the respective payoffs of player 1 and 2 are 150 and 180.

The main result is contained in the next proposition.

Proposition 12.2 Suppose that $f > \frac{200}{T}$. The unique backward induction outcome in the Glazer–Perry mechanism is $x_{1t}^* = x_{2t}^* = 0$ for all $1 \leq t \leq T$.

Proof: Fix any strategy profile of player 1, $\{x_{1t}\}_{t=1}^T$. We first show that for player 2, the strategy profile $y_{2T} = (x_{21}, x_{22}, \dots, x_{2T-1}, 0)$ strictly dominates $y'_{2T} = (x_{21}, x_{22}, \dots, x_{2T-1}, 1)$. In the two strategies, y_{2T}, y'_{2T} , the choices are identical for the first $T - 1$ time periods. Thus, the choice between the two strategies depends only on the payoff arising in period T . Depending on the choice of player 1 in period T , x_{1T} , there are two possibilities. (a) Suppose that player 1 plays B, i.e., $x_{1T} = 1$. The payoff to player 2 from a choice of A, i.e., $x_{2T} = 0$, is 0, while the payoff from a choice of B, i.e., $x_{2T} = 1$, is $\frac{200}{10} - f < 0$ (because player 2 is the last player to choose B). (b) Suppose that $x_{1T} = 0$. The payoff to player 2 from a choice of $x_{2T} = 0$ is $\frac{200}{10}$, while the payoff from $x_{2T} = 1$ is $-f < 0$. In conjunction, (a) and (b) imply that y_{2T} strictly dominates y'_{2T} , so the best response of player 2 in period T to any choice of player 1 is $x_{2T}^* = 0$. Analogously, $x_{1T}^* = 0$.

Let us now consider time period $T - 1$. Fix the strategy of player 1 to be $(x_{11}, x_{12}, \dots, x_{1T-1}, 0)$. Consider two possible strategy profiles for player 2, $y_{2T-1} = (x_{21}, x_{22}, \dots, 0, 0)$ and $y'_{2T-1} = (x_{21}, x_{22}, \dots, 1, 0)$. As above, it is simple to show that the profile y_{2T-1} strictly dominates y'_{2T-1} . A similar calculation can be made for player 1 to show that the optimal choices at time $T - 1$ are $x_{1T-1}^* = x_{2T-1}^* = 0$.

Continue to carry out the backward induction process up to time $t = 1$ and conclude that the unique backward induction outcome is $x_{1t}^* = x_{2t}^* = 0$ for all $1 \leq t \leq T$. ■

Katok et al. (2002) give experimental results for the case $T = 10, f = 50$, for the payoffs given above. They asked one set of students to play the Abreu–Matsushima mechanism, and another set to play the Glazer–Perry mechanism, each over 17 rounds. It was ensured that subjects are not

rematched over the different rounds. The first 3 rounds were practice rounds where no monetary payments were made. By round 4, when incentives are introduced, there was no conformity of play with the prediction of the Abreu–Matsushima mechanism and only 7% of the play conformed with the prediction of the Glazer–Perry mechanism. There appears to be some evidence of learning over time and by round 17, the respective conformity with the predictions of the two mechanisms was 18% and 30%, which, nevertheless is quite low.

Sefton and Yavas (1996) tested consistency of play with the Abreu–Matsushima mechanism. In their experiments, the stage-game payoffs to the two players from (A,A) and (B,B) are, respectively, 480 each and 240 each. They tried various values of T such as $T = 4$, $T = 8$, and $T = 12$ and chose $f = 90$. For the three treatments $T = 4$, $T = 8$, and $T = 12$, $\frac{480}{T}$ equals, respectively, 120, 60, 40. With these payoffs, it can be shown that if $f > 480/T$, then the unique rationalizable outcome, determined by iteratively deleting dominated strategies, is for both players to play B ($x_{1t}^* = x_{2t}^* = 1$). The condition $f > 480/T$ is violated for the case $T = 4$ but it is satisfied for the other two cases, $T = 8$, $T = 12$. Thus, if individuals are fully rational, we should observe all-B choices in the cases $T = 8$ and $T = 12$ and all-A choices in the case $T = 4$ (paying the fine and playing B is profitable in this case).

The experimental findings are just the reverse of this prediction over the 14 periods of the experiment; see Figure 12.7. The percentage of all-B sequences increases gradually over the 14 rounds in the case $T = 4$ (the curve labeled 4T). On the other hand, for the cases $T = 8$, and $T = 12$ (curves labeled 8T and 12T, respectively), the percentage of all-A sequences declines steadily from a low initial level to a near-negligible level. What accounts for these results? For the two cases, $T = 8$ and $T = 12$, a distinct possibility is that subjects are trying to get the higher payoffs from coordinating on the all-B strategy profile as quickly as possible. They are, however, also keen to avoid the fine and so try not to be the first to play B. Irrespective of T , subjects switch to B in the third or fourth rounds and then continue to play B, thereafter.

These results appear to create a degree of skepticism about the possibility of implementation in even more complex mechanisms. Clearly, more empirical research is needed in this area.

Figure 12.7 Percentage of all-B play in various rounds.

12.3 Mixed strategy Nash equilibria

Nash's (1950) fundamental result in game theory showed that every finite strategic form game has a *mixed strategy equilibrium* (MSE). The assumption that the players play mixed strategies is central in economic models, hence, it is important to test if people do so.

In an MSE, players must randomize in such a manner that their opponents are exactly indifferent between their pure strategies. It has been troublesome for classical game theory to justify why players should do so. Binmore et al. (2001) work on another interpretation of the mixed strategy equilibrium. In particular, they stress the role of *equilibrium in beliefs*. The *equilibrium in beliefs interpretation of mixed strategies* argues that individuals belong to different populations of players, and within each population, players only play identical pure strategies. Furthermore, the fraction of players in any population that plays a particular pure strategy, is identical to the probability with which that pure strategy is played in an MSE.²¹ In contrast to this interpretation, the evidence reviewed below shows that players do play mixed strategies, but typically not in the proportions that are predicted by an MSE. But this is not the only violation of an MSE; serial dependence in strategies over time is another violation. Yet, at the aggregate level, there is better conformity with an MSE as compared to individual-level data.

Harsanyi (1973) considered the limiting behavior in a set of games that have pure strategy equilibria, but the payoffs are perturbed. A mixed strategy equilibrium is the limiting strategy profile in this class of simple "purified" games. Yet, these results do not hold for a range of games that economists are interested in, such as repeated games, and principal-agent games. Hence this justification for the use of a mixed strategy equilibrium is quite limited in scope. For a detailed discussion of these issues, the interested reader can consult Gintis (2009, Chapter 6).

12.3.1 Do people play mixed strategy equilibria in games within a general context?

Much of the work on testing MSE has relied on finite (typically two-player) zero-sum games in which players have finite strategies (typically two to five strategies). Furthermore, the games considered have a unique MSE in order to abstract from issues of coordination. In these games, the *minimax* and *maximin* outcomes are identical and also coincide with the MSE.²²

The modern work on testing for MSE began with the paper by O'Neill (1987).²³ O'Neill's (1987) work illustrates many of the results found in subsequent research and, hence, there is merit in exploring this work in some detail.

O'Neill (1987) considered the zero-sum game shown in Figure 12.8. Each player has four possible strategies: Ace, 2, 3, and Joker. Players simultaneously choose their strategies. The payoffs are either +5 or -5 cents. The payoffs corresponding to the strategy profiles for which the row player is the winner are shown in a darker background. In the unique MSE, each player plays the strategies, Ace, 2, and 3 with probabilities 0.2 each and the strategy Joker with a probability 0.4. The

²¹ This is reminiscent of the polymorphic equilibria in evolutionary games; see Chapter 14 for the details.

²² Important work in this regard was done by Von Neumann (1928). See also the Appendix on game theory.

²³ For a review of some earlier work on testing for MSE in the 1960s, see Camerer (2003a, pp. 121–5). In these studies, subjects typically played against computerized opponents and had little idea of what the computerized opponent was trying to achieve. There are also concerns about the subjects having been misled (perhaps inadvertently) about the play of the computerized opponent. Subjects also had inadequate incentives to play. Nevertheless, the aggregate frequency of play in some of these studies was close to the mixed strategy equilibrium for the game.

	Ace	2	3	Joker
Ace	-5, 5	5, -5	5, -5	-5, 5

game is played repeatedly by 25 pairs of subjects for 105 periods for a total of 2625 joint moves. The results on aggregate play are shown in Table 12.4. Each cell in Table 12.4 shows the actual frequency of choices and below it, in brackets, the predicted frequency of the joint play of the strategies by both players in the MSE. The main features of the results are as follows.

1. The MSE implies that each player, in each round, draws a strategy from a multinomial probability distribution with parameters 0.2, 0.2, 0.2, and 0.4. The observed frequencies of *aggregate* play appear very close to the predicted MSE for all strategy profiles. Furthermore, the marginal frequencies of the play of each strategy for the row and the column players (last column and last row in Table 12.4) also seem to bear close proximity to the predicted frequencies.
2. Adding together the predicted MSE frequencies in cases where the row player wins (the shaded cells in Figure 12.8), we get a figure of 0.40. Hence, over a large number of rounds of play of the game, if players follow MSE, the row player should win 40% of the times. The aggregate win frequency of the row player was found to be 0.410.

These results, on the face of it, constitute a stunning validation of MSE predictions, and were interpreted as such by O'Neill (1987). Furthermore, these results, as we shall see, have been replicated for many similar zero-sum games.

In light of this, it is worth considering in some detail, the reappraisal of O'Neill (1987) by Brown and Rosenthal (1990) who interpreted O'Neill's (1987) findings as an unequivocal rejection of the MSE prediction.

1. *Overall winning percentages:* Suppose that the Joker card has greater *salience* relative to the numbered cards, which have, say, equal salience. Suppose that the row player picks out the Joker card with probability x and the three remaining cards with equal probability $\frac{1-x}{3}$. Likewise suppose that the column player picks the Joker card with probability y and the three remaining cards with equal probability $\frac{1-y}{3}$. Furthermore, to capture the salience of the Joker card, suppose that $x, y \in (0.2, 0.8)$. Then the probability that a row player wins in O'Neill's game is 38.3%, which is very close to the MSE prediction. Brown and Rosenthal (1990, p. 1069) write: "In short, the surface that relates winning percentages to independent strategy combinations is quite flat around the minimax strategy. As a result, tests of the minimax model that are based on observed winning percentages are unlikely to reject the minimax model, even when any member of a wide class of alternative models may in fact have generated the data. In statistical terminology, tests based on observed winning percentages for this game lack power."
2. *Frequencies of play of alternative strategy profiles:* One can just as easily generate predicted frequencies from non-minimax play that are actually quite close to the actual frequencies. For instance, suppose that players first try to convince opponents that their choices are purely random. Once the opponents are convinced of this, the players then play a best response to these beliefs of the opponents. Even if players played randomly 80% of the times and a best response only 20% of the times, it can be shown that the resulting frequencies are quite close to minimax. Like the first objection, for the game in Figure 12.8, tests based on matching observed frequencies of play of different strategy profiles have insufficient power to distinguish minimax from non-minimax play.
3. *Statistical closeness of choices to the predictions:* To the naked eye, the observed frequencies seem to have a good match with the predicted minimax frequencies in Table 12.4, but are they close enough in a statistical sense? For all the 16 cells corresponding to the 4×4 payoff matrix, a chi-square test rejects the minimax model at any level of significance. Thus, the observed frequencies could not have been statistically generated by minimax play.
4. *Individual choices:* It is important to note that the predictions of classical game theory are about the choice of strategies for individual players (not aggregate data). The prediction is that individual players will play their part of the MSE. It is easy to reject the hypothesis that individual play conforms to the minimax hypothesis. The chi-square test for the conformity of the choice of strategies of individuals with the minimax outcome gives a test statistic of 348.25 at 150 degrees of freedom. If the strategy choice of individuals was generated by minimax, then the probability of generating this value of the chi-square statistic is zero to at least 15 decimal places.
5. *Homogeneous choices:* One can reject the hypothesis that the data for all pairs of play came from the same multinomial distribution. There is far too much variation in choices of individual cards across all pairs of players.
6. *Effect of past choices on current choices:* When the game in Figure 12.8 is played over repeated rounds, players should draw on a multinomial distribution with parameters 0.2, 0.2, 0.2, and 0.4. Thus, across rounds, the iid (independently and identically distributed) assumption should hold. To test this, given the limited sample sizes, they look at the choice of the Joker card across time. If classical game theory is correct, then in any round, for any player, the choice of the Joker card should be independent of one's own and the opponent's previous choices of the Joker card. Brown and Rosenthal (1990) run logit regressions in which the dependent variable took a value of 1 if a choice of the Joker card was made and

0 otherwise. Among the independent variables are lagged values of the choice of the Joker card for each player.

The explanatory variables turn out to be jointly significant in explaining Joker choices by players. For 19 out of 25 pairs of players, the Joker choice can be statistically determined, at the 5% level, by the independent variables, for at least one player in the pair. The main reason was that players' past choices of the Joker card significantly determined their current choice of the Joker card. Thus, one can reject the hypothesis that the players' choices are uncorrelated with their own past choices.

The autocorrelation in the choices of players could arise either because (1) they are not using minimax, or (2) they are using minimax but are not able to generate iid draws from a underlying multinomial distribution. Brown and Rosenthal (1990) are not able to distinguish between the two explanations. Subsequent research, some of which we review below, has tried to address this question.

The past choices of the Joker card by the opponent also influence the current Joker choice of a player. If players believe that their opponents will play minimax, then this cannot happen. It is plausible that players perceive that opponents will play autocorrelated choices, so they attempt to benefit from them.

7. *Learning*: To examine issues of learning, one could examine the behavior of subjects in the experiment in the final 50 rounds after they had already played 70 rounds. There was no noticeable tendency for the subjects to play minimax in the final rounds.

Slonim et al. (2003) ask if the rejection of minimax is based on the specific features of O'Neill's (1987) game. They consider a range of two-player zero-sum games and sample randomly from these games. Like O'Neill, they find that strategies of players across successive rounds are interdependent. Unlike O'Neill, however, they find that the source of the problem is not too much randomization of choice, but too little. Slonim et al. (2003) find that evidence in support of MSE is more likely to be found in experiments when each of the pure strategies is played with an identical probability (equiprobable play).

Binmore et al. (2001) consider eight games (including the game in Figure 12.8) and look at the evolution of play in such games when they are played a sufficiently large number of times.²⁴ They find that there is temporal dependence of actions on past actions. However, they argue that subjects can only learn to play an MSE through a process of learning, and temporal dependence is evidence of learning. They interpret their results as convergence of observed "aggregate frequencies" to the MSE given sufficient learning opportunities (50–75 practice rounds followed by 150 rounds of the real game).

Mookherjee and Sopher (1994, 1997) consider four constant-sum games in which players could either win or lose, denoted respectively by W and $-W$. A win, W , means either a payment of Rs. 5 (in games 1 and 2), or a payment of Rs. 10 (in games 3 and 4). A loss, $-W$, denotes a payment of zero. Figure 12.9 shows the two 4×4 games, 1 and 3. In these games, each player has four possible strategies labeled 1 through 4. A payoff of pW , $0 < p < 1$ (as in the bottom right hand corner), denotes a lottery in which the player wins with probability p and loses with probability $1 - p$. In the mixed strategy equilibrium for the 4×4 game, players play their strategies, 1 through 4, with respective probabilities $\frac{3}{8}, \frac{1}{4}, \frac{3}{8}, 0$.

The 6×6 payoff matrix for games 2 and 4 is shown in Figure 12.10. Each player now has six strategies labeled 1 through 6. The 4×4 and the 6×6 games are identical because strategy 3 for

²⁴ In total, they ran 13 experiments with 12 subjects each of whom played 2 practice and 5 real games.

the row and column players in the 4×4 game is identical to the joint play of strategies 3, 4, and 5 for the row and column players in the 6×6 game. We indicate this by shading the appropriate region in Figure 12.10. The game was played for 40 periods by 10 pairs of subjects. The games were played repeatedly because the authors were also interested in exploring the learning implications for minimax play.

In each of the two games in Figures 12.9 and 12.10, strategy 2 is dominated by the last strategy (strategy 4 in the 4×4 game and strategy 6 in the 6×6 game). If we eliminate the dominated strategy, 2, the game reduces to the one in Rapoport and Boebel (1992). The unique, symmetric, mixed strategy equilibrium of the 6×6 game is for each player to play the six strategies 1 through 6 with the respective probabilities $\frac{3}{8}, \frac{1}{4}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, 0$. Notice that the equilibrium is symmetric but the game is not.

The percentage choices of strategies in the four games are given in Table 12.5. The prediction of MSE is also shown in brackets in the row labeled Minimax. The results can be summarized as follows:

1. The actual frequencies of play are substantially different from the minimax predictions for all games (except for the column players in Game 4). This contrasts with the results of O'Neill (1987). As in Brown and Rosenthal (1990), using a chi-square test, Mookherjee and Sopher (1994) are able to reject the null hypothesis of equality between the actual and MSE predicted frequencies. They conclude (p. 109) that: “The rejection of the minimax theory at the aggregate level, and not just at the level of individual decision making, implies that it cannot even be treated as an acceptable as if theory.”
2. While minimax is rejected for all games, it does better than equiprobable play (i.e., playing all strategies with identical probabilities). This is not surprising because there is a clear dominated strategy in each game that is easy to spot.
3. As in Brown and Rosenthal (1990), minimax is also rejected on the grounds that players' strategies in various rounds are not independently and identically distributed.

Table 12.5 Percentage of subjects choosing various strategies in the 4×4 and 6×6 games.

Player	Choice 1	Choice 2	Choice 3	Choice 4	Choice 5	Choice 6
Game 1

4. Over time, there is no tendency of play to converge to minimax. However, subjects learn to avoid the dominated action as they play successive rounds of the game. As in some of the findings for coordination games, the choice of strategies during the early stages of the game established important precedents on the divergence between minimax and actual frequencies. This divergence tended to persist over successive rounds.

Rapoport and Boebel (1992) use the same experimental design in the 4×4 zero-sum game, as in O'Neill (1987), but extend it to a 5×5 zero-sum game in which each player has five actions. They reject the minimax solution (and so also the MSE) at the level of the individual and in the aggregate. This is not surprising as these games involve even greater cognitive effort on the part of subjects in experiments.

Budescu and Rapoport (1994) consider the two-player, 3×3 matching pennies game shown in Figure 12.11. Players simultaneously choose between three actions, 1, 2, and 3. In the event that all three actions match, the column player pays two pennies to the row player, otherwise the row player pays a penny to the column player. In the unique MSE, each player plays his strategies with an identical probability of one third.

There are two treatments. In the *dyadic treatment* (D), 60 subjects, who are paired randomly, played 200 rounds of the game in Figure 12.11. The games were played face to face, but communication or coordination was forbidden. In the random treatment (R), subjects were placed in a decision theoretic environment. They were given a dice with only the numbers 1, 2, and 3 on it. Each number was printed on two faces of the dice (so the numbers 4, 5, and 6 were absent). The probability of each number coming up on any single throw of the dice is one third, which is identical to the MSE that subjects are theoretically supposed to play in treatment D. Subjects in

	1	2	3
1	2, -2	-1, 1	-1, 1
2	-1, 1	2, -2	-1, 1
3	-1, 1	-1, 1	2, -2

treatment D were asked to simulate the outcomes on the dice when it is rolled 200 times in an unbiased manner. For any period, when the strategies match, the second player gave two pennies to the first player, otherwise the first player gave a penny to the second player. Under perfect randomization, we would obtain statistically identical outcomes in the two treatments, D and R.

It turns out that the actual choices made by players are influenced not only by their own past choices over the last two periods, but also by the last two choices of their opponent. A logit regression is run in which the independent variables are related to several variables, such as the past play of a player and the opponent, and past success of a particular strategy combination. A statistical test of the hypothesis that all coefficients on all independent variables are zero (which is required by minimax) is rejected for 51.7% of the subjects in treatment D. Thus, players' choices are not statistically independent over time. In treatment R, on the other hand, this figure rises to 73.3%. Thus, as in Rapoport and Budescu (1992) and Budescu and Rapoport (1994), players randomize better in game theoretic environments, relative to decision theoretic environments. One potential reason for this finding (relatively greater temporal dependence in decision theoretic tasks) is that the game theoretic task involves relatively greater use of limited cognitive facilities. Hence, subjects do not recall very well their own and the opponent's past actions, which paradoxically helps them to randomize better.

McCabe et al. (2000) test for the play of an MSE in a three-player matching pennies game. Each player is assigned a neighbor and can choose either heads or tails in the toss of a coin. Payoffs depend on a match with the neighbor's choice. The authors distinguish between two conditions. A *limited information condition* in which players are not given information about the entire history of play, and a *full information condition* in which they are given this information. In the full information condition, players are able to observe the actions of the other player at the end of each round. Hence, if they wished to, they could have all the information that they would need to apply sophisticated Bayesian reasoning. Evidence rejecting MSE is found in the limited information condition, but in the full information condition, on average, play comes close to the predictions of Nash equilibrium in some respects. However, the authors reject the hypothesis that players use sophisticated Bayesian learning to reach the MSE.

Shachat and Swarthout (2008) consider two games shown in Figure 12.12. The first (on the left) is a zero-sum symmetric matching pennies game, and the second game, on the right, is named as the *unprofitable game*.²⁵ The unique Nash equilibrium of the matching pennies game is for the row and the column players to play Left with probability $2/3$. Their respective equilibrium expected payoffs are respectively $2/3$ and $-2/3$. The unprofitable game, unlike most of the other games used to test the minimax hypothesis is not zero-sum, hence, the minimax and Nash solutions do not necessarily coincide. The minimax solution in the unprofitable game is for each player to play Right. The unique Nash equilibrium is for each player to use the equiprobable strat-

²⁵ The matching pennies game is taken from Rosenthal et al. (2003), while the unprofitable game was introduced by Shachat and Swarthout (2004).

	Left	Right
Left	1, -1	0, 0
Right	0, 0	2, -2

	Left	Right
Left	2, 0	0, 1
Right	1, 2	1, 1

egy, i.e., play both strategies with probability one half. Interestingly, in the unprofitable game, both minimax and MSE give an identical expected payoff of 1. One may conjecture that players should not play MSE in the unprofitable game because by playing Right they can guarantee a payoff of 1, while MSE offers no improvement in the expected payoff yet it is more risky (Aumann, 1985).

The two games were played by 60 undergraduate students, evenly divided between the two games, for 200 periods. For the first 23 repetitions of the game, row and column players played against each other anonymously, entering their choices through a computer terminal. For the remaining periods, unknown to the subjects, their opponents were switched from humans to computer machines that played the MSE strategies. The results are as follows.

1. Statistically, z-tests can be used to reject the equality of the proportion of players who play Left with the predicted proportions (0.67 for the matching pennies and 0.5 for the unprofitable game). There is strong rejection of MSE in each case. A chi-square test rejects the null hypothesis that subjects use the same mixed strategy. There is substantial heterogeneity of choices across the subjects.
2. When statistical tests are conducted at the level of individual subjects, MSE is rejected for 41 out of 60 subjects. Serial independence of play is statistically rejected for 26 out of 60 subjects.

In a novel study, Okano (2013) asks if teams of two individuals are more likely to conform to the predictions of an MSE. He considers two games in which teams of two players, and individual players, play against each other. The two games are the game in O'Neill (see Figure 12.8) and the pursuer–evader game (see Figure 12.14); each game has a unique MSE. When data is aggregated across all players, the behavior of teams and individuals is similar and support for the play of MSE is not statistically significant. However, when disaggregated data is examined at the level of the team and the individual, the behavior of teams is in better accord with the predictions of MSE, as compared to that of individuals. This is an interesting result because the disaggregated data has typically provided lesser support for the predictions of MSE. However, the problem of serial correlation of choices remains, although, perhaps surprisingly, the serial correlation is lower for individuals.

12.3.2 *Do people play MSE in games within an economic context?*

The games in Section 12.3.1 were mostly abstract. In this section, we consider games that have an economic context but are nevertheless played with subjects in experiments. The main finding is that when data are examined at the aggregate level, there is mixed support for the MSE, but at the individual level, MSE fails.

Collins and Sherstyuk (2000) consider a model of spatial competition with three identical firms. Consumers are distributed uniformly over an interval of length $[0, 1]$ and they are simply

Figure 12.13 Distribution of locations for pooled data.

Source: "Spatial competition with three firms: an experimental study," Collins, Richard and Sherstyuk, Kalerina, *Economic Inquiry*, 38: 73–94. Copyright © 2007, John Wiley & Sons.

interested in buying from the nearest firm (say, to minimize transportation costs). In the classic two-firm model in Hotelling (1929), the Nash equilibrium in the choice of location for both firms is to locate identically in the middle, at location 0.5. However, in the case of three firms, it is not an equilibrium for all firms to locate in the middle. If they did so, then each would get one third of the market. However, any of the firms can now move infinitesimally in either direction to capture half the market. The equilibrium in the case of three firms is derived in Shaked (1982). We state his result without proof.

Proposition 12.3 (Shaked, 1982): *In a model of spatial competition with three firms and consumers distributed uniformly over the unit interval, each firm chooses a mixed strategy in which it randomizes uniformly over the set of locations in the interval $[0.25, 0.75]$. It is never optimal for any firm to choose a location outside this interval.*

In the experiments implemented in Collins and Sherstyuk (2000), the interval $[0, 1]$ was extended to $[0, 100]$, where the distance is in units of kilometers. A total of 9–12 subjects in the experiments participated in each of the four experimental sessions. Each session lasted for 35 periods, preceded by three practice rounds. Subjects played the role of firms in groups of threes, taking as given the following information. A single consumer is located at each integer location in $[0, 100]$. Each consumer had an inelastic demand of 10 units/period and chooses to buy from the closest firm. If two firms are located equidistant from the consumer, then the consumer buys 5 units each from them (provided that the third firm is not located any nearer, in which case it would buy from the third firm). There was random rematching of players from round to round. In any period, the three subjects participating in the experiment, simultaneously choose their location. The pooled results are shown in Figure 12.13.

Table 12.6 Results for the symmetric condition.

Investment	Empirical distribution			Equilibrium prediction

For the pooled data, 80% of the choices of subjects are within the interval $[0.25, 0.75]$. The aggregate distribution of choices is bimodal with peaks at 40 and 70. Hence, the prediction of the relevant theory that the distribution should be uniform over $[0.25, 0.75]$ does not hold. This is also borne out by the statistical results. The difference between the observed and predicted frequencies is statistically significant. The hypothesis that the pooled sample is drawn from the Nash equilibrium distribution given in Proposition 12.3 is rejected by a Kolgomorov–Smirnov test at the 5% level.

The individual choice of locations of 36 out of 51 subjects are also inconsistent with the predicted Nash distribution at the 5% level. As in many other experiments that test for MSE, there is substantial variation in individual choices from the predicted choices. Insofar as most subjects locate in the interval $[0.25, 0.75]$, one might claim some partial vindication for MSE. But one has to be cautious in making such inferences. As Brown and Rosenthal (1990) showed in their critique of O'Neill's study, a range of other behavioral models might potentially rationalize the data in such a manner.

Rapoport and Amaldoss (2000) consider an investment game between two risk-neutral players in their roles as firms, indexed by $k = 1, 2$. Firms have identical, commonly known, endowments equal to e each and they simultaneously invest amounts $c_k \in \{0, 1, 2, \dots, e\}$ that are non-recoverable (think of these as R&D costs). This is known as the *symmetric condition*.²⁶ The firm that makes the higher investment wins a prize $r > e$ (say, patent rights). Conditional on the profit functions, in an MSE, players invest their endowment, e , with probability $\frac{r-e}{r}$ and choose all other investment levels smaller than e with an identical probability $\frac{1}{r}$.

²⁶ The authors consider two conditions. In condition 1, players are symmetric, so $e_1 = e_2 = e$. In condition 2, players are asymmetric and $e_1 > e_2$, so we may call firm 1 the strong player and firm 2 the weak player. Under both conditions there is an equilibrium in mixed strategies, but these equilibria differ. Here we describe results only for the symmetric case.

Given the results in simpler games in Section 12.3.1 and earlier results in Section 12.2, one may be skeptical of the ability of subjects to play the MSE. A total of 36 subjects were divided into two groups (Group 1 and Group 2) and they played the symmetric game, described above, for 80 successive periods. The results are shown in Table 12.6 for the two cases of a low reward condition ($e = 5$ and $r = 8$) and a high reward condition ($e = 5$ and $r = 20$).

At the individual level, MSE is rejected. However, at the aggregate level there is support for the MSE. The failure at the individual level is sufficient to reject the theory, because the predictions of theory are strictly at the level of the individual players.²⁷ Nevertheless, the success of MSE at the aggregate level is intriguing and deserving of further research. We summarize the findings in a bit more detail for the symmetric case and also the asymmetric case in which the endowments of the firms are different.

1. In the symmetric game, the investment strategy $c = e$ was chosen most often, which is consistent with the predictions. For the low reward game, Game L, in which $r = 8$, the actual average and predicted frequencies of play are statistically similar. For Game H, in which $r = 20$, the investment frequencies of Group 1 subjects statistically conform to the MSE predictions in the aggregate, but those of Group 2 do not. At the level of the individual data, the strategies chosen by players are not iid, contradicting the MSE prediction. A logit analysis shows that strategies depended on the opponent's play as well as the outcome in the previous period.
2. In the asymmetric game, the strategies of the strong players (whose endowment is relatively greater) support the MSE in the aggregate but the strategy choices of the weak players do not. Hence, even at the aggregate level, there is not unqualified support for MSE.²⁸

The thrust of these results, namely, support (albeit not unqualified) for the MSE at the aggregate level but rejection of MSE at the individual level continues in some of the other work that these authors are involved in.²⁹

12.3.3 *Do people play MSE when they have a mixed strategy device?*

Recall the sixth criticism made by Brown and Rosenthal (1990) in Section 12.3.1. The experimenter only observes the actual realization of actions of the two players but not the underlying probability distribution from which the actions may have been drawn. There are at least two reasons why subjects in repeated experiments may fail to produce the sequence of strategies that are consistent with an MSE. One possibility is that subjects simply do not play an MSE. The other possibility is that subjects would like to play MSE but are unable to generate iid sequences, say, on

²⁷ Unless, of course, one invokes the "equilibrium in beliefs" interpretation, which is not supported by the evidence (see above).

²⁸ Dechenaux et al. (2006) argue that the support for MSE is stronger in the Rapoport and Amaldoss (2000) model relative to the claim. Their main argument is that if alternative equilibria are taken into account, then the range of results for which the data will support the MSE prediction is wider. However, Rapoport and Amaldoss (2008) disagree.

²⁹ Rapoport and Amaldoss (2004) consider an all-pay first price auction. In such auctions, all bidders have to forfeit their bids. Think of players incurring sunk cost to win some prize or contract. The winner is rewarded but the losers are not able to recoup their investments. The findings here are similar to Rapoport and Amaldoss (2000). Furthermore, individual-level data can be reconciled using the Experience Weighted Attraction (EWA) model that we consider in Chapter 14. Amaldoss and Jain (2002) consider a model of patent race in which there is an asymmetric equilibrium in mixed strategies. The aggregate behavior is consistent with the predictions of MSE, but the individual behavior is very varied and is inconsistent with MSE. The EWA model with adaptive learning can account for the individual-level data.

account of cognitive limitations. To address this issue, recent work has provided players with a *randomizing device* in games that have a unique MSE. If there is a failure of MSE because subjects cannot generate iid draws from a multinomial distribution, then the provision of a randomizing device provides a clinching test.

A typical *randomizing device* or *mixed strategy device* works as follows.³⁰ Suppose that a player has two strategies, A and B. The player is then allocated X binary choices in total (e.g., $X = 50$ in the case of Bloomfield, 1994) to be distributed between A, B in the proportions $p = \frac{X_A}{X}$ and $1 - p = \frac{X_B}{X}$, where X_A, X_B are, respectively, the number of choices allocated to strategies A, B, and $X_A + X_B = X$. By using proportions in this manner, the subject reveals that he/she would like to play a mixed strategy in which A, B are played with respective probabilities $p, 1 - p$ in each round of play.

In each round of play, a machine then draws a temporally independent choice of strategy for the player from, say, a Bernoulli distribution with parameter p . Or possibly, a computer may be used to randomly play the mixed strategy choices of players against each other, over time. This allows a player to choose iid strategies over different rounds of play with exactly the intended probabilities. In the presence of this mixed strategy device, any observed correlation of actions over the various rounds cannot be due to an inability to generate iid play. Any departure must then be on account of players not wanting to play an MSE. Thus, the mixed strategy device allows us to observe the mixed strategy (Nash or otherwise) that is played by the players.

The point made in the previous paragraph is rather important. Some economists such as Binmore et al. (2001, p. 448) argue that “but we think it a mistake to demand that the players must actively randomize before the minimax theory can be said to be relevant to their play.” There are two issues here. First, a methodological issue about whether we need the assumptions of a model to be descriptive of the real world or whether we should just care about the predictions. Second, if we grant that the argument by Binmore et al. (2001, p. 448) is valid, then the availability of a mixed strategy device should settle the issue of whether players play minimax.

Shachat (2002) considers experimental results that arise with a mixed strategy device. He corrects for a drawback in the mixed strategy device that was implemented in the earlier work, such as that of Bloomfield (1994) and Ochs (1995).³¹ In Shachat (2002), subjects play the O'Neill (1987) game shown in Figure 12.8 but with the following differences. (i) Pairs of subjects are matched anonymously and play 60 repetitions unlike 105 in O'Neill (1987). (ii) Unlike O'Neill (1987), the subjects do not choose strategies face to face but make choices over computer terminals. (iii) The strategies are renamed as Green, Red, Brown, Purple in order to counter the possible salience of the “Joker” strategy. (iv) Stakes are increased. The row player receives 90 cents for a win and 0 cents for a loss; the corresponding figures for the column player are 60 cents and 0 cents. In the MSE, the stage game earnings of the row and the column player are identical and equal to 36 cents.

³⁰ See, for instance Bloomfield (1994), Ochs (1995), and Shachat (2002). Our usage of the term *mixed strategy device* follows Shachat (2002).

³¹ The drawback is related to the distinction between sampling with and without replacement. Suppose that we wish to implement a mixed strategy profile for a matching pennies game to be played over four rounds. Each player can place four balls in the urn. Since the MSE is to play heads and tails with probability one-half each, players should place two balls marked H and two balls marked T in the urn. A ball is now randomly drawn from the urn for each player, in each period, and the strategies marked on them are implemented in that round. However, in Ochs (1995), the balls are not replaced after each draw. Hence, the probability of drawing an H or a T is not 0.5 in each round. Thus, play in each round does not stay iid. With this caveat in the problems with their mixed strategy devices, both Bloomfield (1994) and Ochs (1995), in 2×2 games, find results similar to O'Neill (1987). Namely, that the marginal frequencies of play for the row and column players are close to the MSE predictions in the aggregate data.

Three treatments are conducted. Treatment I does not involve a mixed strategy device. Treatment II implements actions through a mixed strategy device.³² Treatment III is a disclosure treatment in which at the end of each round, the opponents' mixed strategy and the actual action choice are revealed.

For all three treatments, the results are similar to those in Table 12.4. We show the results in Table 12.7 for all three treatments, retaining the strategy names as in O'Neill (1987) for purposes of comparison. In each cell of Table 12.7, the results of Treatments I, II, and III are given in rows 1, 2, 3, while the final row gives the MSE prediction in brackets. The basic results are as follows. (i) Looking at the entries for each cell, the actual frequencies of play are close to the MSE predictions for all treatments, (ii) however, a chi-square test rejects the hypothesis that the observed frequencies are close to the MSE predictions at the 5% level, and (iii) furthermore, the data on win rates for the row players (not shown in Table 12.7) is also close to the MSE prediction of 40% as in O'Neill (1987) and Brown and Rosenthal (1990).

We now move on to other results in Shachat (2002).

³² Each experimental subject fills a *shoe* (device for holding multiple cards) of 100 cards with any composition of the four possible actions reflecting the mixed strategy that the subject wishes to play. The computer then shuffles the shoe in each round and randomly picks the card on the top. The strategies corresponding to the chosen cards are then played.

1. The row player can either win or lose in each round and the probability of winning a round is $p = 0.40$. Thus, we have a binomial distribution of win rates with parameter $p = 0.40$. Over n trials, the predicted variance of the number of wins for the row player is given by $np(1 - p)$. A chi-square test rejects the hypothesis that the sample variance and the predicted variance are the same; in particular, there is excessive sample variance relative to the predicted variance.³³ Similarly, one can statistically reject (1) the binomial probability implied by minimax for individual cards, and (2) the joint action profiles over actions for about 2/3 of the pairs in each treatment. Shachat (2002, p. 206) concludes: “Thus, without much hesitation, one can conclude that the presence of a device that allows subjects to easily randomize over their action sets does not bring the data of observed actions plausibly close to minimax play.”
2. Serial correlation is reduced relative to the findings of O'Neill (1987); however, it still remains. In particular, there is evidence that a player's choice of strategy depends on the previous play by the opponent; a clear indication that at least one of the players uses non-minimax play.
3. Many players seem to be using mixed strategies. However, very few players seem to be using mixed strategies as predicted by the MSE. In total, there were 3,720 decisions made in Treatments I and II. Of these, only 103 (2.8%) correspond to minimax play. On the other hand, equiprobable play in which each pure strategy is played with an identical probability, was more common and represented 13.2% of the choices. However, when subjects play mixed strategies, they play a wide variety of non-minimax strategies. Like Brown and Rosenthal (1990), Shachat (2002) finds that a variety of non-minimax strategies can lead to winning percentages for the row player that are close to the minimax prediction of 40%.

12.3.4 *Do professionals play mixed strategy equilibria?*

Formal economic models simplify all but the most essential aspects of reality in order to explain economic phenomena. Suppose that an economic model makes an MSE prediction that we wish to test in the field. These tests are confounded by at least two important factors. (1) Whether subjects in the field play mixed strategies, as predicted by the simple models. (2) Is the simple economic model a realistic description of the real world? By controlling for (2) in experiments, and by mapping experimental reality to payoffs, we are able to control one source of the confound. However, in experiments, we might not be able to control well for the first source of the confound (ecological validity), hence, giving rise to a trade-off from using experimental data.

One method of addressing the *ecological validity* concern with experimental tests of an MSE is to conduct the experiments with particularly suitable subject pools (artefactual experiments). Ideally, we are interested in a professional subject pool that has the relevant experience and skills.³⁴ Which subject pools and situations should one be looking out for to test for an MSE? The answer is not easy.

³³ The predicted variance is 14.4 for all three treatments and the sample variance for the three treatments is respectively 42.67, 27.4, and 24. The respective p-values are 0.000, 0.029, 0.025. The degrees of freedom are respectively 15, 16, 15.

³⁴ Broadly speaking, ecological validity refers to conducting an experiment in an environment which is suitable for testing some theory. For instance, if we want to detect paternal instinct in humans, then a laboratory experiment with students in which they assume roles of parents and children might not satisfy ecological validity, unless properly controlled for.

One possible source of field data that can be used to test the predictions of MSE is data from professional sports. Although this data source is getting increasing attention, one also needs to consider the potential caveats. Playing successful strategies based on experience in ball sports involves using motor skills that have a basis in our evolutionary history. As in Friedman's famous example, from the play of a successful billiards player, we cannot conclude that the player understands the complicated geometry that lies behind the actions. Rather, Friedman argued, the player behaves *as if* he/she was familiar with such geometry.

Could a successful billiards player solve an interesting economic problem that involved use of complicated geometry? One's a-priori hunch is that this is unlikely. The main reason is that while evolutionary skills may help us to succeed in ball sports, reflex actions, and hand-eye coordination, it is not clear if evolution has enabled us to solve a range of interesting economic problems. If we find that professional sports players use skills developed through evolution to play MSE in sports, we cannot necessarily conclude that the ability to play MSE transfers successfully to other economic problems. It would, of course, be very worthwhile to test this argument; we consider these issues below.

MINIMAX PLAY BY PROFESSIONAL SPORTS PLAYERS

It is not straightforward to use data from professional sports to test for an MSE. Walker and Wooders (2001) who are early pioneers in this field make the following observation (p. 1522):

As empirical tests of the minimax hypothesis, however, sports are generally inferior to experiments. In the classic confrontation between pitcher and batter, for example, there are many actions available (e.g., fastball, curve, change-up), and the possible outcomes are even more numerous (e.g., strike, ball, single, home run, fly ball, double-play grounder). Difficulties clearly arise in modeling such situations theoretically, in observing players' actions, and in obtaining sufficient data to conduct informative statistical tests.

With this caveat, Walker and Wooders (2001) test the minimax predictions, using as their observations the serves of top tennis players.

In tennis, a player can either serve to the left or to the right of an opponent. The opponent can simultaneously anticipate and also move to the left or to the right. Each serve has two outcomes: one player wins the point and the other loses. But, in actual tennis matches there are the following additional factors that are relevant, yet difficult to take into account. (1) Players can vary spin, angle, slice, or speed on the serve. (2) The receiver of a serve can stand far too much to the right (or left) and force the server to serve on the left (or right) or may engage in other body feints. (3) If the first service is faulty, then players are allowed a second serve. So, a two-dimensional strategy space (serve to the left or to the right) is not an innocuous simplification. Walker and Wooders (2001) consider payoff matrices of the following form.

	L	R
L	$\pi_{LL}, 1 - \pi_{LL}$	$\pi_{LR}, 1 - \pi_{LR}$
R	$\pi_{RL}, 1 - \pi_{RL}$	$\pi_{RR}, 1 - \pi_{RR}$

The row player (server) has two choices: serve left or serve right. The column player (receiver) has to guess which way the serve will fall, and in anticipation, move in that direction. Thus, the receiver also has two choices: overplay to the left or to the right. π_{ij} is the probability that the row player wins the point by serving in the direction $i = L, R$ when the receiver overplays in

the direction $j = L, R$. Analogously, $1 - \pi_{ij}$ is the probability that the column player wins under these conditions. Assuming that players care about winning, the payoff is directly proportional to the winning probability. Hence, in a reduced form manner, the payoffs are simply the probabilities of winning. This allows the authors to convert the problem of tennis serves into a two-player zero-sum game. The probabilities π_{ij} are allowed to vary from one match to another and during different stages of the match, such as deuce points and normal play.

In practice, it is difficult to know what π_{ij} should be. Hence, there is no available theoretical distribution with which one might compare the outcomes of actual play. So, Walker and Wooders (2001) test an implication of MSE, namely, that all pure strategies in the support of the equilibrium mixed strategy should have identical payoffs. In the tennis context, this means that serves to the left or to the right should have identical win rates. Data is obtained from videotapes of ten tennis matches from the major Grand Slam tournaments as well as the Master's championship conducted at the end of the tennis year; eight of these matches were the tournament finals.

The results are as follows. For individual matches, the Pearson test is used to test the null hypothesis that the win rates for left and right serves are identical. The value of the test statistic is 30.801, while the p-value is 0.852. Thus, the null hypothesis cannot be rejected at any level of significance. The predicted distribution (identical win rates on left and right serves) is compared with the actual distribution using the Kolmogorov–Smirnov test; the two distributions turn out to be statistically very close. However, the hypothesis of serial independence of first serves is rejected. Players switch their serves too frequently. This is in line with other research in which people find it difficult to generate random sequences. However, while there is serial dependence in play, it seems not to be exploited by the opponents. This result also holds for several other studies that we consider in this chapter; however, some contrary evidence is given in Scroggin (2007).

Palacios-Huerta (2003) tests the idea in Walker and Wooders (2001) for penalty kicks in professional soccer games. There may be some advantages of using data from penalty kicks over tennis serves in testing for minimax play. Issues of spin on the ball are less serious and there are no second kicks (unlike the second serves in tennis). On average, it takes just 0.3 seconds for the ball to travel to the goalpost. Hence, the goalkeeper makes an almost simultaneous decision to react. As in tennis, there are two possible directions: left and right for the kick and for the movement of the goalkeeper.³⁵ The only two possible outcomes are: goal or no goal. The vast majority of kickers are right footed and their natural shooting side is to the right of the goalkeeper. The natural shooting side of the left footed kickers is to the left of the goalkeeper. The goalkeepers take account of the kickers' natural side when they move.

Data is taken on 1,417 penalty kicks over the period 1995–2000 from professional football games. The payoff matrix is as in Walker and Wooders (2001). A little over 80% of the penalty kicks result in a goal. When the goalkeeper moves in the incorrect direction, nearly 100% of the kicks result in a goal. And when he moves in the correct direction, then 60% of kicks result in a goal. The null hypothesis, i.e., that scoring probabilities are identical on both sides of the goalkeeper is rejected at the 5% level for only 3 out of 42 players. Thus, the strategies of the vast majority of players are consistent with minimax. The Kolmogorov–Smirnov test shows that the null hypothesis of aggregate play being identical to the minimax predictions cannot be rejected. Finally, the null hypothesis that the choices of players are serially independent is rejected for only 2 of the 42 players. This result runs counter to the bulk of the evidence elsewhere that shows a

³⁵ The kicker can also kick straight to the center. However, these kicks constitute a very small part of the sample; 7.5% of kickers kick to the center and 1.7% of goalkeepers choose the center (i.e., stay still and not move either to the left or to the right).

serial dependence in actions. One possible explanation is that successive penalty kicks, unlike other experiments done in the lab, are spaced over a relatively large time interval. Chiapori et al. (2002) use a sample of 459 penalty kicks from the French and the Italian soccer leagues and reach conclusions that are similar to Palacios-Huerta (2003) in their support for the minimax hypothesis. However, they consider the role of heterogeneity in more detail.³⁶

The actions chosen by professional sports players may not rely on the same degree of rationality that is embodied in the play of MSE. For instance, based on field data, Bar-Eli et al. (2007) find that goalkeepers could save more penalty kicks if they stood still. Yet, we observe that they typically dive to the left or the right. They propose an explanation based on *norm theory*. It is the norm for goalkeepers to dive because in the event that a goal is scored, they feel worse from inaction (standing still) rather than from action (diving).

IS MSE PLAY TRANSFERABLE ACROSS CONTEXTS FOR PROFESSIONAL SPORTS PLAYERS?

Do experienced professional sports players play mixed strategies and can they transfer their experience to other contexts? Palacios-Huerta and Volij (2008) (henceforth, PH-V) give a strongly positive answer to the question of the portability of the successful play of mixed strategies from one context to the other, but this has been successfully overturned by the results in Wooders (2010). In a persuasive piece of empirical work, Levitt et al. (2010) (henceforth, LLR) reject portability of MSE across contexts.

LLR consider the following two zero-sum games. These games are similar to those in PH-V. The first game, the 2×2 pursuer–evader game, taken from Rosenthal et al. (2003), is shown in the upper panel of Figure 12.14. Players simultaneously choose among the two strategies, Black and Red. If the strategies do not match, the row player (pursuer) gets 1, while the column player (evader) gets 0. If the strategies match, then a six-faced dice is thrown. The payoffs for each player, either 0 or 1, then depend on the outcome of the throw of the dice, as shown in the figure. The MSE of the game is for each player to play Black and Red with respective probabilities $2/3$ and $1/3$.

PH-V consider a similar game that is based on the empirical success percentages from penalty kicks in soccer. The equilibrium mixing proportions in their case are $36 : 64$ for the row player (the pursuer) and $55 : 45$ for the column player (the evader). Insofar as mixing in the proportions $2/3 : 1/3$ is less cognitively challenging, the LLR study gives portability a better chance of success (but theory fails as we shall see below).

The second game used in LLR is a 4×4 game, taken from O'Neill (1987); see the lower panel of Figure 12.14. PH-V also use the same game, but strategies are named after colors (red, brown, purple, green). Each game was played a large number of times. For instance, in LLR, the 4×4 game was played 150 times with players switching roles between column and row players after 75 rounds.

PH-V use two sets of subjects in the experiment: Professional sports players and college students. LLR use undergraduate students and three sets of professional sports players: bridge players, poker players and major league soccer players.³⁷ Mixed strategies do not play an important

³⁶ Heterogeneity can arise, for instance, from the different abilities of the penalty kickers and the goalkeepers, and from the differing abilities to cope with stress, the game situation, and so on. Thus, in general, not all predictions at the level of specific kicker–goalkeeper pairs may survive aggregation to all players. On the other hand, one may examine the role of additional assumptions that allow for such aggregation to take place; this is the route followed in Chiapori et al. (2002).

³⁷ The bridge and poker players were recruited respectively at the 2006 North American Bridge Championship in Chicago, and the 2006 World Series of Poker in Las Vegas. The soccer players were recruited from three major league soccer teams (Los Angeles Galaxy, Chivas USA, and Real Salt Lake).

Black		Red		
Black	0, 1 (if the dice comes up 1 or 2) 1, 0 (if the dice comes up 3, 4, 5, 6)	0, 1 1, 0 (if the dice comes up 1 or 2) 0, 1 (if the dice comes up 3, 4, 5, 6)

role in bridge, however, they are critical in the play of poker. Hence, poker players should have, in principle, sufficient familiarity with the basic idea. The results show that bridge players do not play MSE, hence, in what follows, the results for bridge players are not given.³⁸

Some of the subjects in experiments played against a pre-programmed computer. The computer used two alternative algorithms. (1) An *optimal algorithm* that is designed to play minimax for the first 15 periods and then, in subsequent periods, designed to exploit any suboptimal play by human subjects. (2) An *exploitable algorithm* that simply played all strategies with equal probabilities.³⁹ In LLR, all subjects in experiments (except professional soccer players) played the 2 × 2 game and the 4 × 4 game with humans and with the computer.⁴⁰ There is a unique mixed strategy equilibrium in both these games.

For the data to support the MSE predictions, the following must hold. (1) At the individual level, play should conform to the proportions predicted by MSE.⁴¹ (2) All pure strategies in the support of the mixed strategy should give identical payoffs. (3) In successive rounds of play, the actions of players should be serially uncorrelated. Table 12.8 shows the comparative results of LLR and PH-V for these four predictions for the 2 × 2 game.⁴²

³⁸ Levitt et al. (2010) also suppress the results for the bridge players. However, these can be found in the supplementary material for the paper or in an earlier working paper version of the paper dated 2007.

³⁹ Subjects were told in the first case that “we have programmed the computer to play the theoretically correct strategy in this game. In addition, any deviations that your play has from this correct style of play will be taken advantage of by the computer.” The instructions in the second case omitted any mention of optimal play by the computer.

⁴⁰ Because of time constraints, the soccer players played only the 4 × 4 game.

⁴¹ This is a sufficient condition for play at the aggregate level to conform to the proportions predicted by MSE.

⁴² Here is a full description of Table 12.8 from Levitt et al. (2010, p. 1421): “The columns correspond to the different subject pools tested, while the rows report results for each test. The last two columns report results for a similar experiment carried out by Palacios-Huerta and Volij (2008). Panel I shows p-values from Pearson’s chi-square test for goodness of fit of aggregate frequencies to minimax predictions. p-values for the marginal frequencies of the pursuer and evader are shown in the first two rows, while the third row shows p-values for combinations of plays by both players. The test uses one degree of freedom for the marginal distribution of play and three for the joint distribution. Panel II shows the percentage of individuals (or pairs) that we reject at the 5% level for this same chi-square test. Panel III presents the percentage of players for whom we can reject the null hypothesis of no serial correlation in actions, based on the runs test of Gibbons and Chakraborti (2003).”

The null hypothesis tested in Panel I in Table 12.8 (titled Minimax Play at Aggregate Level) is that the aggregate frequencies of play match the MSE prediction. The p -values needed for rejecting the null hypothesis at the aggregate level are shown in the table for the row player (pursuer), the column player (evader), and for joint play. The MSE predictions are rejected in all three cases at the $p < 0.01$ level for all subject pools: undergraduate students and the two sets of professional players (recall that we have suppressed the result for Bridge players). On all relevant yardsticks of comparison, for aggregate play, the LLR data from professionals is statistically indistinguishable from students. By contrast, in the PH-V data, the aggregate play of professional subjects is consistent with MSE.

Panel II in Table 12.8 (titled Minimax Play at Individual Level) focuses on individual-level data. It shows the percentage of players, in each category, for whom one can reject at the 5% level, the null hypothesis, namely that play conforms to MSE. It turns out that 90% of students and 75% of poker players do not conform to the predictions. In PH-V, by contrast, all professional players statistically conform to the MSE predictions.

Panel III in Table 12.8 (titled Runs Tests) shows the percentage of players for whom one can reject the null hypothesis of no serial correlation in play based on the runs test of Gibbons and Chakraborti (2003). These percentages are relatively small, and much smaller than the findings elsewhere, some of which we have reviewed above.

The findings for the 4×4 game are shown in Table 12.9 and parallel the findings of the 2×2 game in Table 12.8. There is a new panel in Table 12.8 titled “Equality of success rates . . .” This panel shows tests for the null hypothesis that the pure strategies in the support of the mixed strategy give identical payoffs and also that the level of these payoffs conforms to MSE predictions. For the LLR

data, for nearly 2/3 of the students and the poker players, the null hypothesis can be rejected.⁴³ In the PH-V data, by contrast, we cannot reject non-conformity with the MSE predictions for any professional sports players and the rejection rate of students is only 10%.

In conjunction, these findings imply that LLR strongly reject minimax play for professional sports players in the lab. Levitt et al. (2010) write: “In sum, we are left to conclude that none of our subject pools, including professional soccer players, play these laboratory games in accordance with the predictions of minimax, even though there is evidence that they likely employ such strategies in the field . . . It appears that for our experimental subjects, what happens in the field stays in the field.” These results are diametrically opposite to the results reported in PH-V.

What accounts for the difference in results between LLR and PH-V? One possibility is that professional players would like to play minimax, however, they correctly anticipate that they are facing a student population that does not play minimax. Hence, a non-minimax strategy is a best reply. This is rejected by observing play against computers which are programmed to play minimax. When playing against a computer that is playing suboptimally, professional sports subjects do slightly better but still do not play minimax. LLR use post-experimental surveys which reveal that the main reason why players did not play minimax is that players did not place the lab games in the correct context. For instance, soccer players were not able to spontaneously make the link between penalty kicks and the MSE of lab games.

⁴³ The rejection rate for bridge players (not shown in the table) is 37%.

Wooders (2010) undertakes a re-examination of the data in PH-V. In PH-V, students and professional soccer players play two kinds of games. A penalty kick game and the original game in O'Neill (1987). Each of the games is played 200 times between pairs of players. The innovation in Wooders (2010) is to break the results down over the 200 rounds into two equal halves. Minimax predicts that the frequency distribution of the choices (arising under the MSE of each of the two games) should be identical across the two halves. This "stationarity property" is violated for professional soccer players who switch from underplaying relative to the MSE prediction in the first half to overplaying in the second half. Even more strikingly, the behavior of students is closer to the MSE prediction relative to the professionals.

It is fair to conclude that the data rejects portability of MSE play for professional sports players.

12.4 Coordination games

Coordination failures provide an important explanation of human behavior in a wide range of areas in economics (Schelling, 1960, 1978). Coordination problems underpin a range of macroeconomic models, particularly those that use imperfect competition. Models of network externalities and standards also rely on the solution to coordination problems. For instance, a technology or process or a standard might become useful and commercially viable only when a certain critical number of users coordinate on adopting it.

12.4.1 Evidence on coordination failures

Early evidence on coordination failures is provided in Cooper et al. (1989). They consider coordination in the following *battle of the sexes* (BoS) game.

	1	2
1	0, 0	200, 600
2	600, 200	0, 0

In this game, both players have two strategies, 1 and 2. The payoffs are given in points. Dividing the points by 1000 gives the probability of winning a prize.⁴⁴ This practice of giving payoffs in points also applies to the other papers, Cooper et al. (1990, 1993), that we consider below. The two pure strategy Nash equilibria are (1, 2) and (2, 1). There is also a mixed strategy Nash equilibrium in which each player plays strategy 1 with probability 0.25. This gives an expected payoff to each player from the mixed strategy of 150 points, which is worse than coordinating on any of the two Nash equilibria. The experimental evidence indicates that the actual observed frequency of play, when aggregated over all players was close to the mixed strategy equilibrium. The two pure strategy Nash equilibria arose less than 42% of the time. Hence, there were widespread coordination failures.

Cooper et al. (1990) provide evidence on coordination failures from two-player games in which each player has a choice between three pure strategies, 1, 2, 3. The generic game is shown in Figure 12.15. They consider four Type-I coordination games in which $z = 600$ and two Type-II games in which $z = 500$; in each case one of x or y is greater than 600.

⁴⁴ So, if the strategy profile (2, 1) is played, then player 1 wins the prize with probability 0.6 while player 2 wins it with probability 0.2.

	1	2	3
1	350, 350	350, 250	$x, 0$
2	250, 350	550, 550	$y, 0$
3	$0, x$	$0, y$	z, z

Figure 12.15 Type-I game ($z = 600$) and Type-II game ($z = 500$).

Source: Cooper et al. (1990) with permission from the American Economic Association.

These two types of games have the following features. (1) All games are symmetric coordination games. (2) The pure strategy Nash equilibria in each game are (1, 1), and (2, 2). (3) The two Nash equilibria can be Pareto ranked: (2, 2) Pareto dominates (1, 1). (4) In Type-I games, the cooperative outcome that maximizes joint payoffs is (3, 3). (5) In Type-II games, the cooperative outcome that maximizes joint payoffs is (2, 2). To enable assertions (4) and (5) to hold, there are appropriate upper limits on x and y .

The shaded part of the payoff matrix is common to all games played. In both types of games, strategy 3 is dominated, so it should have no effect on which Nash equilibrium is played. The results of the experiments are as follows.

(1) In Type-I games, most players play one of the two Nash equilibria, (1, 1), or (2, 2). In games 3, 4, which are Type-I games, subjects overwhelmingly play strategy 1 (in game 3, $x = 1000$, $y = 0$, and in game 4, $x = 700$, $y = 0$). Hence, subjects do not coordinate on the Pareto efficient equilibrium (2, 2). Thus, coordination failures arise in these games. (2) In Type-I games, the presence of the dominated strategy, 3, alters the equilibrium outcomes. This is indicated by the observed variation in the equilibrium outcomes when x, y are altered. (3) Why is strategy 3 important? One clue is the fact that the cooperative outcome arises when both players play strategy 3, despite strategy 3 being a dominated one (because, $x, y > 600$). Type-II games control for this confound by ensuring that strategy 3 no longer leads to the cooperative outcome; in these games, (2, 2), is the cooperative outcome. Hence, the only reason strategy 3 should have any influence in Type-II games is if players have beliefs that opponents will play a dominated strategy. This reduces the actual play of strategy 3 in experiments and also increases the incidence of the payoff dominant equilibrium (2, 2).

12.4.2 *Focal points and coordination*

In the presence of multiple equilibria, economic agents must form beliefs about which equilibrium is likely to be played. Coordinating on certain actions may give everyone a higher payoff, which makes them salient. It is also possible that some actions are salient in other respects, also termed as *focal points*; salient actions may serve as a coordinating device for players. Following the work of Schelling (1960), Mehta et al. (1994, p. 659) write: “Some labels are more prominent or conspicuous or salient than others; they ‘stick out’ or ‘suggest themselves,’ typically by virtue of analogies or associations of ideas which connect those labels to some aspect of the common experience, culture, or psychology of the players. Players tend to choose those strategies whose labels are salient. An equilibrium that results from such choices is a focal point.”

Mehta et al. (1994) distinguish between the concepts of *primary salience* (actions that are salient for a player) and *secondary salience* (coordinating on actions that are believed to have primary salience for the other players). In order to test for the significance of these concepts, they divided subjects in experiments into two groups: Group C (coordinating condition) and group P (picking condition). Group C’s payoffs depended on coordinating their actions with the actions of others,

5	London (15.9)	Norwich (12.9)	0.054	London (55.6)	Norwich (34.4)	0.238
6	7 (11.4)	2 (10.2)	0.052	1 (40.0)	7 (14.4)	0.206
7	Blue (38.6)	Red (33.0)	0.269	Red (58.9)	Blue (27.8)	0.422
8	John (9.1)	Fred (6.8)	0.002	John (50.0)	Peter (8.9)	0.264
9	Heads (76.1)	Tails (20.5)	0.618	Heads (86.7)	Tails (12.2)	0.764
10	Him (53.4)	Her (40.9)	0.447	Him (84.4)	Her (15.6)	0.734

while the actions of group P were independent of any coordination. Subjects were asked 20 questions. The first 10 questions are shown in Table 12.10. The remaining 10 questions are abstract and involve coordinating on patterns.

A total of 178 undergraduate students participated in the experiment. Group C was relatively more successful at coordinating actions as compared to group P. A *coordination index*, c , is used to measure the probability that individuals who are chosen at random will coordinate on their actions. If individuals make completely distinct choices, $c = 0$, and if they make identical choices, $c = 1$; values of c in between these two extremes denote partial coordination. The two most frequent responses to each of questions 1–10, for the two groups P and C, are shown in Table 12.11, along with the coordination index, c . In order to interpret the results, note that the date of the experiment is December 10, 1990, most participants would have been born in the years 1968–1971, and the subjects in experiments came from the University of East Anglia in Norwich, England.

The coordination index for group C was higher relative to group P for each of the 10 questions. The modal response was the same in 16 out of the 20 questions for both groups. This seems consistent with secondary salience. A large number of individuals choose their birth year or the current year for question 1. The most frequent response for towns was London (the capital), followed by Norwich (where the students study). The color blue is the most common in group P but red is most popular for group C; perhaps people think that red is thought of by others as a more salient representation of colorfulness. Hence, labels do convey important information that can help coordinate actions. However, despite the high degree of salience in the questions, the coordination index is, on average, less than 60% for the first 10 questions for group C. This is suggestive of a degree of coordination, but also of coordination failures.

Bosch-Domènech and Vriend (2013) consider the role of non-Nash strategy profiles in serving as focal points in the presence of Nash equilibria. They consider a simultaneous move two-player normal form coordination game in which the row player chooses a row $(r_1, r_2, \dots, r_n)$ and the column player chooses a column $(c_1, c_2, \dots, c_n)$. A typical game, the 100 treatment, is shown in Figure 12.16; each cell in the payoff matrix shows an identical payoff (0 or 100) for each of the two players. Corresponding to any strategy played by the row player, there are two strategies of the column player that result in a coordinated payoff of 100 for both players. Lack of coordination results in a payoff of zero for both.

There are several Nash equilibria in the game; each results in a payoff of 100 to each player. Hence, one cannot use *payoff dominance* as a selection criterion.⁴⁵ Neither does *risk dominance* help to choose among any of these Nash equilibria.⁴⁶ Players are randomly matched at the end of each round of play, hence, other relevant criteria such as *precedent* cannot help either. No preplay communication is allowed, neither is any feedback given to the players. Finally, strategies carry no *label salience* and the game does not suggest any particular *frame*, *analogy*, or *context*. This rules out the most obvious ways of using classical focal point criteria.

The authors then take one of the Nash equilibria in Figure 12.16, corresponding to a strategy profile (r_j, c_k) and replace the payoff of 100 for each player by some number $x < 100$, leaving the rest of the payoffs unchanged. This gives rise to three “ x treatment” stage games, corresponding to $x = 46$, $x = 87$, and $x = 99$; these are denoted, respectively, by 46 treatment, 87 treatment, and 99 treatment. The original game may, thus, be termed as the 100 treatment. Notice that in any x treatment stage game, the strategy profile (r_j, c_k) no longer constitutes a Nash equilibrium because any one of the players can defect to another strategy that guarantees a payoff of 100. The authors ask, if in any x treatment stage game, the non-Nash strategy profile (r_j, c_k) can serve as a focal point. If the answer turns out to be in the affirmative, then this would demonstrate the power of non-Nash strategy profiles to serve as focal points.

In each x treatment, the subjects in experiments first play a one-shot x treatment stage game with relatively higher stakes and unlimited time. While no feedback is provided, the one-shot game allows players to use deductive reasoning to coordinate their actions. This is followed by 50 rounds of the play of the x treatment stage game with random opponents (the 50-round game). At the end of each round, players are informed of their payoffs but not the strategy of the other player. Each of the rounds is played for real money. The numbers shown in Figure 12.16 are experimental payoff points; 10 payoff points correspond to a payment of 1 euro in the one-shot game and to

⁴⁵ The empirical evidence in Colman et al. (2008) supports the choice of payoff dominant profiles over Pareto-inferior unique Nash equilibrium profiles.

⁴⁶ See the appendix on game theory for the concepts of payoff and risk dominance. Also see below, several coordination games where these selection criteria apply, hence, lending themselves to empirical testing.

0.05 euros in any round of the 50-round games. Thus, a greater degree of coordination among the players at the end of 50 rounds will also be reflected in higher earnings.

The average earnings in euros at the end of 50 rounds for the 46 treatment, 87 treatment, 99 treatment, and the 100 treatment are, respectively, 8.39, 12.27, 14.82, and 5.32. Clearly, the degree of coordination in the x treatments is much higher as compared to the 100 treatment (that has no focal points). The degree of coordination in the 100 treatment was no higher than what one would predict based on random choice of strategies for the row and the column players. Hence, it did not arise from the players using any particular strategy as a focal point; this result holds for the one-shot game and for the repeated play of the game over 50 rounds. Further, the degree of coordination increases as x increases successively from 46 to 87 to 99.

In the one-shot game, there is marginally higher coordination in each of the x treatments relative to the 100 treatment but this is not statistically significant. However, in the 50-round games, this difference attains statistical significance. Thus, players learn to coordinate better with experience. Consider the results over rounds 41–50. Relative to the 100 treatment, expected payoffs are 1.8 times higher in the 46 treatment, 3.1 times higher in the 87 treatment, and 3.5 times higher in the 99 treatment. This increased coordination, reflected in higher expected payoffs, arises from subjects coordinating on the non-Nash focal point. The results over rounds 41–50 show that the non-Nash focal point was used by 45% of the subjects in the 46 treatment, 71% of the subjects in the 87 treatment, and 79% of the subjects in the 99 treatment. Thus, the focal point is used more often as the focal payoff increases.

The results of Bardsley et al. (2010) suggest that it would be very difficult to construct a unified theory of focal points. In two different coordination games they find that coordination is best

described by the *cognitive hierarchy model* in one and by *team reasoning* in the other.⁴⁷ A more formal treatment of focal points in the context of level- k models is given in the next chapter.

12.4.3 Coordination failures in median action games

Van Huyck et al. (1991) document coordination failures in *median action games*; these are static games of full information where players simultaneously choose their actions and have common knowledge of the rationality of the other players. Median action games capture the desire of players to conform to an action or a norm in the sense that deviations of their own actions from the median action are payoff-reducing. These experiments also test for the importance of equilibrium selection principles such as payoff dominance, risk dominance, and the role of history in influencing coordination.

Consider a large number of players, n where n is an odd number. Players, $i = 1, 2, \dots, n$, simultaneously choose actions, $s_i \in \{1, 2, \dots, \bar{s}\}$, where $\bar{s}$ is the maximum value of the positive integer that can be chosen. Denote the median action by M . We focus on pure strategies only. The payoff of player i is given by

$$\pi(s_i, M) = aM - b(M - s_i)^2 + c; \quad a > 0, b > 0. \quad (12.2)$$

Since players choose their actions simultaneously, at the time of choosing their actions, they do not know the median action. Player i expects the median action to be $E_i[M]$. The optimum action for each player that maximizes (12.2) is $s_i = E_i[M]$, which reflects the desire of players to conform to the median action. The calculation of $E_i[M]$ involves an infinite regress. Each player, $i = 1, 2, \dots, n$, must form beliefs about $E_i[M]$, and beliefs about the beliefs of the expected median action, and so on.

Suppose that players could somehow coordinate their actions and beliefs. Then, we are looking for a symmetric pure strategy Nash equilibrium that maximizes the payoffs of all players. The optimum action for each player is to choose $s_i^* = \bar{s}$, so that the median is $M = \bar{s}$. That this is a (strict) Nash equilibrium is easily confirmed from the calculation,

$$\pi(s_i, \bar{s}) < \pi(\bar{s}, \bar{s}) \quad \text{for all } s_i \neq \bar{s} \text{ and for all } i = 1, 2, \dots, n. \quad (12.3)$$

To test for various selection principles, Van Huyck et al. (1991) use three different parameterizations of their problem. In each case, the maximum value taken by any player's action is $\bar{s} = 7$.

1. In game-I, $a = 0.1$, $b = 0.05$, and $c = 0.6$; the associated payoff matrix is shown in Table 12.12.
2. In game-II, when $s_i = M$, payoffs are as in game-I (with $a = 0.1$, $b = 0.05$, and $c = 0.6$). But when $s_i \neq M$, the payoff is zero. Hence, the payoff matrix for game-II is as in game-I but all off-diagonal elements are zero.
3. In game-III, $a = 0$, $b = 0.05$, and $c = 0.7$; the associated payoff matrix is shown in Table 12.13.

Consider now the predictions for each game based on various selection criteria when we restrict attention to a pure strategy symmetric Nash equilibrium. In game-I, there is a conflict

⁴⁷ See Part 5 for an exposition of the cognitive hierarchy model. *Team reasoning* implies that when individuals take actions in a group they might take actions that are optimal from the point of view of an imaginary manager/social planner who maximizes some team objective. This may lead to a coordinated choice of actions; see Sugden (1993, 1995) for an extensive discussion of team reasoning and Colman et al. (2008) for the experimental evidence.

between payoff dominance and security. The payoff dominant action for each player is $s_i = \bar{s} = 7$. However, the maximin or secure action for a player is $s_i = 3$.⁴⁸ In game-II, all off-diagonal elements are zero, so there is no secure option because the minimum payoff corresponding to each action is zero. However, there is a payoff dominant choice, $s_i = \bar{s} = 7$. Thus, unlike game-I there is no conflict between security and payoff dominance, so the prediction, based on the selection principles, is that $s_i = \bar{s} = 7$ should be observed. In game-III, all payoffs along the diagonal are identically equal to 0.70. Thus, payoff dominance has no bite. Security (the maximin strategy) selects $s_i = 4$ in this case.

Groups of nine players played the games over several rounds, so that players could learn to coordinate. The experimenter revealed the median to all players at the end of each round, but not the individual actions. The results are as follows.

1. The first period results are particularly interesting because players' actions cannot depend on any history of play. Rather, in choosing their actions, players can only resort to *deductive*

⁴⁸ This is easily seen from Table 12.12. The minimum payoffs corresponding to each of the actions 1 to 7 are respectively −0.5, 0.05, 0.50, 0.25, −0.10, −0.55, and −1.10. The maximum of these payoffs is 0.50, which corresponds to $a_i = 3$.

reasoning, about what others are likely to play. In game-I, where there is a conflict between payoff dominance and security, 15% choose $s_i = 7$ (the payoff dominant action) and another 15% choose $s_i = 3$ (the secure option). In game-II, the prediction $s_i = \bar{s} = 7$ is satisfied by only 52% of the players. In game-III, the prediction $s_i = 4$ is satisfied by only 41% of the players. Hence, none of the selection principles individually apply very well and there are widespread coordination failures.

2. In the first period, the individual choices of actions are quite dispersed, suggesting that players' beliefs about others are dispersed too. As Van Huyck et al. (1991, p. 897) observe: "The data are inconsistent with any theory of equilibrium selection that assumes that, because a decision maker will derive his prior probability distribution over other decision makers' pure strategies strictly from the parameters of the game, all decision makers will have the same prior probability distribution. Instead, most subjects predict that some participants will be more optimistic or pessimistic than themselves."
3. The actions and beliefs of the players in the first period seem consistent. More optimistic players choose higher actions and more pessimistic players choose lower actions.
4. In repeated play of the games, there seems to be a strong effect of history on subsequent play. The period 1 median was nearly always observed again in period 10. The other results from the first period play also replicate themselves in repeated play, namely, no single selection principle performs well, and there is substantial dispersion in the choices of individual players.

Van Huyck et al. (1993) extend the experiments in Van Huyck et al. (1991) with an important twist. They auction the rights to play the median action game among players. If players have diverse beliefs, then an auction may select the players whose beliefs are most optimistic about the coordination behavior of others. Each player may then coordinate more, reasoning that other players who have incurred resources in the auction will attempt to recoup their resources by facilitating higher coordination in the median action game. This is a form of forward induction. As expected, the degree of coordination is much higher. Further, the speed of convergence to a coordinated outcome is impressive. Crawford and Broseta (1998) build on the earlier work in Crawford (1995) to provide a unified theoretical explanation of Van Huyck et al. (1991, 1993) based on an adaptive learning model. In this model, players have heterogeneous beliefs and they engage in unsophisticated learning based on their observations of the actions of other players. Forward induction effects play a key role in the analysis.

12.4.4 *Coordination failures in weak link games*

Consider the following static game of full information in Van Huyck et al. (1990). Suppose that there are n players. Each player simultaneously chooses some action $s_i \in \{1, 2, \dots, 7\}$, $i = 1, 2, \dots, n$. Denote the minimum action by $\theta = \min \{s_1, s_2, \dots, s_n\}$. Then, the payoff of each player in Treatments A, B is given by the following two possible payoff functions.

$$A : \pi(s_i, \theta) = 0.60 + (0.10)\theta - 0.10(s_i - \theta). \quad (12.4)$$

$$B : \pi(s_i, \theta) = 0.60 + (0.20)\theta. \quad (12.5)$$

In Treatment A, there is a private cost to one's action, while there is none in Treatment B. In both treatments, the payoff is increasing in the minimum action taken by the group. A motivating example is a sequential assembly line production process in a firm, whereby work on one

production process can only begin once a previous production process is completed. Hence, final output moves at the rate of the slowest of the production processes. Or consider a team of software developers. A bug in the program introduced by any member may lay to waste the efforts of all team members.

In Treatments A and B, the game was played with $n = 14$ –16 subjects, repeated over 10 rounds. If players could coordinate their actions and beliefs to maximize their payoffs, then in Treatments A and B, they should coordinate on the payoff dominant action $s_i = 7$ for all i . In addition, there are two further treatments. In Treatment C, the payoffs are as in (12.4) but $n = 2$. In Treatment A', three treatments are played in sequence: $A \rightarrow B \rightarrow A$.

Consider Treatment A first. Since players choose their actions simultaneously, they must form beliefs about the actions of others. If player i expects the minimum action to be $E_i[\theta]$, then, using (12.4), the optimal choice is $s_i = E_i[\theta]$. The game is symmetric with respect to the players, and players are identical, hence, it is plausible that they have identical expectations, so $E_i[\theta] = E[\theta]$ for all i . This implies that, in a symmetric Nash equilibrium, the optimal action is $s_i^* = E[\theta] = a \in \{1, 2, \dots, 7\}$ for all i . Thus, the equilibrium strategy profile is given by $s^* = (a, a, \dots, a)$, so $\theta^* = a$, and the following condition for a Nash equilibrium is satisfied,

$$\pi(s_i, a) < \pi(a, a) \text{ for all } s_i \neq a. \quad (12.6)$$

Using (12.4) and (12.6) we get $a = 7$.

In Treatment B, on the other hand, players are not penalized for the deviation of their actions from the median action. So choosing the payoff dominant action $s_i = 7$ is a dominant strategy. Hence, this is a cognitively less challenging game.

The payoff matrix for Treatment A is given in Table 12.14; for any choice of action s_i by player i , the group minimum cannot be higher, hence, the entries below the diagonal are truncated. From Table 12.14, the secure option is for each player to play $s_i = 1$, which guarantees a sure payoff of 0.70 that is greater than the minimum payoff from any other action (maximin outcome). Thus, there is a conflict between the payoff dominant option of $s_i = 7$ and the secure option of $s_i = 1$.

In repeated versions of the game, there was no preplay communication, and at the end of each repetition of the game, the minimum action in that period was announced to all players but individual actions were not revealed.

Table 12.14 Payoff matrix for treatment A.

		Minimum chosen action, θ						
		7	6	5	4	3	2	1
Your choice of action s_i	7	1.30	1.10	0.90	0.70	0.50	0.30	0.10
	6	–	1.20	1.00	0.80	0.60	0.40	0.20
	5	–	–	1.10	0.90	0.70	0.50	0.30
	4	–	–	–	1.00	0.80	0.60	0.40
	3	–	–	–	–	0.90	0.70	0.50
	2	–	–	–	–	–	0.80	0.60
	1	–	–	–	–	–	–	0.70

Source: Van Huyck et al. (1990).

The first period results are of interest because they test for deductive reasoning. In Treatment A, where there is a conflict between the payoff dominant and the secure option, the payoff dominant action was chosen by 31% of the subjects and the secure action by just 2%. Thus, neither of the two deductive principles is very helpful to explain the data. In all seven experiments, the minimum action in period 1 was never greater than 4. Hence, coordination failures are widespread (because coordination on $s_i = 7$ for all i , maximizes payoffs).

As in Van Huyck et al. (1991), the choices of the subjects in experiments were quite dispersed, suggesting lack of common priors. There was a range of optimistic and pessimistic beliefs but actions were consistent with beliefs. Optimistic players (in the sense of having optimistic beliefs) choose high actions and pessimistic players choose lower actions. Repeated play brings inductive reasoning into play but does not achieve any stable outcome in Treatment A. At the end of ten rounds, play converges towards the most inefficient outcome, $s_i = 1$, in all the seven experiments.

In Treatment B, which is cognitively less challenging, and where the prediction is $s_i = 7$, by period 11, 84% of the players conform to the prediction. By period 15, 96% of the players conform to $s_i = 7$. The payoff dominant equilibrium was still not implemented in most cases because at least one player would choose $s_i < 7$.

In Treatment A', which follows Treatment B, by round 16, 25% of the players choose the payoff dominant outcome $s_i = 7$. However, an even larger percentage, 37%, choose the secure option $s_i = 1$.

Are group sizes important for coordination games? This issue is addressed in Treatment C. When subjects are paired with a permanent partner, by round 21, 42% of the players choose their payoff dominant action. However, when subjects were randomly paired then the positive effect on s_i that arises from permanent pairings was reduced. Hence, it is not just group size that is important, but also how groups are organized. Reducing the group size alone does not automatically improve coordination.

12.4.5 *More evidence on equilibrium selection principles*

Straub (1995) considers eight games, which have *risk dominant* and *payoff dominant* equilibria. The main interest is in observing which, if any, of these equilibria does play converge to over ten rounds of a game in which players are matched anonymously with each other. Whenever the Nash product from both strategies is not identical, then the risk dominant equilibrium is the one that is observed. This contrasts with the expectation of Harsanyi and Selten (1988) that the payoff dominant equilibrium is more likely to be observed. When the Nash products are equal, then the risk dominant equilibrium is associated with the play of a mixed strategy. The frequency of play by the players in this case seems consistent with the risk dominant mixed strategy. However, it seems unlikely that the players used a purely deductive process to reason to a mixed strategy risk dominant equilibrium. And Straub (1995, p. 351) writes: "Instead, it appears much more likely that if the players achieved an equilibrium during a session, they were aided by a (possibly evolutionary) process in which their strategies converged to an equilibrium."

12.4.6 *Coordination and the optimization premium in stag-hunt games*

Battalio et al. (2001) considered three *stag-hunt games* that have identical equilibrium outcomes in pure and mixed strategies. Hence, one may expect subjects in experiments to play the same

Game 2R				Game R				Game 0.6R			
		X	Y			X	Y			X	Y
X	45, 45	0, 35		X	45, 45	0, 40		X	45, 45	0, 42	
Y	35, 0	40, 40		Y	40, 0	20, 20		Y	42, 0	12, 12	

Figure 12.17 Game 2R, game R, and game 0.6R.

Source: Battalio et al. (2001) with permission of The Econometric Society.

equilibria across the three games.⁴⁹ The three games, denoted by 2R, R, and 0.6R, are shown in Figure 12.17.

In all three games, (X, X) is the *payoff dominant equilibrium*, and (Y, Y) is the *risk dominant equilibrium*. In the mixed strategy equilibrium, both players play action X with probability $q^* = 0.8$. Strategy X is a best response for any player when the opponent plays X with a probability $q > 0.8$.

The one main difference between the three games is the *optimization premium*, defined as the difference between the best response to an opponent's strategy and an inferior response. Consider, for instance, the equilibrium (X, X). For game R, the optimization premium for either the row or the column player is $45 - 40 = 5$. The optimization premium for game 2R is 10, double that of game R, and for game 0.6R it is 3, which is 0.6 times that of game R. This explains the logic behind the names of the three games.

For a player who is fully rational in the classical sense, the optimization premium should not matter. The best response functions still intersect at the same point. However, the optimization premium alters the slope of the best response. Hence, it might affect the behavior of players who are less than fully rational. Battalio et al. (2001) test this conjecture.

In the experiments, there are eight subjects in each cohort and each cohort played one of the three games, 75 times. Subjects were randomly paired at the end of each round to minimize reputation effects. No preplay communication was allowed and the opponent in each round was anonymous.

The results for period 1 (where choices are purely deductive) and for period 75 (where choices involve deductive and inductive reasoning) are shown in Table 12.15. In period 1, 63% of all subjects play X, the payoff dominant choice. Since $0.63 < q^* = 0.8$, it is not a dominant strategy to play X. Only 37% play the risk dominant strategy. Across the three games, the tendency to play the payoff dominant equilibrium is not statistically different.

Table 12.15 Experimental results.

Game	Period 1 choices (%)		Period 75 choices (%)		Number
	X	Y	X	Y	
0.6R	64	36	44	56	64
R	70	30	25	75	64
2R	53	47	5	95	64
Total	63	37	24	76	192

Source: Battalio et al. (2001).

⁴⁹ In stag-hunt games, unlike a prisoner's dilemma game, there are two Nash equilibria; one equilibrium is payoff dominant and the other is risk dominant.

All this changes by period 75. Now only 5% play the payoff dominant action, X, in game 2R, while 44% play X in game 0.6R. Thus, the payoff dominant action is more likely to be played when the optimization premium is smallest. Analogously, the risk dominant equilibrium is played more often (95%) when the optimization premium is highest, as in game 2R. Hence, which of the two coordinated equilibria gets played depends on the optimization premium, which is predicted to have no effect in classical game theory.

12.4.7 *Forward induction, timing, and coordination failures*

Cooper et al. (1993) consider two players who play the following sequential game that can be represented in an extensive form.

1. In the first stage, player 1 can choose an outside option which gives him a payoff, X, and end the game. Or, he can choose not to exercise the outside option, in which case the game proceeds to the second stage.
2. In the second stage, the two players play the following battle of the sexes (BoS) game (player 1 is the row player and player 2 is the column player):

	1	2
1	0, 0	200, 600
2	600, 200	0, 0

Payoffs are given as points. Dividing the points by 1000 gives the probability of winning a prize. What outcome do we expect? Suppose that the outside option, $X \in (200, 600)$ and this is known to both players. Then players can try to use *forward induction* in order to solve the game.⁵⁰ Player 2 can now reason as follows. If player 1 has forgone his outside option, then he must hope to get a higher payoff. In particular, when $X = 300$, we call the resulting game BoS-300. In this case, forward induction would suggest to player 2 that player 1 intends to play strategy 2. Coordinating expectations in this manner, player 2 would then play strategy 1. Thus, the prediction is that the players will coordinate on the equilibrium (2,1). We summarize the prediction for this game by hypothesis H1.

H1: In the game BoS-300, the equilibrium outcome is expected to be (2,1).

When $X = 100$, rejecting the outside option is not informative about player 1's intentions. Calling this game BoS-100, we get the next hypothesis.

H2: In the game BoS-100, the outcome is predicted to be identical to the game BoS in which the outside option does not exist.

Classical game theory predicts that the choices of players in extensive form games and their equivalent strategic form representations are identical. The evidence examined earlier in this chapter does not support this prediction. Cooper and Van Huyck (2003) reach similar conclusions for the class of generic 2×2 extensive form games of perfect information. They find systematic differences between the choices made in strategically equivalent normal and extensive forms that could not be ascribed to other factors, e.g., other-regarding preferences. Consider the extensive form described above for the case $X = 300$. Denote by 0, the strategy of player 1 to take

⁵⁰ For the concepts of forward induction and stability, the reader can consult any graduate book in game theory; see, for instance, Fudenberg and Tirole (1991) and Maschler et al. (2013).

his outside option, and let player 1 be the row player. Then, the strategically equivalent normal form corresponding to the extensive form game is:

	1	2
0	300, 0	300, 0
1	0, 0	200, 600
2	600, 200	0, 0

Denote this normal form with an outside option of $X = 300$ by BoS-300-NF.

H3: The outcomes under BoS-300 and BoS-300-NF should be identical.

Recall that in the BoS game, both players simultaneously choose their strategies. Now consider a new game, BoS-SEQ. The payoff matrix is as in the BoS game, but player 1 chooses his strategy prior to player 2's strategy choice. However, player 2 is not informed about the strategy chosen by player 1. Under classical game theory, such *timing issues* should not matter.

H4: The outcomes in the games BoS and BoS-SEQ should be identical.

The results are shown in Table 12.16. Results seem consistent with hypothesis H1, i.e., forward induction has sufficient bite; 90% of the equilibrium outcomes in BoS-300 are (2,1), as predicted. However, all the other hypotheses fail.

In the baseline game, BoS, nearly 60% of the outcomes were disequilibrium outcomes characterized by coordination failures. This result was subsequently replicated by Straub (1995) who found that for the BOS game, the non-coordinated outcome accounted for 60% of the cases, coordinated outcomes at (1,2) for 26% of the cases, and coordinated outcomes at (2,1) for 14% of the cases.

Despite the success of hypothesis H1, 20% of the subjects took the outside option in BoS-300. The results in the BoS and BoS-300 games are quite different. In BoS, nearly an equal number of players coordinated on the two equilibria. However, in BoS-300, 90% coordinated on (2,1), which is player 1's preferred equilibrium. The results in BoS-300 and BoS-300-NF are quite different, a finding that rejects hypothesis H3. In the latter game, in more than half the cases, subjects were not able to coordinate on any of the two equilibria, while in BoS-300 they did so in 90% of the cases.

Hypothesis H2 can also be rejected. The presence of the irrelevant outside option $X = 100$ increases the incidence of the (2,1) equilibrium from 19% in BoS to 63% in BoS-100. The overall

Table 12.16 Experimental results.

Game	Outcome (in percentage)			
	(2, 1)	(1, 2)	(1, 1) or (2, 2)	Outside option
BoS	19	22	59	–
BoS-100	63	3	34	1.8
BoS-300	90	0	10	20
BoS-SEQ	62	4	34	–
BoS-300-NF	32	1	52	15

Source: Cooper et al. (1993).

coordination rate jumps up from 41% to 66%. It would seem that the mere presence of the outside option, even when predicted not to matter, acts as a focal point for expectations about how a player will play.

Hypothesis H4 is also rejected. Timing matters, even when it is predicted not to. The overall coordination rate in BoS-SEQ is 66%, as compared to 41% in BoS.

In a nutshell, different outside options, timing issues, and framing effects (whether the game is presented in normal or in extensive form) have an important bearing on the level of coordination.

12.4.8 *Preplay communication and coordination failures*

Suppose that prior to a two-player BoS or a coordination game being played, players can send each other costless messages (*cheap talk*) about their intentions to play particular strategies. If only one of the players is allowed to send a message, we call it one-way communication (1W) and if both players are allowed to send messages, then we call it two-way communication (2W). In classical game theory, cheap talk is believed by one's opponents if it is in the interests of a player to honor their promises. The role of 1W and 2W is explored in Cooper et al. (1989, 1993, 1994). We report below the results of these experiments, summarized in Cooper et al. (1994). Consider the following battle of sexes game.

	1	2
1	0, 0	200, 600
2	600, 200	0, 0

When this game is played, respectively, under one-way and two-way communication, then denote this game as BoS-1W and BoS-2W.

We already know from Section 12.4.7 that in BoS, the coordinated outcomes, either (2, 1) or (1, 2), were achieved in 41% of cases. In BoS-1W, the coordination rate is 96%, while in BoS-2W, it is 58%. Furthermore, when the row player sends out a cheap talk message, in BoS-1W, 95% of the coordination is on (2, 1), which is player 1's preferred equilibrium. In BoS-2W, both coordination equilibria are played with similar frequencies.

These results suggest that 1W works brilliantly to create almost perfect coordination but 2W is relatively less successful. The reason is that, in 2W, players announced their most preferred strategies (both players announced strategy 2). This was less successful in fostering cooperation. However, in 1W, the row player, by announcing his most preferred strategy, most likely induced an *anchoring of beliefs*, so the equilibrium (2, 1) tended to be played 95% of the time.

Cooper et al. (1992) consider a simple coordination game (SCG); the strategic form is shown in Figure 12.18. The two pure strategy Nash equilibria are (1, 1) and (2, 2). The strategy profile (1, 1) is also the risk dominant equilibrium.

The results for SCG are as follows. In the absence of any communication, players mainly play the risk dominant equilibrium (1, 1). In the presence of one-way communication (1W), the

	1	2
1	800, 800	800, 0
2	0, 800	1000, 1000

Figure 12.18 A simple coordination game (SCG).

Source: Cooper, R., DeJong, D. V., Forsythe, R., and Ross, T. W., "Communication in coordination games," *Quarterly Journal of Economic* (1992) 107(2): 739–71, by permission of Oxford University Press.

equilibrium (2, 2) arises more frequently (53% of the time). However, two-way communication (2W) works the best. The Pareto dominant equilibrium (2, 2) arises 97% of the time, presumably because two-way communication serves to mutually increase the confidence of players about the intent of the other player, overriding the risk dominant equilibrium (1, 1).

12.4.9 Historical accidents and choice among coordination equilibria

In the presence of multiple equilibria, the chosen equilibrium may depend on the history of the game. Van Huyck et al. (1997) explore this idea in the context of the *continental divide game*, a static game of full information in which players simultaneously choose their actions.⁵¹

Suppose that there are n players and each chooses some action s_i , $i = 1, 2, \dots, n$. Let the profile of actions chosen by the n players be $s = (s_1, \dots, s_n)$. Denote the median action by M . The payoff of each player $i = 1, 2, \dots, n$ is given by

$$\pi(s_i, M) = aM - b[s_i - (M)^{1/3}]^2 + c; \quad a > 0, b > 0. \quad (12.7)$$

Consider the special case where $a = 26$, $b = 40$, $c = 86$, and players $i = 1, 2, \dots, n$ choose an action s_i from the finite set $\{1, 2, \dots, 14\}$. The resulting payoff matrix is shown in Table 12.17; the payoff of a player in any cell corresponds to a particular action chosen by the player and the median action chosen.

Focus on the two shaded parts of the payoff matrix. When the median, M , lies between 1 and 7, choosing an action s_i between 1 and 7 (rather than 8 to 14) gives any player a higher payoff. Conversely, when the median lies between 8 and 14, any player receives a higher payoff from choosing an action between 8 and 14 (rather than 1 and 7).

Players choose their actions simultaneously, so they must form beliefs about the actions of others in order to guess the likely median. Since players are ex-ante identical and have identical strategy sets and payoff functions, we look for a symmetric Nash equilibrium in which $s_i^* = d \in \{s_1, \dots, s_n\}$ for $i = 1, 2, \dots, n$, so $M = d$. Thus, we are interested in finding a value of d such that $\pi(d, d) \geq \pi(s_i, d)$ for all i and s_i , where π is defined in (12.7). The solution can simply be read off from Table 12.17. There are two possible solutions, shown by the action–median pairs (3, 3) and (12, 12) with respective payoffs equal to 60 and 112 (check that each solution is a symmetric Nash equilibrium).

Suppose that the continental divide game is played several times. Let the initial median, M , be between 1 and 7. In this case, it is a best response for all players to play an action between 1 and 7. Hence, over time, play is expected to converge to the action–median pair (3, 3). Analogously if the first round median, M , is between 8 and 14, play in subsequent rounds is expected to converge to the action–median pair (12, 12). Figure 12.19 bears out this intuition. All play that begins above the dotted line (*separatix*), in Figure 12.19 converges to a median of 12 over the 15 periods of the experiments conducted in groups of 7 each. Conversely, all play that begins below the *separatix* converges to a median of 3 over the 15 periods.

These results make a powerful case for the role of history in choosing among multiple coordination equilibria. Equilibrium analysis in traditional game theory assumes that play instantly converges to one of the two equilibria. Van Huyck et al. (1997) show that their results are

⁵¹ The term *continental divide* refers to a “divide” (typically a raised partition along the terrain) such that if a drop of water falls on either side of the divide it travels in opposite directions, eventually reaching different bodies of water such as rivers and oceans.

Table 12.17 Payoff matrix for the continental divide game.

		Median choice, M													
		1	2	3	4	5	6	7	8	9	10	11	12	13	14

consistent with two kinds of behavioral models of learning. (i) Models of *myopic best response dynamics* in which players best respond to the observed median in the previous period. (ii) Models of *fictitious play* in which players best respond to the observed frequency of the historical medians. These models are considered in Part 5.

12.4.10 Financial incentives and coordination

Suppose that we have a history of coordination failures in an organization. Brandts and Cooper (2006) consider how financial incentives could be used to overcome such coordination failures. They use bonuses as a particular example of financial incentives in a *corporate turnaround game*. There are four employees and one manager in the game, representing a corporation that has a history of coordination failures. In the experiment, the experimenter plays the role of the manager and the subjects play the role of the employees.

The manager starts off by announcing a fixed wage, W , and a credible performance-contingent bonus, $B \in \{6, 8, 10, 14\}$. Given W and B , each employee simultaneously chooses effort $s_i \in \{0, 10, 20, 30, 40\}$. The production technology is described by a *weak link minimum effort game*, in which the minimum effort level of a team member is decisive for the team outcome. Denote the minimum effort level of the employees by $\theta = \min \{s_1, s_2, s_3, s_4\}$. The payoffs of the firm, π_F , and the workers, π_i , $i = 1, 2, 3, 4$, are respectively given by the following expressions.⁵²

$$\pi_F = 100 + \theta(60 - 4B). \quad (12.8)$$

$$\pi_i = 200 - 5s_i + \theta B. \quad (12.9)$$

An increase in the minimum effort level benefits workers and firms. Each worker derives disutility from effort. Suppose that initially there are coordination failures, for instance, all employees choose zero effort level, $s_i = 0$. Let $B = 6$ and suppose that employee i contemplates an increase in own effort level from $s_i = 0$ to $s_i = 10$. Denote by p the probability that the minimum effort level of the remaining three players is also at least 10. Then, using (12.9), employee i prefers to increase the effort level from $s_i = 0$ to $s_i = 10$ if $200 < 200 - 50 + p \times 60 + (1 - p) \times 0 \Leftrightarrow p \geq 0.83$. Thus, the barrier to eliciting coordination is very high and, in the absence of some sort of “big push,” coordination is unlikely. The barrier is somewhat reduced with a higher bonus rate. For instance, for $B = 14$ we require $p \geq 0.36$. So we expect effort to be increasing in the bonus rate.

In the experiments, subjects played 30 rounds with the same set of players. For the first 10 rounds, $B = 6$. The expectation, given the results from other weak link games, is that coordination failures will arise. The bonus rate is then varied over the next two blocks of 10 rounds each. From rounds 11–20, the bonus rate was increased, while from rounds 21–30 it was cut back. In each block of 10 rounds, subjects are told of the bonus rate that applies to that block of 10 rounds, but not to future blocks. As expected, the minimum effort is low for the first ten rounds; $s_i = 0$ for 71% of the observations and the average θ over the 10 rounds is 5.71. Figure 12.20 shows the minimum effort over rounds 11–20 for various bonus rates.

The findings for rounds 10–20 are as follows.

⁵² The payoffs are given in an experimental currency, pesetas, such that 500 pesetas equalled either 1 dollar or 1 euro.

Figure 12.20 Average minimum effort levels over rounds 11–20 for different treatments.

Source: Brandts and Cooper (2006) with permission from the American Economic Association.

1. An increase in B leads to an increase in the minimum effort level. This increase cannot be ascribed to simply starting the second block of 10 rounds because with an unchanged bonus $B = 6$, the minimum effort does not change. By rounds 16–20 the minimum effort level stabilizes with the new bonus rate but at a higher level.
2. There is no monotonic relation between minimum effort and the magnitude of the bonus rate. Over rounds 16–20, the bonus levels $B = 8$ and $B = 10$ elicit very similar minimum effort levels, while $B = 14$ elicits the lowest minimum effort level. Thus, what seems to be important is the presence of the bonus, rather than its rate.
3. Examining data at the level of individual employees enriches the picture. In the experiments, subjects received feedback on their effort levels, the minimum effort level, and the effort levels of others in the past. Can sterling efforts on the parts of some players rub-off on others in subsequent rounds? Initially, there is only a modest increase in effort after an increase in B . Gradually, however, the groups bifurcate into two types. Define an individual as a strong leader if he/she jumps up two levels of effort over rounds 10 to 11. There is strong evidence that groups that had a larger number of strong leaders had much higher minimum effort levels.

Finally, over rounds 21–30, the increase in bonus that took place over rounds 11–20 is withdrawn. Whilst this reduces effort levels, interestingly, on average, the effort level does not reduce to the level of rounds 1–10. Indeed, in some firms there is hardly any change in the effort level but in others there is a drop.

12.4.11 *Loss aversion and coordination*

Cachon and Camerer (1996) explore the role of loss aversion as a selection principle in coordination games. They use the median action games of Van Huyck et al. (1991, 1993) that we have

Table 12.18 A median action game (payoffs in cents).

		Median action M						
		1	2	3	4	5	6	7
Your choice of action s_i	1	140	150	140	110	60	−10	−100
	2	130	160	170	160	130	80	10
	3	100	150	180	190	180	150	100
	4	50	120	170	200	210	200	170
	5	−20	70	140	190	220	230	220
	6	−110	0	90	160	210	240	250
	7	−220	90	20	110	180	230	260

Source: Cachon and Camerer (1996).

already considered above. In particular, they consider the payoff matrix (with payoffs denominated in cents), shown in Table 12.18.

The payoffs corresponding to any combination of own action and the median action are given in the appropriate cells. Actions of players are allowed to be integer values between 1 and 7. Using arguments analogous to those in Section 12.4.3, all of the elements along the diagonal constitute distinct symmetric pure strategy Nash equilibria. The Pareto optimal outcome is for each player to choose the highest action, $s_i = 7$ for all i . Recall from Section 12.4.3 that we observed coordination failures (the first round median is 4–5) and there is history dependence (after repeated play, the actions converge to the first round median). Indeed, history dependence might itself be considered to be a selection principle.

Recall the intuition behind the effect of *outside options* based on forward induction in Section 12.4.7 above. Suppose that in the spirit of forward induction, subjects are charged a fee of 225 cents to play the game. Subtracting 225 from each entry in Table 12.18, the play of any of the actions 1 through 4 results in a sure loss, irrespective of the median. How should players be expected to respond? Cachon and Camerer (1996) propose *loss aversion* as a selection principle.⁵³ On p. 167 they describe it as follows: “The loss-avoidance principle is that players do not pick strategies that result in certain losses for themselves, if other ‘equilibrium’ strategies are available. People only pick, and expect others to pick strategies that might result in a gain.” The loss avoidance principle would then imply that players neither play strategies 1–4, nor do they expect others to play them. Thus, only strategies 5–7 should be observed in equilibrium.

Assume now that players must pay a fixed fee to play the game with payoffs prior to paying the fee given in Table 12.18. Consider two conditions.

1. Opt-out condition: In this condition, players can either pay the fee of 225 and play the game, or opt-out by not paying the fee, in which case they get nothing.
2. Must-play condition: In this condition, subjects cannot opt out and must play the game after paying the fee.

Forward induction has no bite in the must-play condition. Once an individual has paid a fee in this condition, it signals nothing about the individual’s subsequent intentions. However, forward

⁵³ See Part 1 for a detailed discussion of loss aversion. Essentially it implies that losses bite more than equivalent gains. In the experiments of Kahneman and Tversky (1979), on average, losses bite approximately 2.25 times more than equivalent gains. However, the estimates of loss aversion vary, depending on the context.

	R	S		R	S		R	S
R	7, 7	1, 5	R	5, 5	-1, 3	R	1, 1	-5, -1
S	5, 1	5, 5	S	3, -1	3, 3	S	-1, -5	-1, -1
High payoff game (H)			Medium payoff game (M)			Low payoff game (L)		

Figure 12.21 Three equivalent stag-hunt games.

Source: "Payoff levels, loss avoidance and equilibrium selection in games with multiple equilibria: an experimental study," Feltovich, Nick, Atsushi Iwasaki, and Sobei H. Oda, *Economic Inquiry* 50: 932–52. Copyright © 2011 Western Economic Association.

induction has bite in the opt-out condition. A player who pays a fee of 225 cents in the opt-out condition must then expect to receive a payoff greater than 225 cents, which coordinates actions to the subset of actions 5–7. Loss aversion, however, has bite in both conditions (assuming no changes in reference points). According to the loss-avoidance principle, subjects will not choose or expect others to choose actions that result in losses. The two main results are as follows.

1. In the opt-out condition, coordination improved once the opt-out was introduced. This could be due to both loss aversion and forward induction.
2. In the must-play condition, coordination also did improve. Since forward induction has no bite in this condition, the improvement must be due to loss aversion.

In conjunction, these results imply that some of the improved coordination that has been ascribed to forward induction is due to loss aversion. The authors conclude that loss aversion is an effective selection principle in this class of games.

Feltovich et al. (2012) consider three classically equivalent versions of the stag-hunt game, shown in Figure 12.21. The original game (H) is shown in the left panel. The medium payoff game (M) in the middle panel is derived by subtracting 2 from each payoff in the game H. The low payoff game (L) is derived by subtracting 6 from each payoff in the game H.

Each of the games has two pure strategy Nash equilibria (R, R) and (S, S). There is also a mixed strategy Nash equilibrium in which both players choose R with probability $2/3$. The equilibrium (S, S) is risk dominant and involves the play of the secure option, R. The equilibrium (R, R), on the other hand, is payoff dominant. Classic game theory does not predict any difference between the outcomes of these games.

Feltovich et al. (2012) distinguish between *certain-loss avoidance* and *possible-loss avoidance*. Possible-loss avoidance is invoked by the play of strategy R in game M, while certain-loss avoidance is invoked by the play of strategy S in the game L. Thus, certain-loss avoidance arises when one receives a negative payoff, irrespective of the strategy of the opponent, while possible-loss avoidance arises when not all payoffs corresponding to a strategy are negative. *Loss avoidance* may then be considered to be an overarching criterion that includes these two sub-cases.

If loss avoidance has bite, then we have the following two predictions. (1) Relative to game H, we should observe a lower incidence of the play of strategy R in game M (possible-loss avoidance). (2) Relative to game H, we should observe a lower incidence of the play of strategy S in game L (certain-loss avoidance).

In all treatments, each of the three games was played in a within-subjects design. Treatment O is the only treatment in which each game was played once. Subjects played 40 rounds of each of the three games in the remaining three treatments. In treatment C, there was complete information about the games. In two further, limited information treatments, F and R, the payoff matrix was not revealed to the subjects but subject pairs were fixed (treatment F) or randomly matched (treatment R) in each round. In treatments F, R, at the end of each round, subjects were told of

their payoffs and the strategy chosen by the opponent; over repeated rounds, subjects could figure out the payoff matrix.

The two main findings in the experiments are as follows. First, both predictions are verified. In particular, in all treatments, there is a higher incidence of the play of strategy R in game H relative to game L. In game L, and in the two limited information treatments, respectively, treatments R and F, the risky action R is played 74.6% and 49.9% of the time. The corresponding figures for game H are 20.3% and 44.6%. In treatment C, the strategy R is played 88.9%, 84.0%, and 79.0% of the time, respectively, in games L, H, and M. Overall, certain-loss avoidance is more prevalent in the data as compared to possible-loss avoidance. Second, loss avoidance has increasing bite as the game is played repeatedly over several rounds, revealing a role for subject experience.

12.4.12 Achieving coordination with gradual growth in group sizes

There is a view that coordination seems harder to achieve in larger groups relative to smaller groups. A nice summary of the evidence for the *minimum effort weak link game*, for fifth round choices of the players, is given in Table 12.19 from Weber (2006). Consider the game in Section 12.4.4 where the action of players is a choice $s_i \in \{1, 2, \dots, 7\}$ and the payoffs depend on the chosen action and the minimum action in the group. The coordinated play of 7, the highest action, is Pareto optimal, while for a given s_i , the worst outcome for player i occurs when the group minimum is the lowest action, 1.

For group sizes of 2, Van Huyck et al. (1990) find a high degree of coordination (86% play 7). However, as group sizes increase (even to size 3) there is a rapid drop in the coordination rate and for group sizes of 8 or more, the minimum for the fifth period, averaged across players/sessions, is the worst possible outcome, i.e., the play of action 1.

Weber (2006) conjectures that in real life, there must be a lot of coordination in large groups such as firms and communities. So how do large groups achieve coordination? The intuition in this paper is that successful groups grow gradually from a small enough size where cooperation might already be existent. The norm of cooperation is then learnt by successive entrants, who also cooperate.

In order to test this intuition, he runs three kinds of sessions. In the control session, 12 subjects played the weak link game for 12 periods. In the remaining two sessions, the *history* and the *no-history* sessions, groups were grown gradually from size 2 to size 12 across 22 periods. These two

Table 12.19 Distribution of fifth period group minimum in various minimum action games.

growth sessions started with only 2 players who played the weak link game initially for 7 periods. Then, additional individuals were added to the group, in a pre-announced and commonly known manner, until there were 12 individuals in the group by the last period. In the history session, entrants could observe the history of the group, while in the no-history session, they could not.

The results are as follows. First, the minimum action fell to zero in all five control groups with a group size of 12; this replicates earlier findings. Second, in the history and no-history sessions, small groups, of size 2, were able to coordinate successfully. Successful coordination is defined as the following condition: Prior to the growth of the group size, in all but one session, groups must have achieved the Pareto optimal outcome, of a group minimum of 7, for at least two consecutive periods. Third, it was extremely difficult to produce successful coordination even with good histories, i.e., those designed to produce coordination. For three of the history groups, by the time the groups achieved full size, the group minimum was the worst possible action, i.e., 1. However, in three history groups, a high level of coordination was achieved and the minimum stayed at the Pareto optimal level of 7 as the group expanded. Fourth, growing groups never produce coordination in the no-history condition. Thus, the success of “growing coordination” in the lab is mixed and depends on very specific conditions.

One might wish to see if people achieve greater coordination in one game, having successfully achieved coordination in another game, where, possibly, it was easier to achieve coordination. These portability issues are considered by Cason et al. (2012) who consider two games.⁵⁴ A median action game, in which coordination is easier to achieve, and a minimum action game in which coordination failures are more widespread. The authors define the concept of a *behavioral spillover*, which occurs if observed coordination in a game is higher when played in a sequence with another game rather than played on its own. Such spillovers can be positive or negative.

A possible application of these ideas is that firms may wish to allocate sequential tasks in order to maximize the degree of cooperation among the team members. The authors also wish to examine the effects on cooperation of stable groups, relative to groups whose members change randomly. For instance, Duffy and Ochs (2009) show that in contrast to random matching of opponents, the cooperative outcome in a prisoner’s dilemma game is more likely to emerge with a stable partner, which facilitates the development of a cooperative norm.

Cason et al. (2012) run four treatments. In SeqMin, the minimum action game is played for 10 periods, followed by 10 periods of the median action game. The treatment SeqMed reverses this order of play. In the treatment SeqMedDiff, the players are rematched after 10 periods, using a *perfect strangers matching protocol*.⁵⁵ In the treatment Sim, both games were played simultaneously. Table 12.20 shows the frequency of cooperation on the Pareto optimal allocation in the last round, round 10, in which each game is played.

The degree of cooperation reported in the median action game in these experiments (last column of Table 12.20) is unusually high relative to, say, Van Huyck et al. (1991) that was reviewed above. The most important result is evidence of behavioral spillovers. When the median action game precedes the minimum action game (SeqMed), there is much greater coordination in the minimum action game, relative to (i) playing the minimum action game on its own, or (2) simultaneously playing the two games (Sim).

⁵⁴ Other experiments have also noted such spillover effects of coordination; see, for instance, Van Huyck et al. (1991) and Camerer and Knez (2000).

⁵⁵ This protocol requires that no two players can be rematched together after having been previously matched once.

Table 12.20 Frequency of Pareto optimal coordination in period 10.

Treatment	Minimum action game	Median action game
SeqMin	10%	80%
SeqMed	80%	90%
SeqMedDiff	60%	100%
Sim	27%	73%

Source: Cason et al. (2012).

These results are in the spirit of Weber's (2006) findings. Successful experience of coordination (in the median action game) gives rise to behavioral spillovers that lead to greater coordination in the minimum action game. Indeed, even in the perfect strangers treatment (SeqMedDiff), there is greater cooperation in the minimum action game relative to the case where the minimum action game is played first (SeqMin). The transmission mechanism for behavioral spillovers is less clear. The authors construct measures of entropy that relate the cognitive ease of playing various games and advance this as a possible factor. Future research can fruitfully explore these issues further.

12.4.13 Intergenerational advice and coordination

We have seen above that in weak link games, unless groups are very small (say, size 2), the common finding is that coordination is hard to achieve. Chaudhuri et al. (2009) test an intergenerational version of the Van Huyck et al. (1990) model in which each generation can pass on some advice to the succeeding generation. The hope was that the cooperative outcome could arise with sufficient intergenerational advice, i.e., generations would, so to speak, *talk themselves to efficiency*.

Groups of 8 subjects play the minimum effort game for 10 periods. They are then replaced by their laboratory descendants who play for another 10 periods and so on. Several variants of these games were considered.⁵⁶ Game 1, the *replicator or no-advice game*, is as in Van Huyck et al. (1990), except that there are 8 subjects instead of 14–16 and no intergenerational advice is allowed; this is referred to as the VBB game (after the names of the authors). Game 2, the *progenitor game*, is a game played by a group of 8 subjects for the first time, with no advice. In Game 3, the *advice plus history game*, six generations played the game; each generation played the game for 10 periods. In this game, each subject could (1) view the history of all predecessors in all of his/her generations, and (2) receive *private* advice from the immediately preceding generation. Advice took the form of free-form messages. The incentive to provide advice arose from making the payoffs of each generation depend on the payoffs of the next generation. Game 4, the *advice only game*, is identical to Game 3, except that subjects cannot observe the history of the game. Game 5, the *public advice game*, is the most important for the results. This game was run for nine generations. The first generation in Game 5 received advice from the progenitor generation of Game 2. The first five generations of Game 5 played the *public advice with almost common knowledge condition*.⁵⁷ This took the form of advice from previous generations printed on pieces of paper that were available to all

⁵⁶ We mainly describe the results from Block I games. In Block II games, the authors also controlled for the quality of advice given.

⁵⁷ The authors use the *almost common knowledge* concept based on the idea of a common p -belief in Monderer and Samet (1989).

Figure 12.22 Minimum action chosen under different treatments in Block-I games.

Source: "Talking ourselves to efficiency: coordination in inter-generational minimum effort games with private, almost common and common knowledge of advice," Chaudhuri, Ananish, Schotter, Andrew, and Sopher, Barry, *Economic Journal*, 119: 91–122. Copyright © 2008 The Authors. Journal compilation © Royal Economic Society 2009.

subjects. All subjects were aware of this, but did not know how carefully, if at all, other subjects read the pieces of paper. The last four generations in Game 5 played the *public advice with common knowledge condition*. This was achieved by reading aloud the advice from previous generations.

The results are shown in Figure 12.22 and can be summarized as follows. First, the results of Game 1 are similar to the results of Van Huyck et al. (1990), except that there was an even lower level of coordination. The introduction of purely private advice, in Game 4, made matters even worse relative to Game 1, and relative to the Van Huyck et al. (1990) results. Game 3, the advice plus history game, elicits slightly more coordination. In the public advice game with almost common knowledge, there is some evidence of higher coordination in the initial generations, however, the minimum drops to a low level. Coordination levels improve significantly when the public advice game with common knowledge is introduced in generation 6. This immediately increases the group minimum action to 7 for all 10 rounds. In none of the subsequent generations/rounds did the minimum fall below 5 and was at the Pareto optimal level in 30 out of 40 rounds.

In Block II games, the same games, 1 through 5, are run, however, the quality of advice is controlled. In these games, the authors find a quality threshold. If advice is sufficiently exhortative, public, and exceeds the quality threshold, unanimously for all subjects, then the efficient outcome (a minimum of 7) is highly likely to be achieved.

The role of intergenerational advice has also been examined by Schotter and Sopher (2003, 2007). Schotter and Sopher (2003) consider the role of intergenerational advice in the following BoS game.

	1	2
1	150, 50	0, 0
2	0, 0	50, 150

The row and the column players have identical strategies, 1 and 2. There are two pure strategy Nash equilibria (1, 1) and (2, 2). There is also a mixed strategy equilibrium, which we ignore. A

baseline, *advice plus history*, treatment is run for 81 generations. Each generation plays the BoS game once and passes on advice, both in terms of the choice of strategy and free-form advice, to the succeeding generation. The incentive for providing advice arises because payoffs of one generation are made conditional on the payoffs of the next generation. Subjects in this treatment can also examine the history of play of all preceding generations.

When the baseline treatment had run for 52 periods, three further continuation games were run. In one, the baseline treatment was allowed to run for 29 more periods (till period 81). The remaining two continuation games were called Treatment I and Treatment II. Treatment I, the *advice only treatment*, begins with a history of 52 periods of play of the baseline treatment and then continues for 81 more periods. In this treatment, advice is offered to successive generations, but subjects are not allowed to view the history of the game. In Treatment II, the *history only treatment*, played for 66 periods (after a history of 52 periods of the baseline game), subjects could not seek any advice from the previous generation but could view the history of the game.

The results are shown in Figure 12.23 for the time periods following the 52 periods for which the baseline treatment had already run. In each treatment, we get *punctuated equilibria*. Punctuated equilibria are considered in Part 5. For the moment, these are equilibria in which a convention seems to get established for some time, only to disappear and then be re-established again. Interestingly, when a convention gets established, some generational advice comes along, suggesting a departure from the convention. At other times, once a convention is established, advice comes along to adhere to it, but such advice is often not followed.

The greatest success in achieving an equilibrium outcome arose in the baseline treatment (advice plus history); coordination is observed 47 times out of 81. History-only (Treatment II) is the least successful in eliciting a coordinated equilibrium; 19 out of 66 times and a continuation probability of the equilibrium of 0.315. Advice-only (Treatment I) did better than Treatment

II but worse than the baseline treatment. A coordination equilibrium was achieved in Treatment I in 39 out of 80 times with a continuation probability of an equilibrium equal to 0.512.

12.4.14 *External arbiter recommendations*

In each of the Nash equilibria in a coordination game, conditional on the play of the other players, it is a best reply for each player to play their part of the equilibrium strategy profile. Hence, external recommendations of an arbiter to players to play their part of the equilibrium strategy profile should be self-enforcing. Van Huyck et al. (1992) perform experiments to test this conjecture. They consider the three coordination games shown in Figure 12.24.

In game A, all coordination equilibria give identical payoffs. In game B, the coordination equilibrium (1, 1), is payoff dominant. In game C, all three equilibria give the same aggregate payoff but the coordination equilibrium (2, 2) is the most equitable. In game A, whenever the external arbiter suggested the play of any equilibrium, nearly 100% of the subjects complied with the recommendation. However, in games B and C, the arbiter's recommendations can be in conflict with the two focal principles of payoff dominance (game B) or equality (game C).

When the recommendations were in conflict with these two focal principles, they were ignored by a majority of the players. In game B, for instance, only 48% of the players complied with a recommendation to play strategy 2 and an even lower percentage, 38%, with a recommendation to play 3. In game C, in the absence of the recommendation, most subjects (82%) chose the equitable outcome (2, 2). When any of the inequitable outcomes was recommended, the compliance rate was less than 50%. Thus, in the presence of multiple equilibria, recommendations to play a particular Nash equilibrium are self-enforcing only if they do not conflict with some other salient principle, in this case payoff dominance and equity.

12.4.15 *Communication, experience, and coordination*

Brandts and Cooper (2007) and Cooper (2006) examine the role of communication and experience in the *corporate turnaround game* described in Section 12.4.10. This is a *weak link game* in which a manager interacts with four employees and offers them a fixed wage and variable levels of bonus in different treatments. The payoffs of the workers depend on the wage, bonus, the actions that they take, and also on the minimum action taken by any member in the group. Starting from a history of coordination failures, and, typically a low bonus level, can the manager take actions to turn around his company?

Brandts and Cooper (2007) modify the corporate turnaround game to include the possibility that (i) the manager sends messages to the workers (one-way communication), and (ii) the manager and the workers both send messages to each other (two-way communication). They also allowed for the possibility of a computer replacing the human manager in order to check if coordination is particularly enhanced by human to human contact.

Figure 12.25 Average minimum effort in different treatments and rounds.

Source: "It's what you say, not what you pay: an experimental study of manager-employee relationships in overcoming coordination failure," Brandts, Jordi and David J. Cooper, *Journal of the European Economic Association*, 5: 1223–68. Copyright © 2010 John Wiley and Sons.

The results are shown in Figure 12.25 that plots the average minimum effort for different rounds/treatments. All graphs begin from round 10; the minimum effort prior to round 10 is zero, i.e., there is a history of coordination failures. The computer-manager and the no-communication treatments are statistically indistinguishable and lead to low effort levels. Communication enhances effort and two-way communication is more effective in eliciting higher effort than one-way communication. Incentives in the form of bonuses enhance effort; however, communication is even more effective in eliciting effort. Hence, the title of the paper, "It's what you say not what you pay."

The authors conjecture that communication is cognitively more salient relative to bonuses. It may be more cognitively taxing to infer that higher bonuses are paid in the expectation of higher effort and that all other workers do interpret bonuses in the same manner. The exact form of communication that enhances coordination is surprisingly simple: request more effort, point out the mutual benefit of higher effort, and imply that employees are well paid. Insofar as the mutual benefits are financial, the communication strategy seems to stress financial incentives.⁵⁸

In an artefactual experiment, Cooper (2006) replicates the Brandts and Cooper (2007) experiments for experienced managers taking the executive MBA course.⁵⁹ Their performance in a

⁵⁸ The role of communication in this study ties in with results from other work in median action games, e.g., Blume and Ortmann (2007). However, one main difference, other than the application to the corporate turnaround game, is that in Brandts and Cooper (2007), communication is considered in conjunction with financial incentives.

⁵⁹ All managers have at least ten years of work experience of which at least five years were in a supervisory role. The average annual earning of a manager is in excess of \$120,000.

Figure 12.26 Average minimum effort level in different treatments and rounds.

Source: Cooper (2006).

corporate turnaround game, that has a history of coordination failures, is compared with the performance of undergraduate students. Feasible bonus levels, B , are restricted to the set of integers from 6 to 15, and the effort levels s_i are chosen from the set $\{0, 10, 20, 30, 40\}$, as in Section 12.4.10.

The results are shown in Figure 12.26 for the case of firms where, in round 10, there was coordination failure in the sense that the minimum effort level was 0. These results serve two purposes. First, they increase confidence in the external validity of the Brandts and Cooper (2007) experiments. From Figure 12.25, following a history of coordination failures, the managers achieve greater coordination slightly faster than the undergraduate students. However, by approximately round 13, the undergraduates catch up with the managers and the average minimum effort levels of the two subject pools looks very similar and comparable. Second, the method of communication that is effective in the lab experiments is very similar to that in the artefactual field experiments.

12.4.16 *Coordination in repeated games*

Dal Bó and Fréchette (2011) conduct experiments on cooperation in repeated games. The game that they consider is shown in Figure 12.27. The parameter c takes three possible values, 32, 40, 48, and they consider two possible continuation probabilities of the stage game, $p = \frac{1}{2}$ and $p = \frac{3}{4}$. This gives six possible treatments, each corresponds to the pair (c, p) . Subjects are randomly rematched at the end of each round of the stage game in each treatment and there is no discounting.

The treatments are designed to test various hypotheses. For instance, in the treatment $(c, p) = (32, 0.5)$, the only possible equilibrium is (D, D). To see this, consider the grim strategy that if a player observes D once, then he always chooses D. If C is played every period, then, conditional on the opponent also playing C every period, the payoff of the player is $\frac{32}{1-0.5} = 64$. Suppose

	C	D
C	c, c	12, 50
D	50, 12	25, 25

Figure 12.27 A coordination stage game.

Source: Dal Bó and Fréchette (2011) with permission from the American Economic Association.

that one party plays C every period and the other defects to D for one period. The payoff of the defector, given the strategies, is $50 + 0.5 \left(\frac{25}{1-0.5} \right) = 75 > 64$. In all other treatments, cooperation can be sustained in the repeated game as an equilibrium outcome. Furthermore, the following cases also make (C, C) a risk dominant equilibrium of the stage game: $(c, p) = (48, 0.5)$, $(40, 0.75)$, $(48, 0.75)$.

The results are as follows. In the case $(c, p) = (32, 0.5)$, where cooperation cannot be sustained as an equilibrium outcome, the outcome (C, C) converges to very low levels as players gain experience in the game, which is in line with earlier results, e.g., Bereby-Meyer and Roth (2006). However, the other cases in which cooperation can be sustained as a subgame perfect outcome, do not necessarily produce greater cooperation as subjects learn with experience. Thus, a cooperative prediction is necessary but not sufficient to produce cooperation in repeated game experiments. It is also not necessary that cooperation increases with experience when the cooperative outcome is subgame perfect and also risk dominant at the same time.

Comparing relative cooperation rates in finitely and infinitely repeated games, an earlier literature concluded that the gains in terms of the cooperative outcome were small; see Roth (1995) for a summary of the evidence. Some later studies, such as Dal Bó (2005), find larger gains in cooperation. Other findings reveal the beneficial effects for the cooperative outcome of (i) the quality of public signals in infinitely repeated games with imperfect public signals (Aoyagi and Fréchette, 2009), and (ii) fixed matching relative to random matching of opponents (Duffy and Ochs, 2009).

12.5 Bargaining games

In this section, we consider several kinds of bargaining games, their theoretical framework, and the relevant empirical evidence. Section 12.5.1 considers normative bargaining games, inspired by the seminal work of Nash (1950b). Section 12.5.2 considers bargaining models using non-cooperative game theory that are based on sequential offers and counteroffers by players (Stähl, 1972; Rubinstein, 1982). We consider the cases of full information, and one-sided and two-sided asymmetric information. Section 12.5.3 considers non-standard theories that do not fit any of the two frameworks in Section 12.5.1, 12.5.2. Finally, in Section 12.5.4, we explore the pattern of search and lookups of subjects, using MOUSELAB software, when they play bargaining games with a view to inferring their cognitive processes.

12.5.1 Normative bargaining solutions

The Nash (1950b) bargaining solution is the leading normative model of bargaining in economics. We first outline the model and then consider empirical tests of its axioms and predictions. The main focus here is on unstructured bargaining.

Consider a bargaining game in which there are two players, 1 and 2. The set of feasible expected utility payoffs of the players is denoted by $S \subset \mathbb{R}^2$; a typical element of S is denoted by $x = (x_1, x_2)$, where $x_i, i = 1, 2$ is the expected utility of player i . The disagreement payoffs of the players should they fail to conclude an agreement are given by $d = (d_1, d_2) \in S$. The Nash bargaining solution easily generalizes to more than two players.

Definition 12.1 A bargaining problem is denoted by (S, d) such that (i) S is compact, convex, and bounded above, and (ii) there exists at least one element $x \in S$ such that $x_i > d_i, i = 1, 2$. Let B denote the set of all bargaining problems. The solution to any problem $(S, d) \in B$ is given by a function $f(S, d) : B \rightarrow \mathbb{R}^2$, where $f(S, d) \in S$.

In Definition 12.1, S is convex, so all linear combinations of the possible bargaining outcomes are feasible. The compactness of S holds if, for instance, the feasible outcomes consist of a finite number of distinct alternatives and lotteries over them (recall that elements of S are the pairs of expected utilities of the two players). Nash was interested in the solution, f , when the following axioms hold.

1. Pareto optimality: Let $z = (z_1, z_2) \in S$ be the solution to the bargaining problem (S, d) , i.e., $f(S, d) = z$. Then there does not exist an $(x_1, x_2) \in S$ such that $x_i \geq z_i, i = 1, 2$. Thus, the bargaining solution does not lead to an outcome that is less desirable for both players relative to another feasible outcome.
2. Symmetry: (S, d) is a symmetric bargaining problem if (i) $d_1 = d_2$, and (ii) if $(x_1, x_2) \in S$, then $(x_2, x_1) \in S$. For symmetric bargaining problems, if $f(S, d) = (z_1, z_2)$, then $z_1 = z_2$. Thus, if the players are identical for all relevant purposes, then so must be the solution.
3. Independent of irrelevant alternatives: Let $(S, d) \in B$ and $(T, d) \in B$ such that $T \subset S$. If $f(S, d) \in T$, then $f(S, d) = f(T, d)$. Thus, if the best outcome in (S, d) lies in the smaller set T , then the outcome is unchanged if we consider the more restricted bargaining problem (T, d) .
4. Independence of equivalent utility representations: Consider some $(S, d) \in B$ and $f(S, d) = (z_1, z_2)$. Now consider another bargaining problem $(S', d') \in B$ such that the relation between (S, d) and (S', d') is as follows.

$$S' = \{(a_1x_1 + b_1, a_2x_2 + b_2) : (x_1, x_2) \in S\}; d' = (a_1d_1 + b_1, a_2d_2 + b_2), a_1 > 0, a_2 > 0,$$

then $f(S', d') = (a_1z_1 + b_1, a_2z_2 + b_2)$. This is a reasonable property because points in S are pairs of von Neumann–Morgenstern utilities, which are invariant with respect to positive affine transformations.

Remark 12.1 From the fourth property, independence of equivalent utility representations, the knowledge of the utility level of the other player should not affect the bargaining outcome. This is because the utility of the other player is invariant with respect to a positive affine transformation.

Proposition 12.4 (Nash, 1950b): Consider the bargaining problem $(S, d) \in B$. There exists a unique solution, $f^*(S, d)$, that satisfies Properties 1–4, above. This unique solution is given by

$$f^*(S, d) = \arg \max_{x \in S, x > d} (x_1 - d_1)(x_2 - d_2). \quad (12.10)$$

Example 12.3 Consider a Nash bargaining game in which players share a fixed sum of money, M , so that for any $x = (x_1, x_2) \in S, x_1, x_2 \geq 0$, and $x_1 + x_2 = M$. Then, from

Proposition 12.4, we have $f_i^*(S, d) = d_i + \frac{M-d_1-d_2}{2}$, $i = 1, 2$. Each player gets his disagreement payoff plus a share of half the net surplus. Thus, a higher outside option, d_i , ensures a more favorable bargaining position for the player. This solution is often called a “split the difference” solution.

The key properties that determine the Nash bargaining solution are 3 and 4. Pareto optimality (Property 1) is not critical. Suppose that we replaced Property 1 by Property 5, below.

5. Strong individual rationality: Consider the bargaining problem $(S, d) \in B$ and its solution $f(S, d)$. Strong individual rationality requires that $f(S, d) > d$.

Proposition 12.5 (Roth, 1977): Consider the bargaining problem $(S, d) \in B$. There exists a unique solution, $f^*(S, d)$, that satisfies Properties 2–5, above. This unique solution is given by (12.10).

The next proposition shows that symmetry (Property 2) is fairly innocuous too.

Proposition 12.6 (Roth, 1978): Consider the bargaining problem $(S, d) \in B$. Then, any solution, $f^*(S, d)$, that satisfies Properties 3–5 is of the form

$$f^*(S, d) = \arg \max_{x \in S, x > d} (x_1 - d_1)^{\theta_1} (x_2 - d_2)^{\theta_2}; \theta_1 + \theta_2 = 2 \text{ and } \theta_1 > 0, \theta_2 > 0. \quad (12.11)$$

Comparing (12.10), (12.11), symmetry simply imposes the restriction $\theta_1 = \theta_2 = 1$. In the absence of symmetry, we can consider other interesting issues such as differential bargaining powers of the two players; these are captured by the relative sizes of θ_1, θ_2 .

From the discussion above, the Nash solution fundamentally relies on Properties 3 and 4. Hence, these properties have been the main focus of empirical work that we shall review below.

Consider now the implications of relaxing symmetry. Define the maximum possible payoffs of each player, m_i , $i = 1, 2$, while still restricting to the set S as follows.

$$m_1 = \max \{x_1 : x_1 > d, (x_1, x_2) \in S\}; m_2 = \max \{x_2 : x_2 > d, (x_1, x_2) \in S\}.$$

Proposition 12.7 (Raiffa, 1953): Consider the bargaining problem $(S, d) \in B$. Then any solution, $h(S, d) = z$, that satisfies Properties 1, 2, and 4 (but not 3), satisfies

$$\frac{z_1 - d_1}{z_2 - d_2} = \frac{m_1 - d_1}{m_2 - d_2}.$$

In Proposition 12.7, the non-unique solution has the property that the gains to the two players in the optimal solution, relative to the disagreement point, are in the same proportion as the maximum possible gains relative to the disagreement point.⁶⁰

Two early empirical studies of the Nash bargaining solution were conducted by Nydegger and Owen (1975) and Rapoport et al. (1977). Both allowed unstructured face to face bargaining. The monetary payoffs were interpreted as the utilities of the players and players knew their own and the other player's monetary payoff; this is the *full information condition*.⁶¹ Both studies rejected Property 4, independence of equivalent utility representations. The Nydegger and Owen

⁶⁰ Kalai and Smorodinsky (1975) showed that an extra property (individual monotonicity) ensures that the solution in Proposition 12.7 is unique.

⁶¹ This created obvious problems (see Remark 12.1) that were rectified later by Roth and Malouf (1979), see below.

results supported Properties 1–3. By contrast, the Rapoport et al. results rejected Property 1 and observed violations of Property 2, although these were not statistically significant (this study was not designed to test Property 3). Even though there were departures from the Nash bargaining solution towards the equitable solution, the Nash solution was able to predict which player would come out ahead, say, players with a higher disagreement payoff. Although not directly related to the Nash bargaining solution, the early studies by Siegel and Fouraker (1960) and Fouraker and Siegel (1963) also found a tendency for the outcomes of bilateral bargaining outcomes to be in the direction of payoff equality.

Early studies that used the *partial information condition* (players know their own payoffs only), however, confounded between monetary prizes and the utilities of the players, which did not allow for a clean test of the theory. Roth and Malouf (1979) solved this problem through a novel framework that we consider below. Suppose that (S, d) is defined in monetary units. So S is the set of feasible monetary payoffs and $d = (d_1, d_2)$ gives the monetary payoffs if there is disagreement. Consider the larger class of bargaining problems B^* in which S is compact but not convex. Since the elements of the set S are no longer von Neumann–Morgenstern utilities, Property 4 does not apply. Consider, therefore, an alternative property, Property 6.

6. Independence of ordinal transformations, preserving interpersonal comparisons: Consider a bargaining problem $(S, d) \in B^*$ with the solution $f(S, d) = (z_1, z_2)$. Let $(x_1, x_2), (y_1, y_2) \in S$. Consider the transformations t_1 and t_2 that satisfy the following two conditions.

$$\begin{aligned} t_i(x_1, x_2) &\geq t_i(y_1, y_2) \text{ if and only if } x_i \geq y_i, i = 1, 2. \\ t_1(x_1, x_2) - t_1(d_1, d_2) &\geq t_2(x_1, x_2) - t_2(d_1, d_2) \text{ if and only if } x_1 - d_1 \geq x_2 - d_2. \end{aligned}$$

Now consider a second bargaining problem $(S', d') \in B^*$ that is related to (S, d) through the transformations t_1 and t_2 , i.e.,

$$S' = \{(t_1(x_1, x_2), t_2(x_1, x_2)) : (x_1, x_2) \in S\}; d' = (t_1(d_1, d_2), t_2(d_1, d_2)).$$

Then we require the relation between the solutions to problems (S, d) and (S', d') to be

$$f(S', d') = (t_1(z_1, z_2), t_2(z_1, z_2)).$$

Proposition 12.8 (Roth and Malouf, 1979): *Consider a bargaining game $(S, d) \in B^*$ and suppose that Properties 1, 2, 3, 6 are satisfied. Then the unique solution to the problem is the equal gains solution, $f = E$ such that $E(S, d) = z$ where z is a Pareto optimal point in S that satisfies, for all other Pareto optimal points (x_1, x_2) in S the condition*

$$\min\{z_1 - d_1, z_2 - d_2\} > \min\{x_1 - d_1, x_2 - d_2\}.$$

From Proposition 12.8, the solution to the problem under monetary payoffs and Properties 1, 2, 3, 6 is Pareto optimal and it maximizes the minimum gain to any player, while restricting to the set of Pareto optimal outcomes. This is the sense in which it may be termed as an equitable solution. Unlike Property 4 on which the Nash bargaining solution is based, Property 6 allows interpersonal comparisons of payoffs.

The earlier experiments, reviewed briefly above, did not allow players to know the von Neumann–Morgenstern utilities of others. Rather, under conditions of full information, players simply knew each other's monetary payoffs. The experiments of Roth and Malouf (1979)

permitted players to know the utility of the opponents, corresponding to the monetary payoffs. It is worth spelling this out in some detail because it formed the template for work in unstructured bargaining in several important subsequent contributions.

The principle behind this is as follows. Consider three outcomes, x_1, x_2, x_3 and suppose that an individual reveals the following preferences: $x_1 \succeq x_2 \succeq x_3$. If a utility function u represents the preferences $\succeq$, then we must have $u(x_1) \geq u(x_2) \geq u(x_3)$. Since u is defined only up to an interval scale, we may normalize $u(x_1) = 1$ and $u(x_3) = 0$. Consider the lottery $L = (x_1, p; x_3, 1 - p)$. Then the expected utility of this lottery is $EU(L) = p$. Suppose that we could elicit the probability p such that the individual reveals that he is indifferent between L and $(x_2, 1)$. Then, we must have $u(x_2) = p$. Thus, if players can observe the relevant p for other players, they can observe the utility function of the opponent. This key insight was then used to design the following experiment.

Two players bargained over the probability, p , that they receive a (possibly non-identical) prize, in an unstructured manner. This took the form of bargaining over lottery tickets. The proportion of tickets that each player gets in the lottery bargaining, gives the probability of winning a prize. For instance, a player who successfully bargains for 65% of the lottery tickets wins his prize with probability 0.65. If players fail to reach an agreement, both get nothing, so $d = (0, 0)$.

There were two information conditions. In the *full information condition*, players knew their own and the opponent's prize, while in the *partial information condition*, they only knew their own prize. The full information condition satisfies Property 6 and the partial information satisfies Property 4. The two players played four games in sequence, shown in Table 12.21. In Games 2 and 4, player 2 is restricted to get no more than 60% of the lottery tickets, while in the other two games there are no such restrictions.

To apply the method outlined above, let $u(x_1) = 1$ be the utility from receiving own prize and $u(x_3) = 0$ be the utility from not receiving it. Then for any intermediate outcome (winning prize with probability p) the expected utility is p , which is independent of the size of the respective prizes of the players. Games based on such experiments are known as *binary lottery games* (Roth and Malouf, 1979; Roth et al., 1981).

Under each information condition, both players play the four games in Table 12.21. Hence, the feasible utility payoffs, $S \in B$, are identical in each information condition. The sample is quite small (11 pairs in the full information condition and 8 pairs in the partial information condition). However, the value of this exercise is to understand how one properly constructs the relevant hypotheses and predictions of the various bargaining models.

Table 12.21 Description of the four bargaining games. D is the percentage difference between the lottery tickets received by player 2 and player 1. M and SD are the means and standard deviations of D.

Game	Prizes for individual players (\$)		Maximum % of lottery tickets allowed for individual players		D under Full Information		D under Partial Information	
	Player 1	Player 2	Player 1	Player 2	M	SD	M	SD
1	1	1	100	100	0	0	0	0
2	1	1	100	60	-1.909	12.169	1.325	8.335
3	1.25	3.75	100	100	-34.600	19.277	2.500	4.629
4	1.25	3.75	100	60	-21.636	22.482	-2.500	4.106

Source: Roth and Malouf (1979).

The four main predictions are as follows.

1. Properties 1–4 predict an equal 50–50 split in all four games: By definition, Property 1 (Pareto optimality), is consistent with all possible division of the 100 tickets between the two players. Since Game 1 is symmetric (recall that $d = (0, 0)$), Property 2 (symmetry) requires that each player gets 50% of the tickets. Since, a 50–50 split is optimal in Game 1, it should also be optimal in the more restricted Game 2 (Property 3, independence of irrelevant alternatives). Property 4 (independence of equivalent utility representations) requires Games 1 and 3 to have identical outcomes (use $a_1 = 1.25$, $b_1 = 0$, $a_2 = 3.75$, $b_2 = 0$ and recall that disagreement payoffs are zero). By the same reasoning, Games 2 and 4 should have identical outcomes.

Define D as the percentage difference between the lottery tickets received by player 2 and player 1.

2. Given the first prediction, the Nash solution (Proposition 12.4) predicts $D = 0$ in all four games. However, under both information conditions, Raiffa's solution (Proposition 12.7) predicts $D = 0$ for Games 1 and 3 and $D = -25$ for Games 2 and 4. Raiffa's solution does not require Property 3 (independence of irrelevant alternatives), so the outcomes in Games 1 and 2 will be different. The outcome in Game 1 under Raiffa's solution, like the Nash solution, is a 50–50 split. Using Proposition 12.7, in Game 2, $\frac{m_1 - d_1}{m_2 - d_2} = \frac{m_1}{m_2} = \frac{100}{60} = 1.6667$. Since all lottery tickets must be used up, the ratio of prizes must be $\frac{z_1}{z_2} = \frac{62.5}{37.5} = 1.6667$. Thus, the predicted Raiffa solution for Game 2 is a split of the lottery tickets to players 1 and 2 in the respective percentages 62.5 and 37.5. So $D = 37.5 - 62.5 = -25$. Property 4 applies to Raiffa's solution, so Games 1 and 3 should have identical outcomes, and so should Games 2 and 4.
3. In the “partial information condition,” Games 1 and 3 should have the same Nash bargaining solution and so should Games 2 and 4: Property 4 requires that each player should know only their own utility function. Since the utility function of the other player is invariant with respect to positive affine transformations, the bargaining solution should not be sensitive to the knowledge that a player has of the other player's utility functions.
4. In the full information condition, the data should respect Properties 1–3 but not necessarily Property 4: In the full information condition, players share utility and monetary payoff information; the latter enables Property 6 to hold and the solution is as in Proposition 12.8. Thus, we expect the solution to be between the Nash outcome, f^* , and the equal gains solution E .

The results are shown in Table 12.21 (M denotes mean and SD denotes standard deviation of D). There is no variation in the results in Game 1; all 19 pairs come up with 50–50 splits in both information conditions. This is consistent with the Nash and Raiffa solutions.

In the *partial information condition*, based on a comparison of the mean outcomes for D , the outcomes in Games 1 and 3 are statistically indistinguishable and so are Games 2 and 4. This is consistent with the third prediction above; hence, there is strong confirmation for the Nash bargaining solution. Thus, as predicted, in the partial equilibrium condition, players go in the direction of equal splits of the lottery tickets.

In the *full information condition*, the outcomes in Games 1 and 3 are statistically different and so are the outcomes in Games 2 and 4. In the full information condition, players bargain in the direction of splitting lottery tickets in such a way that equalizes the expected monetary payoff from the prizes. Thus, the player with the smaller prize tended to get a larger share of the lottery

tickets. The set of feasible utility payoffs is unaffected by the two information conditions, yet the actual outcomes are very different, hence, empirical studies that do not differentiate between the two cases do not fully capture the complexity of this sort of bargaining.

A total of 99% of the bargaining outcomes were Pareto optimal under both information conditions (this supports Property 1). Property 3, independence of irrelevant outcomes, holds in the full information case but is not supported in the partial information case for Games 3 and 4. This means all games are statistically identical, which supports prediction 1 for the Nash solution.

A series of further experiments were then conducted by Alvin Roth and several co-authors to explore extensions of the framework described above. Roth et al. (1981) looked for sociological factors such as norms or conventions that may govern the bargaining outcomes, in addition to the standard factors considered by theory. They conjectured that these norms, if any, must relate to known objects such as money. However, for unfamiliar objects, such norms may not apply. Their unfamiliar object is an intermediate good, *chips*, that can be converted into money at rates that may or may not be mutually known to the players. The authors find that the results accord with their conjectures.

Roth and Murnighan (1982) find that the bargaining results are sensitive to the information possessed by players with different levels of payoffs. For instance, a critical determinant of their bargaining results is whether the player with the smaller monetary payoffs (there were two prizes, \$5 and \$20) knows the prizes of both players. When the player with the \$5 prize knew both prizes, the bargaining outcomes were mainly equal division of the lottery tickets or equal expected values. However, when the player with the \$5 prize did not know the other player's prize, then the distribution of agreements was unimodal at equal divisions of the lottery tickets. Results are also sensitive to whether information on payoffs is common knowledge or not. Disagreements increased when it was not common knowledge that the \$5 player knew both prizes, possibly for reasons to do with reciprocity and intentions. These results suggest that there are nuances in the data that are not captured by any of the existing models, yet among the ones that are available, the Nash bargaining solution does reasonably well.

Murnighan et al. (1988) find that the *risk attitudes* of players have an influence on the bargaining outcome. In the first stage, they elicit the risk aversion parameters of the players. In the second stage, players play the binary lottery bargaining game, above. When the disagreement payoffs were high, more risk averse players did better as compared to games in which the disagreement payoffs were low. The disagreements in the bargaining game were found to be increasing in the size of the disagreement payoff.

Roth et al. (1988) document a *deadline effect*. Most of the bargaining agreements occur close to the deadline for the conclusion of bargaining. They wished to test experimentally anecdotal and folk wisdom that is encapsulated in popular phrases such as "eleventh hour agreements." Clearly, field data would be very hard to obtain for such testing, however, this question can easily be explored using experimental data. Subjects were allowed to bargain for a maximum of 9–12 minutes; bargainers could also send messages to each other over computer terminals but were prevented from violating anonymity. If subjects could not reach an agreement in the allocated time, they received a payoff of zero. The results are shown in Figure 12.28. Most of the action happens in the last 30 seconds; 41% of the agreements are reached during this time. Breaking down the last 30 seconds into 5 second components, 53% of the agreements occur in the last 5 seconds. The classical axiomatic approaches do not have a role for deadline effects.⁶²

⁶² The authors conjecture possible theoretical directions in section IV of their paper.

Figure 12.28 Frequency of agreements and disagreements over the whole period (left panel) and in the last 30 seconds (right panel).

What accounts for the bimodal distribution of outcomes at the equal split and the equal expected levels? Could it be that players are trying to coordinate on focal bargaining outcomes, and can coordination failures be used to explain these results? Initial work by Roth (1985) was supportive of an implication of this hypothesis, namely, that disagreements between players should increase as the relative payoffs become more inequitable. However, a later attempt by Roth et al. (1988) shows that the results are not very supportive of this hypothesis (in fact they do not get a bimodal distribution of outcomes).

There is also a significant theoretical literature on coalitional bargaining that also fits here, but there is not enough experimental evidence yet to enable one to make an assessment of its importance.⁶³

12.5.2 *Positive bargaining solutions*

BARGAINING UNDER FULL INFORMATION

Most experimental tests of positive bargaining models have revolved around the following two-person, sequential, bargaining game in which players have self-regarding preferences. Time is divided into discrete periods $\{1, 2, 3, \dots, T\}$ with generic element t . The problem is to agree on the division of a pie of size c . Delaying agreements is costly, say, due to time discounting, or loss in production as in a labor dispute. The discount factors of players 1 and 2 are, respectively, $\delta_1 \in [0, 1)$ and $\delta_2 \in [0, 1)$; these capture the cost of delay.

Player 1 makes the initial offer in period 1 and offers in every odd period, while player 2 makes counteroffers in even periods. In any odd period, t , an offer by player 1 is a proposed division of the pie $(x_1, x_2) = (x, c - x)$. The offer is either accepted or rejected by player 2. If player 2 accepts, the game ends with respective payoffs $\delta_1^{t-1}x$ and $\delta_2^{t-1}(c - x)$. If player 2 rejects, then the game

⁶³ The interested reader can consult the recent survey by Bandyopadhyay and Chatterjee (2012) and follow up the references therein.

proceeds to the next time period, $t + 1$. Since $t + 1$ is even, player 2 makes a new offer; the game now proceeds as in round t with the roles of the two players reversed. If an offer made at time T is rejected, then both players get their *disagreement payoff* of 0 each. Such a game is often called a T period game; see Ståhl (1972) who initially considered this problem formally. The solution is by backward induction.

Example 12.4 When $T = 1$, we get the ultimatum game that is considered in Chapter 5. In this case, since players are assumed to have self-regarding preferences, player 1 makes the smallest possible offer to player 2, which is immediately accepted by player 2; if c is denominated in cents, then $(x_1, x_2) = (c - 1, 1)$.

Most experiments consider the cases $T = 1, 2$, and 3. Let us consider the cases $T = 2, 3$ first and assume that money is infinitely divisible.

Example 12.5 Let $T = 2$. At $t = 2$ player 2 knows that disagreement payoffs are zero, so player 1 will accept an offer of zero, thus, he makes an offer $(x_1, x_2) = (0, c)$. At $t = 1$, when player 1 makes an offer, he must offer at least $\delta_2 c$, thus, $(x_1, x_2) = (c - \delta_2 c, \delta_2 c)$, which is immediately accepted by player 2. This is the unique backward induction outcome. Notice that when $T = 2$, the bargaining outcome is predicted to be independent of δ_1 , which is a testable prediction; we report the empirical tests, below.

Example 12.6 Let $T = 3$. Using the same logic as in Example 12.5, at $t = 3$, player 1 offers $(x_1, x_2) = (c, 0)$, which is accepted by player 2. At date $t = 2$, player 2 offers $(x_1, x_2) = (\delta_1 c, c - \delta_1 c)$, which is accepted by player 1. At $t = 1$, player 1 offers $(x_1, x_2) = (c - \delta_2(c - \delta_1 c), \delta_2(c - \delta_1 c))$, which is immediately accepted by player 2. In addition to testing for the unique backward induction outcome, there are two further implications that can be tested when $T = 3$. (a) The unique outcome is influenced by the discount factors of both players, δ_1, δ_2 . (b) Comparing the outcomes for player 1 in the two cases, $T = 2$ and $T = 3$, player 1 receives an extra payoff of $\delta_1 \delta_2 c > 0$ when $T = 3$.

In each of the examples above, the subgame perfect outcome is Pareto optimal, which in the current context requires that no money is wasted. The fraction of the shared pie depends only on the delay costs.

Proposition 12.9 (Rubinstein, 1982): As $T \rightarrow \infty$, in the alternative offers bargaining game (described above), player 1 offers to player 2 the following split of the pie that is immediately accepted by player 2,

$$(x_1^*, x_2^*) = \left(\frac{1 - \delta_2}{1 - \delta_1 \delta_2} c, \frac{\delta_2(1 - \delta_2)}{1 - \delta_1 \delta_2} c \right).$$

From Proposition 12.9, when the discount rates are identical, $\delta_1 = \delta_2 = \delta$, the bargaining outcome is $(x_1^*, x_2^*) = \left(\frac{c}{1 + \delta}, \frac{\delta c}{1 + \delta} \right)$. In particular, when players are sufficiently patient, so that $\delta = 1$, then we get $x_1^* = x_2^* = \frac{c}{2}$. Thus, the Nash bargaining or cooperative solution and the alternating offers bargaining solution, or the non-cooperative solution, coincide in this case.

We have already described the results of the ultimatum bargaining game ($T = 1$) in Chapter 5. In particular, Güth et al. (1982) who conducted the first such experiments, found that the modal proposal of players who played the game for the first time was a 50–50 share.

These experiments led to a paper by Binmore et al. (1985) that generated some debate. They begin with the observation (p. 1178) that “The work of Güth et al. seems to preclude a predictive

role for game theory insofar as bargaining behavior is concerned. Our purpose in this note is to report briefly on an experiment that shows that this conclusion is unwarranted.” They studied a two-player game with $c = 100$ pence and $T = 2$. The size of the pie shrunk from 100 to 25 from period 1 to period 2, so, the implied discount factors are $\delta_1 = \delta_2 = 0.25$. Thus, the prediction (see Example 12.5) is that in period 1, player 1 offers (0.75, 0.25) in dollar terms, which is immediately accepted. Example 12.5 relied on money being infinitely divisible. If the smallest unit is a cent, then the prediction is that player 1 makes an opening demand of 0.74–0.76 dollars and player 2 accepts any demand by player 1 that is lower than 0.74 dollars.

There were two features in Binmore et al. (1985) that created subsequent controversy. First, they played two bargaining games that reversed the order of the players in the following manner. In game 1, subjects in their role as player 2 switched to being player 1s in game 2. However, in game 2, player 1s did not know that, in fact, they were not playing against anybody; the experimenters simply wished to observe their choices subsequent to the role reversal. Second, the authors gave explicit instructions to the players (in capitals) that “You would be doing us a favour if you simply set out to maximize your earnings.” Insofar as actual bargaining considerations may involve other factors, e.g., fairness concerns, this potentially reduces the validity of the results.

The results were as follows. In game 1, the results of Güth et al. (1982) were replicated; modal settlements were 50–50 and the predictions in Example 12.5 are rejected. In game 2, after the role reversals, the modal demand by player 1 was just below 0.75 dollars and in 30 out of 81 cases, the demands were in the interval [0.74, 0.76]. The authors took this as support for classical bargaining theory and concluded (p. 1179): “The results (shown in Table 1) indicate little support for the view that a substantial proportion of the population are ‘fairmen’ as opposed to ‘gamesmen.’”

Güth and Tietz (1988) responded by conducting experiments on two games, similar to those in Binmore et al. (1985) with (i) $\delta_1 = \delta_2 = 0.9$ and, (ii) $\delta_1 = \delta_2 = 0.1$. They allowed for role reversals among players 1 and 2, exactly as in Binmore et al. (1985). However, they omitted the instruction: “You would be doing us a favour . . .” Using Example 12.5, the prediction in the first game is that player 1 offers $(x_1^*, x_2^*) = (0.10c, 0.90c)$, which is immediately accepted by player 2. In the second game, the prediction is $(x_1^*, x_2^*) = (0.90c, 0.10c)$.⁶⁴ The average demand by the first mover in the two games is, respectively, 0.76c and 0.67c. Thus, not only were they unable to replicate the earlier results, the results did not support the theoretical predictions of the classical model. The authors conclude “Our main result is that contrary to Binmore, Shaked and Sutton, ‘gamesmanship’ is clearly rejected, that is, the game theoretic solution has nearly no predictive power.”⁶⁵

Ochs and Roth (1989) then conducted a series of careful experiments using a 4×2 design shown in Table 12.22. They varied the basic alternating offers bargaining game along two dimensions: heterogeneity in discount factors, and the number of time periods, $T = 2, 3$. The games are played over 10 rounds with different opponents. In the first column in Table 12.22 are the combinations of discount factors, δ_1, δ_2 , used in the four games.⁶⁶

In period 1, each chip is worth \$0.30 to each bargainer. In period 2, each chip is worth δ_1 (\$0.30) to player 1 and δ_2 (\$0.30) to player 2. In period 3, these respective values are δ_1^2 (\$0.30) and

⁶⁴ One difference from the strict sequential game experiments was that if player 2 rejected the initial offer from player 1, yet in the counter offer claimed less than the initial offer, then this was treated as a disagreement.

⁶⁵ Another follow-up study by Neelin et al. (1988) imposed identical discount factors and considered two-player alternating offers bargaining games lasting over two, three, and five rounds. The results rejected the Stahl–Rubinstein model and also, equal splits.

⁶⁶ In order to implement different discount factors, the binary lottery procedure of Roth and Malouf (1979) is used but the lottery tickets or chips are redeemed for money at different rates for the two players.

Table 12.22 Description of various bargaining games in Ochs and Roth (1989).

δ_2^2 (\$0.30). Using Examples 12.5, 12.6, the subgame perfect equilibrium predictions for each game can now be readily calculated. These predictions are noted in cells 1–8 in Table 12.22 and are expressed in terms of chips and money (notice that the predictions are made over a range of values to reflect that chips can take only integer values).

One can now directly test if experimental data supports the predictions in Table 12.22. However, there are also two secondary *qualitative predictions*.

1. From Example 12.5, we know that when $T = 2$, the solution should only depend on δ_2 . Thus, the outcomes for cells 1 and 2 on the one hand, and cells 3 and 4 on the other, are predicted to be identical. Since player 2 is relatively more patient in cells 3, 4, he is predicted to receive a higher payoff as compared to cells 1, 2 where he is less patient.
2. From Examples 12.5, 12.6, we also know that, keeping discount factors constant, player 2 is predicted to receive a lower payoff when $T = 3$ rather than $T = 2$ (the opposite holds for player 1).

The results are shown in Figures 12.29, 12.30. The legend shows the information plotted for each cell, which includes the maximum and minimum offers. The dotted horizontal line shows equal division, the continuous horizontal line shows the perfect equilibrium offer and the hatched line shows the interval that contains the perfect equilibrium, taking account of integer values of chips.

In general, the subgame perfect prediction of the alternating offers bargaining game is a poor predictor of the experimental data. Other than cell 1, the estimated population mean plus minus two standard deviations does not include the theoretical prediction. Both qualitative predictions are also violated by the data. The first qualitative prediction fails because the difference in sample means between cells 1 and 2 is statistically different at the 95% confidence level; a similar result

Figure 12.29 Opening offers to player 2 for cells 1, 2, 5, and 6 in Table 12.22.

Source: Ochs and Roth (1989) with permission from the American Economic Association.

also holds for cells 3 and 4. In contrast to the second qualitative prediction, player 2 has a higher payoff when $T = 3$ rather than $T = 2$, in two out of the four possible comparisons. A second set of predictions refers to the acceptance decision of player 2 to the opening round offer. Theory predicts that the equilibrium offers should be immediately accepted. However, in 16% of the cases, the opening offers were rejected; this is a pervasive feature in bargaining experiments.

Figure 12.30 Opening offers to player 2 for cells 3, 4, 7, and 8 in Table 12.22.

Source: Ochs and Roth (1989) with permission from the American Economic Association.

Surprisingly, following a rejection of the opening offer by player 2, 101 of the 125 counterproposals by player 2 are on disadvantageous terms. Kennan and Wilson (1990) observe that in many strikes, the terms on which parties eventually settle are worse than the terms they rejected in earlier rounds of negotiations. Collating various studies, Roth (1995) shows that the incidence of bargaining disagreements in experimental and field studies is not very different. Despite the different methodologies, there is a striking similarity in the rejection behavior of subjects in Binmore et al. (1985), Neelin et al. (1988), and Ochs and Roth (1989): The respective percentage of first round rejections in the three studies is 15, 14, and 16, followed by disadvantageous counterproposals in

75, 65, and 81% of the cases, respectively. This is difficult to reconcile with the view that players are rational and have self-regarding preferences.

The preferred explanation of Ochs and Roth (1989) for such disadvantageous counteroffers is that (p. 365) “the unobserved element in the bargainer’s utility function may have a component related to the perceived ‘fairness’ of a proposal.” Thus, players may reject insulting offers even at the cost of a reduction in their payoffs. But this is not the only explanation. Güth and Tietz (1990) reject this explanation and favor an alternative one in which players switch between the heuristic of *strategic* and *equitable* considerations.

An important insight into the potential reason for disadvantageous counterproposals was given by Bolton (1991). He suggested that the utility of players depends on two arguments: own payoffs and relative payoffs. Thus, while players may make disadvantageous counterproposals, their relative payoffs from such proposals might be sufficiently greater to compensate for the lower absolute amounts. Indeed, this model formed the basis of the ERC model of Bolton and Ockenfels (2000) that we have considered in Chapter 6.

As a test of his proposal, Bolton (1991) considered two treatments. In the first treatment, players are paid tournament style incentives (winner takes all). In the second treatment, players are paid classical incentives, i.e., a share in the pie. The conjecture is that in treatment 1, since no pie is being shared, fairness considerations will not be as important, hence, we would get results more in accord with the classical theoretical prediction. There is partial support for the predictions. Inexperienced subjects show no noticeable effect of the two treatments. However, the behavior of experienced subjects, for some configurations of the discount factors, is consistent with the predictions. Clearly, a full account of the relevant data is an open problem.

De Bruyn and Bolton (2008) first use ultimatum games data reported in Roth (1995) to estimate a parameter of fairness. Then, they use this estimate to test the “out of sample” predictions of a new model, based on the original idea in Bolton (1991). This is a worthwhile attempt at discovering which kinds of models may explain results from bargaining games in a more satisfactory manner. They consider a utility function similar to that in Bolton and Ockenfels (2000), which is given by

$$U(r) = \begin{cases} \left(r - \frac{b}{2} \left(r - \frac{1}{2}\right)^2\right) c & \text{if } r < 0.5 \\ rc & \text{if } r \geq 0.5 \end{cases}, \quad (12.12)$$

where c is the size of the pie that is to be distributed in an ultimatum game, and r is the relative share of the player (we omit player subscripts). The utility function in (12.12) assumes that the reference point of the player is a share of one half of the pie. When the player gets less than half the pie, he suffers a reduction in utility, as his payoff falls further below the equitable share. The single parameter, $b > 0$, controls the extent of this reduction in utility. The utility function is unbounded below ($U \rightarrow -\infty$ as $b \rightarrow \infty$ and $r < 0.5$) but it is bounded above by c .

Players are assumed to choose their strategies with some noise, as in models of *quantal response equilibrium* (QRE); see Chapter 13 for the details. In a QRE, for each observed share r offered by the proposer, the responder plays a mixed strategy over the two actions: accept or reject. Taking account of the probability with which the responder chooses his two actions, the proposer also plays all his actions, various possible choices of r , with strictly positive probability. Each player plays the action that gives a higher expected payoff, with a higher probability; under QRE, players play *better responses* rather than *best responses*. A QRE is a fixed point in beliefs such that the strategy of each player is optimal, given the equilibrium beliefs and the strategies, in turn, generate the equilibrium beliefs.

Figure 12.31 Predictions of the model (bold line) versus the actual data in Roth et al. (1991) (dotted line) for offers and rejections in ultimatum games.

Source: De Bruyn and Bolton (2008). Reproduced with permission. Copyright, INFORMS, <http://www.informs.org>

The authors then use this model to predict out of sample data from the experiments reported in Roth et al. (1991). The fit is quite good, as can be seen from Figure 12.31. The authors show that their model predicts better in out of sample data as compared to the Fehr and Schmidt model (see Chapter 6).⁶⁷ The simple QRE also predicts the data quite well, but when it is combined with the ERC model, it predicts even better. For the results from the ultimatum game, this is an alternative explanation to a reciprocity-based explanation. The imposition of a reference point of $r = 0.5$ in (12.12) is reasonably close to its estimate in the data ($\hat{r} = 0.521$). Obviously, in other sorts of experimental games, such a reference point need not be the most suitable one, hence, the authors recommend that (p. 1786) “the reference point should not be assumed but rather freely estimated.”

There is evidence of greater efficiency of outcomes when in experiments subjects engage in face to face bargaining, relative to anonymous bargaining in which individuals make choices over computer terminals. Face to face bargaining may open up many other channels, such as social identity, body language, and facial cues, that would be blocked in anonymous bargaining. To the extent that these channels are important in real-life bargaining, anonymous bargaining misses out on some important factors, even as it allows extensive communication through computer terminals.

An early empirical study that attempts to address issues of communication is reported in Roth (1995, Table 4.6). He ran ultimatum game experiments ($T = 1$) with three conditions. The baseline condition is the standard anonymous game condition. A second condition, *unrestricted face to face communication*, allows unrestricted communication for 2 minutes, prior to the actual game. A third condition, *social face to face communication*, restricts communication to social conversation only (e.g., name and year in school) but not to conversation related to the bargaining game. The disagreement rate is 33% in the baseline condition but in the next two conditions, the disagreement rates, respectively, 4% and 6%, are not statistically distinguishable. These results suggest that it is not the content of the communication that is important in enhancing agreements. Rather, as

⁶⁷ Perhaps a fairer comparison should instead have been with a non-linear Fehr–Schmidt model augmented by the QRE framework.

Roth (1995, p.295) puts it: “powerful social motivations that may have little to do with bargaining may be responsible for the observed behavior.”

A related issue is that of experimenter scrutiny. Are the results affected because the subjects in an experiment perceive that they are being watched over by the experimenter? Early results by Hoffman et al. (1994) suggested that they do. But, Roth (1995, pp. 299–300) questions several aspects of these experiments.⁶⁸ However, in properly controlled experiments, Bolton and Zwick (1995) do not find evidence of experimenter scrutiny on the bargaining results. There is also evidence of the effect of cultural factors in bargaining when $T = 1$.⁶⁹

Binmore et al. (1989) examine the role of outside options. In Example 12.3, above, we considered a Nash bargaining game in which players share a fixed sum of money, M , and for any $x \in S$, $x_1, x_2 \geq 0$ and $x_1 + x_2 = M$. The solution is given by the *split the difference formula*. Continue to assume that the disagreement payoffs of both players are zero. Now introduce outside options for each player. In a sequential bargaining game, an outside option for any player is a number $b_i \geq 0$ such that if the player unilaterally exits the game, he receives a payoff of b_i . Assume that the outside options of the two players are given by the tuple (b_1, b_2) ; these payoffs satisfy $b_1 \geq 0, b_2 \geq 0$ and $b_1 + b_2 \leq M$. This alters the nature of the bargaining problem. At any date, the player making the offer must ensure that the other player gets at least the outside option. The set S is now defined as $\{(x_1, x_2) : b_1 \leq x_1, b_2 \leq x_2, x_1 + x_2 \leq M\}$.

Since $d_1 = d_2 = 0$, the solution to a Nash bargaining game, using the *split the difference formula* is $\frac{M}{2}$. In the presence of the outside option, if $b_i \leq \frac{M}{2}$ for $i = 1, 2$, then this remains the solution. However, if for any player, the constraint $b_i \leq \frac{M}{2}$ is violated, then this player gets $x_i = b_i$ and the other player gets $M - b_i$ (the constraint $b_i \leq \frac{M}{2}$ cannot be violated for both players because $b_1 + b_2 \leq M$). Such a solution is known as the *deal me out solution*.⁷⁰

Consider a pie of initial size £7 to be divided among two players, using a sequential alternating offers bargaining game in which player 1 makes offers in odd periods. In three different groups, the outside option of player 2, b_2 , is £0, £2, and £4. The outside option of player 1, $b_1 = 0$. At each stage, the payoffs are reduced by a factor of $\delta = 0.9$. The game terminates either if an offer is accepted, or a player takes his outside option, or the payoffs shrink to become negligible in some experimentally defined sense.

To explain the solution, suppose, for simplicity that $\delta = 1$, so that in the absence of the outside option, the *split the difference outcome* is (3.5, 3.5). Consider now the *deal me out solution*. When the outside option of player 2 is £0 or £2, we have the case $b_i \leq \frac{M}{2}$, so the 50% split, (3.5, 3.5), is still the equilibrium outcome. However, as soon as the outside option becomes greater than £3.5, as in group 3, where it is £4, then player 2 should get £4 (57.14% of the pie) and player 1 should get $7 - 4 = £3$ (42.86%) of the pie.

Now consider $\delta = 0.9$. In the *deal me out solution*, when $\delta = 0.9$, player 2 gets 47.3% of the pie in groups 1 and 2 and 57.1% of the pie in group 3. Split the difference (Example 12.3) predicts the shares of player 2 in the three groups to be, respectively, 47%, 64%, and 76%.

The results are shown in Figure 12.32. The horizontal axis is the fraction of pie offered by player 1 to player 2. The height of the histograms captures the frequency of each offer for each of the three groups. The deal me out solution is shown by the solid line connecting the predicted equilibrium

⁶⁸ For instance, variations in the degree of anonymity were confounded with other factors and some of the results are reported for some games in the paper but not for others.

⁶⁹ See, for instance, Roth et al. (1991) and other results reported in Chapter 5.

⁷⁰ The alternating offers bargaining game with an outside option that corresponds to this solution is described in Appendix 1 in Binmore et al. (1989).

points (47.3% in groups 1 and 2 and 57.1% in group 3). The split the difference solution is also similarly shown as the dashed line.

The main contribution of Binmore et al. (1989) is to show that the deal me out solution describes the data from experimental bargaining games better, relative to the split the difference solution. There are a large number of bargaining disagreements (see the hollow squares and the squares with a dot in Figure 12.32) that are inconsistent with the predictions of any of the main sequential bargaining theories. However, focusing just on those bargaining outcomes where there are agreements, there are spikes in the data that are consistent with the predictions of the deal me out solution. In group 2 games, in 11 out of 25 games, the share of player 2 was between 50% to 51%, while in group 3 games, in 7 out of 25 games, the share was between 57% to 58%. The results for group 3 are the most interesting. In 4 out of 25 cases, player 2 received a fraction of the pie that was well below 57.1%; this is inconsistent with both deal me out and split the difference solutions. Of the remaining 21 cases, in 18 cases the agreed splits are closer to the deal me out solution as compared to the split the difference solution. The authors also note that their results are consistent with fairness considerations in bargaining, conditional on players not settling below their outside option.

Zwick et al. (1992) test for the predictions in Proposition 12.9 by implementing an experimental design in which there is a probability, p , in each round, that the game will terminate. Thus, in any round, if a player rejects an offer, then the game ends with probability p . Otherwise, with probability $1 - p$, the player can make a counter offer. They chose three values of $p = \frac{1}{10}$, $\frac{1}{3}$, and $\frac{5}{6}$. When $p = \frac{5}{6}$, this game is similar to an ultimatum game (which corresponds to $p = 1$), and when $p = \frac{1}{10}$ and $\frac{1}{3}$, respectively, the game is expected to last for 10 and 3 rounds. The results are as follows. First period demands are neither consistent with the predictions in Proposition 12.9,

nor with equal splits. However, focusing attention on the final accepted offers, mean demands were closer to equal splits rather than to the predictions of Proposition 12.9.

BARGAINING UNDER ASYMMETRIC INFORMATION

One-sided asymmetric information

We explore first *one-sided asymmetric information* in the bilateral bargaining game experiments of Rapoport et al. (1995). Consider a single indivisible object that a seller, S, wishes to sell to a buyer, B, at some price p_t at time $t = 0, 1, 2, \dots$. The seller's cost of the object, c , is known to both parties, but the buyer's valuation, v , is private information. The seller believes that v is drawn from some commonly known density of prior beliefs, $\phi(v)$. At any time, t , the seller sets a price, p_t , that the buyer can either accept or reject. If the buyer rejects, then the game proceeds to the next round where the seller makes a new price offer, p_{t+1} . If the buyer accepts at time t , then the game ends and the payoffs of the seller and the buyer are, respectively, $\delta^t(p_t - c)$ and $\delta^t(v - p_t)$, where $0 \leq \delta \leq 1$ is the common discount factor.

We are interested in a sequential equilibrium of this bargaining game. This is a price sequence $(p_t)_{t=0}^{\infty}$ and the binary decision of the buyer $d_t \in \{0, 1\}$ $t = 0, 1, 2, \dots$ to accept ($d_t = 1$) or reject ($d_t = 0$) such that the following conditions hold. Conditional on any history of the game: (i) The price p_t , at any time, maximizes the profit of the seller, conditional on his belief about the type of the buyer at time t and the subsequent strategies of the players. (ii) The buyer's decision at any time t , d_t , is optimal, given his beliefs and the subsequent strategies. (iii) Beliefs should be consistent with Bayes' rule wherever possible.

Proposition 12.10 (Fudenberg et al., 1985; Gul et al., 1986) *Suppose that $c = 0$, and ϕ is a uniform distribution.*

(i) *If ϕ is uniform over $(0, 1]$, then there is a unique equilibrium sequence of prices given by*

$$p_t = \gamma^t p_0, \quad t = 1, 2, 3, \dots \quad (12.13)$$

where,

$$p_0 = \frac{\gamma(1-\delta)}{1-\gamma\delta}, \quad \gamma = \frac{1}{\delta} \left(1 - \sqrt{1-\delta}\right). \quad (12.14)$$

The strategy of a buyer with valuation v is to accept whenever $p_t \leq \frac{v}{\gamma} p_0$.

(ii) *If ϕ is uniform over $[0, 1]$, then the equilibrium is not unique.*

The intuition behind Proposition 12.10 is not difficult to understand. Both sides have market power. The seller's market power comes from being a monopolist, hence, he can control the sequence of prices. The buyer's market power arises from his superior information. The seller would like to sell his good early on account of time discounting, yet he does not want to set "too low" a price because the buyer's valuation might be high.

When $0 < \delta < 1$, it follows from (12.14) that $0 < \gamma < 1$, hence, the optimal price sequence in (12.13) is a strictly decreasing one. The seller sets a high price initially, and gradually decreases it over time at an exponential rate. The idea is to engage in *intertemporal price discrimination*, so that he can sell initially to the high valuation buyers and later to the low valuation buyers. The reason that high valuation buyers do not wait long enough for the price to drop even further is that the rate of price drop slows down sufficiently over time, so that the extra benefit from a lower price is swamped by the delay costs on account of time discounting.

When $\delta = 1$, the buyers are infinitely patient and are willing to wait forever for the price to drop. In this case, the seller will want to sell at the earliest date by offering the lowest possible price, $p_0 = 0$ (because $c = 0$ in Proposition 12.10), thus, the seller's profit is zero. At the other extreme ($\delta \rightarrow 0$), using L'Hopital's rule, $\lim_{\delta \rightarrow 0} p_0 = \lim_{\delta \rightarrow 0} \gamma = 0.5$. A simple calculation shows that p_0 is decreasing in δ . Thus, $p_0 \leq 0.5$.

This discussion outlines the predictions of the model that can be experimentally tested. Three values of δ are used: a high value $\delta = \frac{9}{10}$ (condition H), a medium value $\delta = \frac{2}{3}$ (condition M), and a low value $\delta = \frac{1}{3}$ (condition L).⁷¹ The authors chose the distribution of valuations ϕ to be uniform over $[0, 1]$; from Proposition 12.10, this allows a multiplicity of equilibria that also include the equilibrium described in Proposition 12.10(i). A discrete counterpart of the distribution ϕ was implemented by letting the buyer's valuations take equally probable integer values \$0, \$1, . . . , \$100.

Consider first the prediction $p_0 \leq 0.5$ and that prices are declining in δ . For each value of δ , mean p_0 falls as δ increases, exactly the opposite of the theoretical prediction. When evaluated at the level of individuals, the theoretical prediction holds only for 2 out of 48 subjects. Mean p_0 is significantly higher than 0.5 in condition H for all iterations, statistically not different from 0.5 in condition M and lower than 0.5 in condition L.

A second prediction is the exponentially declining prices. Prices do fall over time in all sessions, however, they do not fall exponentially, which is critical to the incentive compatibility of the mechanism. A linear trend with an extra quadratic term fits as well as an exponentially declining trend. Experienced sellers choose linear descending prices.

The seller's profit should fall as δ increases and in the limit, as $\delta \rightarrow 1$, the profit should be zero. The predictions for the buyer's profits in this zero-sum game are just the reverse. However, the results show that the seller's profits are close to \$25 for all values of δ and in all sessions. The expected valuation of the buyer is \$50, and the seller's expected profits are just half of this, so there could be some bargaining norms in operation such as equal expected splits. Even when high valuation buyers have had experience of the game, they do not attempt to free ride on low valuation buyers. They typically accept the first or second instance where they find that the offered price is lower than their valuation. Thus, they accept the seller's offers "too soon" relative to the predictions of theory. This feature contributes to the high observed efficiency of the outcomes.

Overall, the authors take the position that their results constitute a rejection for the sequential equilibrium predictions of theory. They write (p. 391): "The equilibrium predictions capture very little of the qualitative features of the data . . . we find that subjects follow simple rules of thumb in choosing strategies, reflected in the behavioral consistencies revealed in the study . . . Rather, the decision rules adopted by buyers and sellers violate any possible sequential equilibrium of the mechanism under investigation, or described by fictitious strategies."

Forsythe et al. (1991) consider two-player, pie-splitting games in which an informed player, I, knows the size of the pie. The uninformed player, U, believes that the state of the world is *good*, pie size π_g , with probability p , and the state of the world is *bad*, pie size $\pi_b < \pi_g$, with probability $1 - p$. Both players are risk neutral, expected utility maximizers. Players are allowed to bargain for a fixed length of time and if they do not successfully conclude an agreement, both players get zero. The players are allowed to send unconstrained messages to each other, hence, the structure of the experiments makes it difficult to write down the corresponding theoretical model.

Following Myerson (1979), any Nash equilibrium of this game may be implemented by a direct revelation mechanism of the following type. Player I moves first and announces the state of the

⁷¹ Each of these conditions was iterated three times in each session. In session 1, all 48 subjects participated, and in sessions 2 and 3, a subset of 16 subjects participated. In each session, each subject played 18 two-player bargaining games; 9 as seller and 9 as buyer.

world: good, g , or bad, b . Player U can then shrink the pie by a fraction $1 - \gamma_j$, $\gamma_j \geq 0$ in state $j = g, b$; this corresponds to a *strike* by the player. Thus, in the good and bad states, respectively, the pie available for redistribution reduces to $\gamma_g \pi_g$ and $\gamma_b \pi_b$ (so $\pi_j - (1 - \gamma_j) \pi_j = \gamma_j \pi_j$). Letting $x_j \geq 0$ be the share of player 2 in state $j = g, b$, the state-dependent payoffs of players I, U are, respectively, $(\gamma_g \pi_g - x_g, x_g)$ and $(\gamma_b \pi_b - x_b, x_b)$. A mechanism is denoted by $\mu = (\gamma_g, x_g, \gamma_b, x_b)$. An incentive compatible (IC) mechanism must ensure that in each state, player I reveals the true state of the world, thus

$$\gamma_g \pi_g - x_g \geq \gamma_b \pi_g - x_b \text{ and } \gamma_b \pi_b - x_b \geq \gamma_g \pi_b - x_g. \quad (12.15)$$

The inequalities in (12.15) imply that an incentive compatible mechanism must satisfy

$$(\gamma_g - \gamma_b) \pi_b \leq x_g - x_b \leq (\gamma_g - \gamma_b) \pi_g. \quad (12.16)$$

A mechanism is *efficient* if there exists no allocation of outcomes such that at least one of the following three players (each type of player I is a distinct player) can be made better off, without making anyone worse off: Player U, player I who observes the good state, and player I who observes the bad state.

Proposition 12.11

- (i) *Strikes are not efficient in the good state, i.e., $\gamma_g = 1$.*
- (ii) *In an efficient mechanism, the right-most inequality in (12.16) must bind.*

Proof: (i) First notice that since $\pi_b < \pi_g$, (12.16) requires that $\gamma_g \geq \gamma_b$, thus, the incidence of strikes in the good state is always lower. Suppose that we have a mechanism $\mu = (\gamma_g, x_g, \gamma_b, x_b)$ such that $\gamma_g < 1 - \varepsilon < 1$. Now consider an alternative mechanism $\mu^* = (\gamma_g^*, x_g, \gamma_b^*, x_b) = (\gamma_g + \varepsilon, x_g, \gamma_b + \varepsilon, x_b)$. Player U's payoff is unaffected because x_b, x_g are unchanged. However, in each state of the world, a smaller fraction of the pie is destroyed due to strikes, hence, the payoff of player I must increase. Thus, the original mechanism $\mu = (\gamma_g, x_g, \gamma_b, x_b)$ in which $\gamma_g < 1$ is not efficient. It follows that in any efficient mechanism, $\gamma_g = 1$, and no strikes take place.

(ii) Suppose that $x_g - x_b < (\gamma_g - \gamma_b) \pi_g$. Then, a small increase in γ_b that does not disturb the inequality, does not affect the payoff of player U. But this increases the payoff of player I, because less of the pie is now shrunk, thus, such a move is efficient. Continue to increase γ_b until $x_g - x_b = (\gamma_g - \gamma_b) \pi_g$. ■

Consider a non-cooperative game in which player U makes a non-negotiable (take it or leave it) demand to player I. A well-known result in bargaining theory shows that the risk-neutral player U must find it optimal to demand π_g whenever $p\pi_g > \pi_b$, where p is the probability of the bad state (otherwise player U demands π_g). This is known as the *strike condition*. The same condition holds in a cooperative game (the optimal mechanism) as we now show.

Proposition 12.12 (Forsythe et al., 1991):

- (i) *Strikes are not efficient when $p\pi_g < \pi_b$.*
- (ii) *However, in an efficient mechanism strikes can exist if $p\pi_g > \pi_b$.*

In order to predict the shares of the players (determined entirely by x_g, x_b), the authors use the *random dictator axiom* in Myerson (1984). The outcomes in this case are as if each of the two players chooses the allocation as a dictator in a dictator game, with equal probabilities. Thus, we get the mechanism

$$\mu = \begin{cases} (1, \frac{1}{2}\pi_g, \frac{1}{2}, 0) & \text{if } p\pi_g > \pi_b \\ (1, \frac{1}{2}\pi_b, 1, \frac{1}{2}\pi_b) & \text{if } p\pi_g < \pi_b \end{cases} \quad (12.17)$$

When player I proposes in the dictator game, he imposes the mechanism $\mu = (1, 0, 1, 0)$ in which strikes never occur ($\gamma_g = \gamma_b = 1$) and player U gets a zero payoff ($x_g = x_b = 0$). When player U proposes in the dictator game, there are two possibilities. If $p\pi_g > \pi_b$, the player should always demand a pie of size π_g , so he imposes the mechanism $\mu = (1, \pi_g, 0, 0)$; thus, strikes occur if the state turns out to be bad. If $p\pi_g < \pi_b$, then strikes are never optimal, so player U imposes the mechanism $\mu = (1, \pi_g, 1, \pi_b)$ in which he gets the entire surplus in each state. Noting that the proposals made by the two players are equiprobable gives us (12.17).

Four games were considered in the experiments. The strike condition is “on” in games I and II ($p\pi_g > \pi_b$) and “off” in games III and IV ($p\pi_g < \pi_b$). If the predictions of the theory are found to hold, then one may be able to conclude that strikes are perhaps an efficient response to asymmetric information.

The results are as follows. Incentive compatible efficiency (Proposition 12.11) enables one to sort out individual-level data in a large number of cases. For instance, strikes happened more frequently in games I and II as compared to games III and IV. However, the predictions of the theory are not perfect. Strikes do happen in good states in games I and II and also in the bad state in games III and IV (where they are not predicted to happen at all). However, these violations happen in about 8% of the cases.

One does obtain *bargaining impasse* (strikes) even under full information (see Section 12.5.3). However, this paper makes the sharper prediction that the difference in the incidence of strikes in games I and II, relative to games III and IV, is significant. Thus, to a large extent, these results indicate that strikes are a response to information asymmetries between players. However, this does not solve all the puzzles. The incidence of strikes should be similar across games I and II, yet the incidence is significantly different (39.2% in game I and 17.2% in game II; the prediction in both games is 50% because $p = 0.5$). This result holds true not only for the bargaining games but also for the games where the players choose as dictators in order to test Myerson’s random dictator axiom (Proposition 12.12).

Myerson’s random dictator axiom is not very useful in organizing the data. The authors conjecture that the reason for this failure was a violation of the basic assumptions of the model such as risk neutrality and homogeneity of preferences by the subjects in the experiment.

Two-sided asymmetric information

Radner and Schotter (1989) consider bargaining experiments with *two-sided asymmetric information*. The focus is on a particular mechanism, the *sealed-bid mechanism*. Consider a single indivisible object that a seller, S, wishes to sell to a buyer, B, in a static game. The seller’s valuation (or cost), v_s , and the buyer’s valuation, v_b , are private information to the respective players. The joint distribution of v_s and v_b is given by Φ , and it is commonly known. The privately known values, v_s and v_b , are also sometimes known as *reservation values* because the seller will not accept a price below v_s and the buyer will not pay a price above v_b .

In the sealed-bid mechanism, the seller and the buyer simultaneously submit bids. The seller’s bid, p_s , is an asking price and the buyer’s bid, p_b , is an offer price. If $p_b \geq p_s$, then the two parties trade the object at a price $p = \frac{p_b + p_s}{2}$. If $p_b < p_s$, then there is no trade and each party gets a payoff of zero. In the event of an agreement, the respective payoffs of the seller and the buyer are, respectively, $\pi_s = p - v_s$ and $\pi_b = v_b - p$.

This is a static Bayesian game in which each party has a type: the seller’s type is v_s , drawn from some set of “cost” types C and the buyer’s type is v_b , drawn from some set of “valuation” types V .

In equilibrium, each player chooses a type-contingent strategy. When both v_b, v_s are drawn from uniform distributions over $[0, 100]$, then Chatterjee and Samuelson (1983) showed that the following type-contingent linear bidding strategies constitutes an equilibrium (an exercise asks you to prove it).

$$p_b = \begin{cases} v_b & \text{if } v_b < 25 \\ \frac{25}{3} + \frac{2}{3}v_b & \text{if } v_b \geq 25 \end{cases} \quad (12.18)$$

$$p_s = \begin{cases} v_s & \text{if } v_s > 75 \\ 25 + \frac{2}{3}v_s & \text{if } v_s \leq 75 \end{cases} \quad (12.19)$$

Both optimal bidding strategies are stepwise linear. The buyer's bidding strategy equals the true valuation if $v_b < 25$ but thereafter, the buyer *shades his bid* (because the bid increases less than one for one with v_b). By contrast, the seller initially shades his cost until $v_s = 75$ and thereafter, bids his true cost. Figure 12.33 shows a plot of (12.18) and (12.19). The diagonal line shows *truthful bids*. The seller's optimal bid is shown by the dashed line that is either above or on the diagonal, so he typically tries to overstate his true cost. The buyer's optimal bid, shown by the continuous line, reveals that the buyer typically understates his valuation.

To test the predictions of this model, one can test if the behavior of subjects is sensitive to the cutoff points, as shown in (12.18) and (12.19). The equilibrium in linear strategies is not the only equilibrium. There are a multitude of other equilibria in this model (Leining et al., 1989). However, the equilibrium in linear strategies, when players are not allowed preplay communication, is the most efficient across all possible equilibria; this holds even when preplay communication is allowed prior to bargaining. It is most efficient in the sense that it maximizes the ex-ante expected total profits $E(\pi_s + \pi_b)$, where the expectation is taken with respect to Φ (Myerson and Satterthwaite, 1983). An important motivation behind the experiments is to see if subjects choose the equilibrium in linear strategies, and if such an equilibrium is efficient.

Radner and Schotter conducted eight different experiments. The optimal linear strategies in (12.18) and (12.19) come from the first set of experiments. We only describe their experiments

Figure 12.33 Optimal linear bidding functions for sellers and buyers.

Source: Reprinted from *Journal of Mathematical Psychology*, 42: 133–66, Daniel, T. E., Scale, D. A., and Rapoport, A., "Strategic play and adaptive learning in sealed bid bargaining mechanism." Copyright © 1998, with permission from Elsevier.

1, 2, and 5 that give the clearest test of theory. In the second set of experiments, at the end of each round, the bids of all participants were publicly revealed (without compromising subject identity). In the fifth experiment, the distributions for v_b and v_s were non-uniform but symmetric.

The two main findings of the experiments, based on data pooled across all buyers on the one hand and across sellers on the other, are as follows. First, an eyeball test suggests that both sellers and buyers seem to employ linear bidding strategies. For the seller, this is confirmed by running regressions of p_s on an intercept term, v_s , v_s^2 and v_s^3 . An F-test did not reject the hypothesis that the coefficients of v_s^2 and v_s^3 are jointly zero. Likewise, when one runs a regression of p_b on an intercept term, v_b , v_b^2 and v_b^3 , an F-test does not reject the hypothesis that the coefficients of v_b^2 and v_b^3 are jointly zero.

Second, it can be confirmed that there are cutoff points that are consistent with (12.18) and (12.19) such that the behavior of buyers and sellers is different on each side of the cutoffs. For the sellers, the actual bidding strategies on both sides of the cutoff are consistent with the predictions. But buyers did not shave their bids as much as predicted and they change their bids almost one for one with their valuations. This was a factor in the high actual efficiency of this mechanism in the experiments.

One feature of the Radner and Schotter (1989) study is that they maintain fixed pairings of subjects, so one may wonder if their results are confounded by reputational factors. Daniel et al. (1998) address this concern in an experimental design that has three differences from the Radner–Schotter study. First, they conduct their experiments over 50 rounds to allow for learning possibilities. Second, they randomly rematch partners after every round to reduce reputational confounds. Third, the experiment is conducted on computer terminals, rather than manually, and each subject is given the complete history of his bids so far.⁷² In experiment 1, the authors attempt to replicate the results of Radner and Schotter, and in experiment 2, they test some additional features of the solution.

In experiment 1, the seller's cost is distributed uniformly over the interval $[0, 100]$ and the buyer's valuation is distributed uniformly over the interval $[0, 200]$. The optimal linear bidding strategies in this case are given by

$$p_b = \begin{cases} v_b & \text{if } v_b \leq 50 \\ \frac{50}{3} + \frac{2}{3}v_b & \text{if } 50 < v_b \leq 150. \\ 116.7 & \text{if } v_b > 150 \end{cases} \quad (12.20)$$

$$p_s = 50 + \frac{2}{3}v_s \text{ for all } v_s \in [0, 100]. \quad (12.21)$$

The optimal bidding strategies are shown in the left panel of Figure 12.35. Relative to the experiments in Radner and Schotter, the buyer's optimal strategy has two kinks, hence, this is an even more demanding test of theory.

In experiment 2, the buyer's valuation is distributed uniformly over the interval $[0, 200]$ as in experiment 1. However, the seller's cost is distributed uniformly over a very narrow interval $[0, 20]$. The optimal linear bidding strategies in this case (see right panel of Figure 12.34 for a pictorial representation) are given by

⁷² This experimental design (with the three newer features) was initially used by Rapoport and Fuller (1995). They replicated the findings of Radner and Schotter. In the main, they found that subjects either behaved in accordance with the optimal linear bidding strategies or they simply stated their reservation values truthfully.

Figure 12.34 Optimal bidding strategies for buyers and sellers in experiment 1 (left panel) and in experiment 2 (right panel).

Source: Reprinted from *Journal of Mathematical Psychology*, 42: 133–66, Daniel, T. E., Scale, D. A., and Rapoport, A., “Strategic play and adaptive learning in seated bid bargaining mechanism.” Copyright © 1998, with permission from Elsevier.

$$p_b = \begin{cases} v_b & \text{if } v_b \leq 50 \\ \frac{50}{3} + \frac{2}{3}v_b & \text{if } 50 < v_b \leq 75. \\ 63.3 & \text{if } v_b > 75 \end{cases} \quad (12.22)$$

$$p_s = 50 + \frac{2}{3}v_s \text{ for all } v_s \in [0, 20]. \quad (12.23)$$

The focus of this study is on individual behavior (as compared to average behavior), which provides a more accurate test of the theory. Ten buyers and ten sellers are randomly matched with each other over 50 rounds for each of the two experiments. The results are interpreted using *spline regressions*.⁷³

For experiment 1, three of the ten sellers are truth-tellers (so they bid their costs), while the behavior of the remaining seven sellers is consistent with their predicted bidding strategy in (12.21). Except for one buyer, the regression fitted well either the linear optimal bidding strategies of buyers (six out of ten buyers), or buyers are truth-tellers. For all ten buyers, in the middle range, $50 < v_b \leq 150$, the optimal linear strategy, $\frac{50}{3} + \frac{2}{3}v_b$, fits well the observed play. Thus, the more satisfactory experimental design successfully replicates the findings of Radner and Schotter.

Consider now the results of experiment 2. For all ten sellers, the bidding behavior falls between the optimal linear bidding strategy and truth-telling. The R^2 values are quite low. It is as if sellers bid independently of their reservation values. In the last 25 rounds, sellers adjust their bids downwards, relative to the first 25 rounds, suggesting evidence of learning. Several other bargaining studies do not find evidence of learning; see, for instance, Neelin et al. (1988) and Weg et al. (1990). It is likely that subject feedback, as in Daniel et al. (1998), plays an important role in the efficacy of learning. In contrast to sellers, the bidding behavior of buyers is more consistent with linear bidding strategies, although buyers typically bid below their optimal linear strategies. Sellers earned significantly less, while buyers earned significantly more as compared to the predicted optimal linear strategies. It is as if the sellers struggled to settle on their optimal bids in this case, and buyers took advantage of suboptimal bidding by sellers.

⁷³ In other words, regressions are run for each of the regions that separates the cutoff points in the optimal strategies and the ends of the best fit lines are smooth-pasted together.

Figure 12.35 The trade and no-trade regions in a two-sided asymmetric information bargaining game.

Source: Reprinted from *Games and Economic Behavior* 38: 127–55, Valley, K., Thompson, L., Gibson, R., and Bazerman, M., “How communication improves efficiency in bargaining games.” Copyright © 2002, with permission from Elsevier.

Radner and Schotter (1989) found that when face to face communication and bargaining occur simultaneously, the bargaining outcomes achieve nearly full efficiency. Valley et al. (2002) design sealed-bid experiments to isolate the source of this efficiency in a two-player bargaining game with unstructured bargaining and varying degrees of pre-bargaining communication. Suppose that the valuation of buyers and sellers is distributed uniformly over $[0, 1]$. The optimal linear bids of the two players are then given by

$$p_b = \frac{1}{12} + \frac{2}{3}v_b \text{ and } p_s = \frac{1}{4} + \frac{2}{3}v_s. \quad (12.24)$$

Trade only takes place if $p_b \geq p_s$, or, using (12.24), if $v_b - v_s \geq \frac{1}{4}$; the relevant region in which trade takes place is shown in Figure 12.35 in the top left hand corner. In the experiments, the authors assume that the valuations of the two players are drawn uniformly from the interval $[0, 50]$, and trade takes place if $p_b \geq p_s$, or if $v_b - v_s \geq 12.5$.

The authors use a 3×2 design; there are three prebid communication conditions (no/written/face to face⁷⁴) and two feedback conditions (no feedback/feedback⁷⁵). Thus, the sealed-bid mechanism had four stages. In stage I, players received information on the realization of their private values, v_b, v_s . In stage II, one of the three communication treatments were run. In stage III, bargaining took place via the sealed-bid mechanism, and in Stage IV, one of the two feedback treatments was implemented. Trade only took place when $v_b > v_s$, which occurred for 192 out of the 343 observations; we shall mainly focus on these results below.

⁷⁴ In the written communication, players were given a 13 minute period in which to exchange unrestricted messages delivered to each other by courier. In the face to face treatment, players could communicate for a 6 minute period with each other.

⁷⁵ In the no feedback treatment, players were told of the outcome once all the rounds of play were completed. In the feedback treatment, players were informed at the end of each round, if a trade had occurred or not, the price at which a trade had occurred, and profits, etc.

In Figure 12.36, the observations that represent trade are shown as filled-in diamonds and those in which no trade took place are shown as hollow squares. The two diagonal lines shown in Figure 12.36 are the same as those in Figure 12.35 in order to separate the trade and the no-trade regions. The sealed-bid mechanism under no communication predicts that no trade should occur within these lines (this area is also known as the Chatterjee–Samuelson no-trade region). This prediction is borne out in panel A in Figure 12.36, confirming the earlier results of Radner and Schotter (1989). However, once we allow for communication, in panels B and C, this result no longer holds. Now one observes a lot of trades within the diagonal lines, more so under face to face communication as compared to written communication.

Define *high value trades* as those where $v_b > v_s + 12.5$ and *low value trades* where $v_s < v_b < v_s + 12.5$. In the no communication treatment, the proportion of high and low value trades was, respectively, 89% and 11%. In the written communication treatment, these figures were 83% and 44%, while in the face to face treatment, these figures were 94% and 74%. Thus, communication, especially face to face communication, was particularly effective in realizing not only high value trades but also low value trades. Thus, face to face communication captured 94.1% of the total available surplus from trade. This is significantly better than the corresponding figure of 82.3% under no communication. However, there is little evidence of any learning over successive rounds.

What accounts for greater efficiency under communication? The authors find that the actual strategy of players is significantly different from the predicted strategy in which bids depend on own valuation alone. A strategy in which one's bid depends on the valuation and bids of others, fits much better the bargaining data. For instance, fitting the classical linear strategies for the buyer as in (12.24), the regression line is $p_b = 3.24 + 0.65v_b$ and $R^2 = 0.57$. However, adding further explanatory variables about the seller's valuation and bids gives the regression $p_b = -0.52 + 0.25v_b + 0.10v_s + 0.57p_s$ and $R^2 = 0.85$; both newly added variables were individually significant.

The authors term bidding strategies where bids depend on the types and actions of others as *dyadic strategies*. In fact, in 73 of the 129 cases where there are positive gains from trade, in the presence of communication both players name an identical price. It need not be the case that both players reveal their true valuations to each other (although 8 out of 129 did), however, even if sellers overstate their costs and buyers understate their valuations, they are mostly able to negotiate on an identical price that allows trades to take place. Furthermore, there is a lower inaccuracy in stated valuations when communication is face to face rather than written. Hence, coordination achieved by interpersonal communication allows the observed efficiency level to exceed the Myerson–Satterthwaite upper bound.

12.5.3 *Self-serving bias and focal points in bargaining*

In this section, we consider two theories of bargaining that are motivated by neither the normative framework nor by the framework of the sequential alternating offers bargaining game. Güth (2012) makes a particularly strong criticism of the approach described in Sections 12.5.1 and 12.5.2, and takes up important issues that we do not consider here.⁷⁶

⁷⁶ We encourage the interested reader to browse through the edited book by Bolton and Croson (2012) for a rich variety of alternative models of bargaining that we have not discussed here. These models incorporate the roles of overconfidence, beliefs, trust, procedural fairness, reference points, gender, and culture, etc.

Figure 12.36 Trade outcomes for the no-communication, written, and face to face treatments.

Source: Reprinted from *Games and Economic Behavior* 38(1), Kathleen Valley, Leigh Thompson, Robert Gibbons, and Max H. Bazerman, "How communication improves efficiency in bargaining games," 127-55. Copyright (2002), with permission from Elsevier.

Section 12.5.2 highlighted one possible factor for bargaining disagreements and impasse: the presence of asymmetric information. We now consider the role of *self-serving bias* in creating such *bargaining impasse* under full information. Insofar as such explanations are supported by the evidence, at the very minimum, they show that asymmetric information may be sufficient, but not necessary for observed bargaining disagreements. A self-serving bias arises when people attempt to rationalize their actions by either selectively drawing only supporting evidence from memory, or using selectively self-serving aspects of the evidence from a situation.

Loewenstein et al. (1993) created a hypothetical situation in which a plaintiff sues a defendant for damages worth \$ x . Subjects are then randomly allocated to the roles of the plaintiff and the defendant, provided with the relevant case material, and asked to guess the damages awarded by a judge. The differences in their estimates are statistically significant and are partial to their own roles in the situation. Yet, both parties have access to identical information, so issues of asymmetric information are absent.

Babcock et al. (1995) test this hypothesis further by considering two treatments that differed in the timing of the assignment of roles as plaintiff and defendant. In treatment 1, the roles were assigned prior to handing over of the case material, while in treatment 2, the roles were assigned afterwards. Consistent with the predictions of a self-serving bias, players gave more biased judgments in treatment 1. The authors also tried several treatments to debias the self-serving bias of subjects. There are two findings. First, it is quite hard to debias players. Second, while the debiasing procedure may make players more aware of the self-serving bias of others, they nevertheless show little awareness of their own bias.

In another debiasing experiment, Babcock et al. (1996) made subjects aware of the self-serving bias and told them that listing the weaknesses in their own reasoning may reduce the bias. The subjects were then asked to list the weakness in their own case. This did significantly reduce the bias. Such a debiasing procedure may also have policy implications.

Babcock and Loewenstein (1997) outline a simple theory of bargaining impasse. Parties in a bargaining situation may be subject to a self-serving bias in that they confound between what really serves their own interests and what is a fair bargaining outcome. This hampers bargaining negotiations in the following ways. First, by focusing on self-serving agreements, the bargaining parties narrow down the set of possible agreements. Second, if parties believe that their self-serving bargaining position is also fair, then they interpret the intransigence of the other party in rejecting their offer as unfair and opportunistic. Insofar as issues of reciprocity may be involved in the bargaining process, this hardens the bargaining position of both parties. Third, the bargaining parties are typically unwilling to settle below their perceived fair distribution of the pie (Loewenstein et al. 1989).

The authors make a case for reinterpreting the existing findings of bargaining under asymmetric information using their framework. While the authors make plausible suggestions (pp. 119–121) on how this could be done, one would need sharp, controlled, experiments to test these issues more formally. For some further potential pitfalls in testing theories of asymmetric information in the lab, see Roth (1995, Section 2a).

Isoni et al. (2013) test for the insights of Schelling (1960) on *tacit bargaining*, using experimental games. Schelling argued that payoff-irrelevant cues may serve to coordinate the actions of players on some mutually beneficial bargaining outcome. It might well be that the players benefit asymmetrically from such coordination but being rational, they realize that if all players were to follow the relevant cues, they would be better off. Thus, such cues may serve as an *equilibrium selection device*. There are many possible payoff-irrelevant cues, such as spatial cues, geographical cues, and precedent based cues.

Figure 12.37 Games G1 and G2.

Source: Isoni, A., Poulsen, A., Sugden, R., and Tsutsui, K. (2013). "Focal points in tacit bargaining problems: experimental evidence." *European Economic Review* 59: 167–88.

Example 12.7 (Schelling, 1960, pp. 58–67): *Two opposing army commanders look to maximize the territory that they can gain, yet not come into conflict with each other. How far should they go? When shown a map, the respondents in Schelling's study choose a river between the two territories as the limit of advance of each commander. The cue here is spatial and it is payoff irrelevant. Both commanders gain asymmetrically unless the river divides their advance exactly evenly.*

We shall consider the evidence from coordination games as applied to level- k models in Chapter 13 (Crawford et al., 2008). The empirical evidence in Crawford et al. (2008) shows that the salience of some cues that successfully induce coordination in symmetric games may be lost in asymmetric games. One of the aims of Isoni et al. (2013) is to show that the salience of cues can still be a useful coordinating device in asymmetric games. The authors conjecture that the difference in results can perhaps be reconciled on two grounds. (i) In Crawford et al. (2008), the games were framed as matching games, while they framed them as bargaining problems. (ii) There are differences in the strategic complexity of the games in the two sets of papers.

Figure 12.37, also known as a bargaining table, shows 2 games out of the 24 games used in the study. Each of two players is assigned a color, light gray or dark gray. The left square in each game is colored light gray and is called the light gray player's base while the right square is colored dark gray and it is termed, the dark gray player's base. The numbers on discs in each bargaining table are amounts of money in UK pounds. Each player must choose one or both discs. An agreement is reached only if each player claims the disc that the other does not; in this case, players get the monetary payoff shown on their chosen disc. If the choice of discs overlaps, then both players get zero.

Each bargaining table in Figure 12.37 has nine columns. Taking out the middle column in either of games G1 or G2, the four columns on the left and the right sides constitute the *left and right sides* of the bargaining table. It is conjectured that these sides may have spatial salience for the choices of the two players. Players whose base is on the left side are called left players and players whose base is on the right are called right players.

Which disc should each player choose? Perhaps they could use some spatial-cues and choose the disc closest to their base. Using this reasoning, in the left hand side bargaining table of Figure 12.37, the left side player may choose the disc with number 6 and the right side player may choose the disc with number 5. If both players followed such spatial cues, then both may successfully coordinate.

Figure 12.38 Description of a bargaining table for one of the 24 games in Isoni et al. (2013).

Source: Isoni, A., Poulsen, A., Sugden, R., and Tsutsui, K. (2013). "Focal points in tacit bargaining problems: experimental evidence." *European Economic Review* 59: 167–88.

Each player has the following choices: choose none of the discs, the near disc, the far disc, or both discs. Writing out the normal form for the game in the left panel of Figure 12.37, there are two strict Nash equilibria, (near, near) and (far, far) with respective payoffs (6, 5) and (5, 6). In the game shown in the right panel of Figure 12.37, the payoffs from the two strict Nash equilibria are both (5, 5), hence, this game is termed as an *equality-compatible game*. Can players use some tacit agreements to play one of the two strict Nash equilibria?

The results in Figure 12.37 are compared with those from the game in Figure 12.38, where spatial cues based on proximity are absent, because both discs are equidistant from the light gray and dark gray bases. If it turns out that there is relatively more coordination in the games in Figure 12.37, then it provides evidence for spatial cues.

The results are as follows. Spatial cues provide a strong coordinating device. In particular, there is an *own side effect*; 69–82% of the left players choose a disc from the left side of the table. By contrast, only 13–21% of the right players choose a disc from the left side; 64–81% of right players choose a disc from their own side. Only 7–16% of left players choose a disc from the right side. The differences in choices of the players are confirmed to be statistically significant. Thus, the central column appears to have been perceived as a boundary by the players, akin to the river in Example 12.7. The spatial focal points retain their significance in both equality compatible and equality incompatible games, suggesting a role of such cues even in asymmetric games. However, the class of games with interesting economic insights that also have spatial focal points might not be very large.

12.5.4 Inferring cognition through search and lookups in a bargaining game

One indirect test of game theoretic predictions is to see if the human cognitive process is consistent with traditional game theoretic reasoning. Of course, the solution concepts in game theory, such as Nash equilibrium, do not make any direct assumptions about the cognitive process. Indeed, a static Nash equilibrium does not even make any assumptions about the beliefs of players about other players. Hence, observations on the cognitive process of humans do not necessarily constitute a direct refutation.

Some economists may argue that if the predictions of game theory are accurate, then even incorrect assumptions about the cognitive process do not constitute a refutation.⁷⁷ There are two main responses to these arguments; see the introductory chapter for more details. First, as shown in this chapter, several predictions of classical game theory fail the “direct test” of not being in accord with the evidence. Second, if a model with refuted assumptions makes correct predictions, it could be purely due to chance or due to the role of assumptions that are not properly understood within the model.

This leaves open the question of how one may observe the cognitive processes used by humans when they play games. Suppose that we have a static, full information, 2×2 normal form game in which the row and the column players have two strategies each. Suppose also that we can observe the pattern of the *lookups* and *searches* of the players as they try to compute their strategies. Consider three kinds of searches by the row player. (1) Up and down over one’s own payoffs. (2) Left or right over the opponent’s payoffs. (3) Transiting frequently from own to the opponent’s payoffs. The first two patterns of searches are consistent with a player using game theoretic solution concepts such as Nash equilibrium. The third pattern of search seems to be suggestive of a concern for one’s payoffs relative to those of other players (i.e., social preferences).

One important method of identifying the pattern of lookups and searches is offered by the use of the MOUSELAB software.⁷⁸ This method is increasingly used in behavioral economics. We explain the method, using a three-round bargaining game from Johnson et al. (2002).⁷⁹

In the spirit of the alternative offers sequential bargaining game of Rubinstein (1982), suppose that two players, 1 and 2, bargain over the division of a pie over three rounds ($T = 3$; see Example 12.6). The players make offers sequentially, and Player 1 makes the first move. When it is the turn of any player to make a move, the player offers a split of the pie. The other player either agrees (in which case, the agreed upon split is made) or rejects and makes a counteroffer. No counteroffers can be made subsequent to round 3. The size of the original pie is \$5, but it shrinks to \$2.50 in the second round, and \$1.25 in the third round, to capture time discounting; otherwise players do not discount future payoffs. The outside option of each player is zero.

Suppose that we take as given the typical game theoretic assumptions, such as common knowledge of rationality, and selfish concern for own-payoffs. The subgame perfect equilibrium can now be computed by starting from the optimal offers in round 3 and folding the game tree backwards. In round 3, when it is the turn of player 1 to move, and the size of the pie is \$1.25, he offers \$0.01 to the opponent and proposes to keep \$1.24 for himself. It is individually rational for player 2 to accept this offer because the outside option is zero. In round 2, when it is the turn of player 2 to make the offer, he knows that any offer to player 1 that is lower than or equal to \$1.24 will be rejected, so he makes an offer of \$1.25 to player 1 and keeps $\$2.50 - \$1.25 = \$1.25$ for himself. In round 1, when player 1 makes the offer, he knows that any offer to player 2, lower than or equal to \$1.25, will be rejected by player 2. Thus, he offers \$1.26 to player 2 and keeps $\$5.00 - \$1.26 = \$3.74$ for himself. Thus, in the subgame perfect equilibrium, player 1 offers \$1.26 to player 2 (at the very first node), keeping \$3.74 for himself and this is immediately accepted

⁷⁷ This methodological view goes back to the “as if” reasoning of Milton Friedman (see the introductory chapter). Gul and Pesendorfer (2007) use a similar argument to criticize the research agenda in neuroeconomics that we consider elsewhere.

⁷⁸ See, for instance, Payne et al. (1993) for an overview of studies using the MOSUSELAB software in the domain of individual choice.

⁷⁹ Several important results that we refer to in this section were produced earlier in the pioneering work of Camerer et al. (1994).

Figure 12.39 The MOUSELAB computer display for the three-round bargaining game.

Source: Reprinted from *Journal of Economic Theory* 104: 16–47, Johnson, E. J., Camerer, C. F., Sen, S., and Rymon, T., “Detecting failures of backward induction: monitoring information search in sequential bargaining.” Copyright © 2002, with permission from Elsevier.

by player 2. The objective of Johnson et al. (2002) is to use MOUSELAB software to test if the cognitive process of the players is consistent with this outcome.

It is worth understanding the basic structure of the MOUSELAB interface, as well as the arguments for and against it. We shall also encounter the use of the MOUSELAB interface in the context of tests for the level- k model, below. The MOUSELAB computer display in the three-round bargaining game of Johnson et al. (2002), described above, is shown in Figure 12.39.

The display has two columns of three boxes each. The boxes in the first column show the size of the pie in each round, while the boxes in the second column show the role of the player in each round. The contents of each box appear as blanks. In order to examine the contents of any box, subjects can use the mouse to move the cursor to that box, which immediately opens and reveals the contents. In Figure 12.39, the subject has moved the cursor to the first box in column 1, which reveals the contents to be \$5. The box immediately closes when the cursor is moved outside the box. In order to make an offer, players move the cursor over the dollar scale which is present horizontally at the bottom of the box. Subjects can then click any amount to make an offer. The software records the activity of the subjects every 16 milliseconds, which provides a detailed account of which boxes are opened and the order in which they are opened. This pattern of information acquisition reveals the lookups and searches of each player.

An important assumption in interpreting the results of the MOUSELAB experiments is that the pattern of information acquisition mirrors the structure of the cognitive process or information usage. Critics, steeped in traditional game theory, might object to the MOUSELAB method in the bargaining game by giving the following two arguments.

1. It is possible that subjects in experiments are memorizing the information relevant for the game by searching the game forward, as revealed in their information acquisition process. However, once memorized, they could be using the information to solve the game

backwards. Hence, information search during the play of the game may not be particularly informative of the cognitive process. Johnson et al. (2002) give the following response to this potential criticism. First, memorizing the information content of boxes is more cognitively taxing than opening boxes and searching for information in MOUSELAB. Second, players opened the same box more than once, suggesting that they were not successfully memorizing. Third, from one game to the next, the size of the pies was altered, making memorization even more difficult, while keeping the equilibrium outcome unchanged.⁸⁰

2. Game theory makes no assumptions about information search and information usage. In order to test this, Johnson et al. (2002) look at a subset of the subjects who are trained in the use of backward induction. The search and lookups of these subjects can then be compared to non-trained subjects to detect any differences.

If subjects behaved in the manner assumed by classical game theory, we should expect that they play the equilibrium outcome. Call such subjects “equilibrium players.” If players are equilibrium players, then player 1 should offer \$1.26 to player 2, keeping \$3.74 for himself, which should be immediately accepted by player 2.

How might boundedly rational subjects play the bargaining game? Johnson et al. (2002) make the following conjecture.⁸¹ Suppose that players are of two types, naive and partially sophisticated. A player 1 who is naive, interprets any round of play as an ultimatum game and ignores future rounds of play. Such players make an offer of 40% of the pie (the average offer in ultimatum game experiments), i.e., \$2.0 to player 2 in round 1. A player 1 who is partially sophisticated, believes that all other players are naive. Such players look one step ahead, and ask what would be the counteroffer made by a naive player in the next round. For instance, in round 1, a partially sophisticated player 1 thinks that in round 2, the counteroffer made by a naive player 2 will be 40% of the pie of size \$2.50 (so player 1 will be offered \$1 and player 2 will keep \$1.50). Thus, looking ahead, in round 1, a partially sophisticated player 1 offers \$1.51 to player 2, which should be immediately accepted if the beliefs of player 1 are accurate.

Proposition 12.13 *The first round offer made by player 1 to player 2 is as follows: Equilibrium players offer \$1.26, naive players offer \$2.0, and partially sophisticated players offer \$1.51.*⁸²

In the trained subjects treatment, subjects are trained in backward induction. The findings are as follows.

1. Baseline treatment: In the baseline treatment, untrained human subjects play against untrained human opponents. The average first round offer by player 1 is \$2.11. Offers below \$1.80 are rejected half the time. This is in line with earlier results from similar bargaining experiments. The information searches using MOUSELAB reveal that players spend less time searching backward among the boxes, relative to searching forward, which is contrary to the expected lookup patterns of equilibrium players. In 19% and 10% of the trials, respectively, players do not even look once at the second and the third round pie sizes. On average, subjects in the role of player 1 spend 62% of their time looking at the first round pie size. About 31% of the time is spent looking at the size of the second round pie, leaving

⁸⁰ The size of the pies was \$5 + a, \$2.50 + b, \$1.25 + c, such that $a - b + c = 0$. The reader can check that the equilibrium outcome is identical in each case to the game in the text with $a = b = c = 0$.

⁸¹ The conjecture is based on the supposition that all players are *level-k* types. We give a formal treatment of the level- k model in Chapter 13.

⁸² Depending on the tie breaking rules, these numbers can respectively be \$1.25, \$2.0, and \$1.50.

only about 7% of the time for looking at the third round pie. Furthermore, a strong correlation is found between searching the boxes in a backward direction and the closeness of one's offer to the equilibrium offer. Similar results were found on the pattern of searches for subjects in their roles as player 2.

2. Robot treatment: In the robot treatment, subjects play against a robot in order to switch-off their social preferences, if any. Robot players are programmed to behave selfishly and play the subgame perfect outcome. In their roles as player 1, human subjects, on average, offer \$1.84 to robot opponents (as compared to \$2.11 in the baseline treatment). Thus, concern for others, alters the equilibrium offer by only \$0.27. In their roles as player 2, human subjects frequently reject the robot's opening offer of \$1.25, which is inconsistent with the behavior of equilibrium players. If subjects are trained in backward induction, then they learn quickly to make near-equilibrium offers to robot subjects (\$1.22).
3. Mixture treatment: In this treatment, subjects who had previously been trained in backward induction in the robot treatment, play against untrained human subjects. Trained subjects start by offering relatively low offers that the untrained subjects reject; over time, the trained subjects learn to raise their offers. Conversely, the untrained subjects start by making high offers but learn, over time, that lower offers are also accepted, so they reduce their offers. The average offers in later rounds are the outcome of this "tug of war" between the two kinds of subjects. The average first round offer is \$1.60, which is lower than the robot treatment but higher than the baseline treatment. Hence, the presence of some equilibrium types moves aggregate behavior towards, but not all the way to, the equilibrium prediction. Across all treatments, the departure of actual behavior from equilibrium behavior seems to arise from a combination of cognitive limitations (untrained players) and social preferences (human or robot opponents).

12.6 Asymmetric information, signaling, and cheap talk

In this section we consider signaling games that are more cognitively challenging as compared to the games considered so far. We assume that the reader is familiar with the basics of signaling games.⁸³

12.6.1 *Evidence from a generic signaling game*

The signaling game shown in Figure 12.40 is experimentally tested in Brandts and Holt (1992); it is based on Spence's (1973) job market signaling model. The two panels show the same game but different equilibria (see below). There are two players, a sender (player 1) and a receiver (player 2). Nature moves first at the oval circle in the middle and chooses one of two types for player 1, H or L, with respective probabilities, $2/3$ and $1/3$.⁸⁴ The chosen type is revealed only to player 1 whose pure strategies are given by A and B. Player 2 has two pure strategies, C and D, but does not know the type of player 1. This is indicated by the two vertical dotted lines connecting the

⁸³ For the basics, see the appendix on game theory.

⁸⁴ In the signaling experiments that we report, players have common priors about the probability with which nature initially moves. When such priors are not told to the subjects they might have to learn about them from repeated play of the experiment. The long-term outcomes in the experiments in the two cases of known and unknown initial probability distribution of moves by nature are quite different; see Drouvelis et al. (2012).

Figure 12.40 The signaling game in Brandts and Holt (1992).

Source: Brandts and Holt (1992) with permission from the American Economic Association.

two information sets of player 2; for instance, when player 1 chooses the action A, player 2 does not know whether the game has proceeded to the upper or the lower node on the right hand side information set. The payoffs are shown at each terminal node.

For a detailed consideration of this game and the associated equilibria, the reader can consult the appendix on game theory. There are two equilibria and both are pooling equilibria, shown respectively in the left and right hand side panels of Figure 12.40; the equilibrium strategies are shown by the bold lines. For instance, in the panel on the left hand side, labeled as Intuitive Equilibrium, both types of player 1 choose the action B. On observing action B, player 2 does not update prior beliefs about the type of player 1, and his best reply is the action C. The restriction on “out of equilibrium beliefs” that suffices to support this pooling equilibrium is that if player 2 observes the action A, then player 1 is believed to be of type L; clearly, action C is optimal for player 2.

The second pooling equilibrium is shown on the right hand side of Figure 12.40. It can be ruled out using the Cho and Kreps (1987) equilibrium dominance criterion, hence, it is labeled as the Unintuitive Equilibrium. Refinements that are stronger than the equilibrium dominance criterion, such as divinity and strategic stability, can also be used to rule out the pooling equilibrium on the right. Hence, if the unintuitive equilibrium is not played in experiments, then this result is also consistent with these other theories.

The experiment had three parts, a, b, and c; each part ran over four rounds (or matchings). In *part a*, 8–12 subjects in each two-hour session, played different rounds of the signaling game. Subjects were split into two equal groups of senders and receivers and placed in separate rooms. Subjects chose their actions simultaneously and then pairs were randomly matched in the two rooms. In *part b* of the experiment, subjects played a slightly different game in which an extra action I (standing for irrelevant) is added to the set of actions of the receiver. Action I is dominated by the other two actions (C and D), so it can be pruned to generate the game in Figure 12.40. However, if it is not pruned, then the equilibrium dominance arguments cannot be used. Part b is played over matchings 5–8 of the two sets of players in the two rooms. This is followed by *part c* of the experiment with matchings 9–12, played with the original game (without action I). The results are shown in Table 12.23.

To understand Table 12.23, consider the first row. This is the data from the first set of matches in part a of the experiments in which there are a total of four matches. There were 8 type-H senders, all of whom choose B. Of the 8 type-L senders, only 1 chose B, all others chose A. For the receivers, 9 out of 9 receivers responded to the message B by choosing the action C, and 6 out of 7 responded to the message A with action D. The other rows can be read off analogously.

Table 12.23 Type-contingent messages sent by senders and message-contingent actions of the receivers for the matchings in each of the parts, a, b, and c.

Part/matching	Signals given type		Responses given signals	
	B/H	B/L	C/B	D/A
a/1	8/8	1/8	9/9	6/7
a/2	8/8	2/8	9/10	2/6
a/3	12/12	1/4	13/13	3/3
a/4	12/12	1/4	13/13	3/3
b/5	12/12	–	12/12	–
b/6	4/4	4/8	8/8	4/4
b/7	12/12	–	12/12	–
b/8	8/8	3/4	11/11	1/1
c/9	16/16	–	16/16	–
c/10	12/12	3/4	15/15	0/1
c/11	4/4	9/12	12/13	2/3
c/12	12/12	3/4	15/15	1/1

Percentage for part b:	100	58	100	100
Percentage for part c:	100	75	98	60

Source: Brandts and Holt (1992).

Consider, as our theoretical prediction, the intuitive equilibrium shown in the left panel in Figure 12.40. In this equilibrium, type H plays B, which is consistent with the results in Table 12.23. However, type L senders in the experiments mostly choose A in part a of the experiments, which is inconsistent with the pooling equilibrium.

In part a, the response of the receivers to message B is almost always C (and to A it is mainly D). This gives type L senders a payoff of 60 from choosing A and 100 from choosing B. Type L senders seem to learn this lesson as the experiment progresses through various rounds. Whereas the proportion of type L senders who send message B is only 21% in part a, this percentage rises to 58 in part b and 75 in part c of the experiments. The unintuitive equilibrium in which the sender sends message A and the receiver responds with C is played in only 7 decision pairs, mostly in the initial rounds of the experiment when subjects are less experienced. The choices of 112 decision pairs in parts b and c give no evidence for the unintuitive equilibrium.

One may interpret these results as good evidence that subjects play a sequential equilibrium. This comes as a bit of a surprise given the widespread failure of subjects to play equilibrium strategies in less cognitively demanding games (see above). Furthermore, Bayes' rule plays a critical role in signaling equilibria, yet we know from Part 7 that humans do not follow this rule very well. In the initial rounds, the play is not consistent with sequential equilibrium. However, with repeated rounds of the experiment, it does become closer to the equilibrium. Another possibility is that in repeated rounds of experiments, subjects could just be playing simple learning strategies such as adaptive play and reinforcement learning. For instance, in the experimental results of Brandts and Holt (1992), the reason that type-L senders eventually switch to playing strategy A could be that once played, they realize that it has a higher payoff, so they continue to play it. Learning dynamics are examined in a follow-up paper by Brandts and Holt (1993) in which

they show that plausible learning dynamics that converge to an equilibrium might contradict the intuitive criterion.

The intuitive criterion will not work when both players can potentially earn higher payoffs by defecting from the equilibrium action to an out of equilibrium action. A range of other refinements have been given to deal with this case. It is beyond the scope of this book to provide the details, but many excellent sources are available.⁸⁵ The *divinity* and *universal divinity* criteria proposed by Banks and Sobel (1987) are refinements that can be used when the intuitive criterion fails. Although both types of senders might have an incentive to play an out of equilibrium action, the incentive to play such an action may be stronger for one of the types, say type- t . The word “stronger” means here that for a relatively larger range of posterior beliefs of the receiver, it is more attractive for type- t senders to play an out of equilibrium action. Universal divinity requires that receivers should then place a posterior belief of 1 that the sender type is type- t when they observe this out of equilibrium action. When universal divinity does not help in distinguishing between the sender types who could have sent an out of equilibrium message, further theoretical criteria are available. However, empirical support for these is weak; such criteria include Kohlberg and Mertens (1986) *never-a-weak-best-response* (NWBR) criterion and the most ambitious of these refinements, i.e., Kohlberg and Mertens (1986) notion of *stability*.

Banks et al. (1994) test if the refinements of sequential equilibrium have empirical support. They use the following nesting of equilibria: *stable* $\subseteq$ *NWBR* $\subseteq$ *Universally Divine* $\subseteq$ *Divine* $\subseteq$ *Intuitive* $\subseteq$ *Sequential* $\subseteq$ *Bayesian Nash*. Kohlberg and Mertens (1986) show that every game contains at least one stable equilibrium. Thus, the existence of all the various kinds of equilibria in the empirical study is guaranteed. Four subject pools played 7 different games in 13 experiments. The main results are as follows. (1) Refinements that, roughly, require greater cognitive faculties relative to the intuitive equilibrium (i.e., divinity, NWBR and stability) do not do very well. By and large, the play by subjects in experiments is not supportive of these refinements. (2) All of the games, except one, had a pooling equilibrium. But subjects do not play the pooling equilibrium. (3) The authors do not find consistent support for any of the various alternative decision rules that subjects might have been using, such as minimax and the principle of insufficient reasoning.

12.6.2 An application to a limit entry pricing game

Cooper et al. (1997b) conduct experiments using the *limit entry pricing game* of Milgrom and Roberts (1982). In this two-period model, an incumbent monopolist faces a downward sloping demand curve and has private information on the cost. The monopolist can either be a high cost type, M_H , or a low-cost type, M_L ; the prior probability of each type is 0.5. In the first period, the monopolist chooses to produce a quantity, q , at the price, p . The quantity choice is observed by a potential entrant in the market, who then decides either to enter (IN) or stay out (OUT).

In the second period, if the entry does not occur, then, the monopolist produces the monopoly output, q_m , at the price p_m . If entry occurs, then both firms play the Cournot outcome, producing the Cournot quantities at the price p_c . The profit of the incumbent of type M_i , $i = H, L$ over the two periods, denoted by $\Pi_I(M_i)$, is given by

$$\Pi_I(M_i) = \pi_{II}(p) + \delta\pi_{II}(p_j); j = m, c.$$

⁸⁵ The interested reader can consult one of many graduate level game theory texts, e.g., Fudenberg and Tirole (1991). The paper by Banks et al. (1994) has a self-contained and rigorous discussion of the various equilibrium refinements. Camerer (2003, pp. 414–18) gives a more intuitive discussion.

$\delta > 0$ is the discount factor and π_{Ii} is the profit of the incumbent of type M_i , $i = H, L$ in a single period. First period profit, $\pi_{Ii}(p)$, depends on first period price, p . The second period profit, $\pi_{Ii}(p_j)$, $j = m, c$, depends on the second period price p_j that is determined by the entrant's decision, IN (price p_c) or OUT (price p_m). The entrant's payoff, which only materializes in the second period, depends on the type of the incumbent, M_i , and is given by $\pi_E(M_i)$. It is $\pi_E(p_c)$ from the IN decision and some exogenously specified outside option $\bar{\pi}_E \equiv 0$ from the OUT decision.

In their experiments, Cooper et al. (1997b) allow the incumbent monopolist to choose discrete output levels $q = 1, 2, \dots, 7$. The incumbent's payoff over the two periods, $\Pi_I(M_i)$, for each level of first period output and the entrant's decision, is shown in Table 12.24. For instance, when $q = 1$, then $\Pi_I(M_H) = 150$ if the potential entrant enters and $\Pi_I(M_H) = 426$ if the potential entrant stays out. Two treatments are run for the entrant. These are differentiated in Table 12.25 by the background color. In Treatment I (the lighter background), the expected payoff of the entrant from IN is lower than from OUT. By contrast, in Treatment II (the darker background), the expected payoff from IN is relatively higher.

The next Lemma follows immediately from Table 12.25.

Table 12.24 Type-contingent payoffs of the incumbent in the market entry game.

Quantity choice	High cost type, M_H		Low cost type, M_L	
	IN	OUT	IN	OUT
1	150	426	250	542
2	168	444	276	568
3	150	426	330	606
4	132	408	352	628
5	56	182	334	610
6	-188	-38	316	592
7	-292	-126	213	486

Lemma 12.1 Suppose that the entrant has full information about the incumbent's type. In Treatments I and II, the entrant enters if the incumbent's type is M_H and stays out otherwise.

Proposition 12.14 Suppose that the entrant has full information about the incumbent's type.

- (i) The high cost incumbent, M_H , chooses a quantity $q = 2$ in the first period for an aggregate payoff of 168.
- (ii) The low-cost incumbent, M_L , chooses a quantity $q = 4$ in the first period for an aggregate payoff of 628.

Proof: Using the entry decisions of the entrant, given in Lemma 12.1, and the data in Table 12.24, the highest payoffs for types M_H and M_L , respectively, correspond to $q = 2$ and $q = 4$. ■

The traditional rationale behind limit pricing has been that a high quantity (thus, a low price) chosen by the incumbent may signal to a potential entrant that the profits are low, hence, making entry more costly. We state this formally.

Definition 12.2 (Limit Pricing): A monopolist is said to engage in limit pricing if the type-contingent quantity chosen in the first period, q , exceeds the quantity chosen under full information.

Using Proposition 12.14 and Definition 12.2, type M_H engages in limit pricing if $q > 2$ and type M_L engages in limit pricing if $q > 4$. The next proposition summarizes the main results that are checked against the experimental data.⁸⁶

Proposition 12.15 Consider Treatment I.

- (a) There exist pooling equilibria for output levels 1–5. The out of equilibrium beliefs are that if output differs from the equilibrium level, then the incumbent is of type M_H . In all these pooling equilibria, the entrant enters. If the Cho–Kreps intuitive criterion is invoked, then the only pooling equilibria that survive are output levels 4 and 5. Of these two equilibria, pooling at $q = 4$ satisfies “efficiency” in the sense of Milgrom and Roberts (1982).
- (b) There are two separating equilibria. In both these equilibria, type M_H chooses $q = 2$, and conditional on observing $q = 2$, the entrant enters. In the first separating equilibrium, type M_L chooses $q = 6$, and on observing $q = 6$, the entrant does not enter. In the second separating equilibrium, type M_L chooses $q = 7$, and on observing $q = 7$, the entrant does not enter. These equilibria are supported with out of equilibrium beliefs, which require that if output differs from the equilibrium level, then the incumbent is of type M_H . Of these equilibria, only the first separating equilibrium is consistent with the intuitive criterion.

Proof: (a) Let us consider a particular case of the pooling equilibrium at $q = 3$ (the other cases are analogous). The incentive compatibility condition requires that none of the types find it profitable to choose any $q \neq 3$. In a pooling equilibrium, the prior beliefs of the entrant are not updated, hence, the entrant must make his decision based on his expected payoff (last column of Table 12.25). The expected payoff of the entrant in Treatment I is relatively greater from choosing OUT rather than IN, hence, the entrant does not enter. Thus, from Table 12.24, the payoffs of

⁸⁶ Readers who are rusty with the basics of signaling games may wish to have a quick look at the Appendix on game theory.

types M_H and M_L in the pooling equilibrium are, respectively, 426 and 606. If any of the types of the incumbent decides to choose an out of equilibrium action $q \neq 3$, then the out of equilibrium beliefs require the entrant to believe that the incumbent is of type M_H , so the entrant enters ($\because 300 > 250$). From Table 12.24, there exists no $q \neq 3$ such that either of the incumbent types M_H and M_L get a higher payoff relative to the respective equilibrium payoffs. Each incumbent type gets a strictly positive payoff that is greater than the outside option, which is normalized to zero, hence, the participation constraint is satisfied. The other pooling equilibria can be checked to hold in a similar manner.

The plausibility of the out of equilibrium beliefs can be checked against the intuitive criterion. Continue with the case of the pooling equilibrium at $q = 3$. If type M_L chooses another action, he must not be able to get more than the equilibrium payoff of 606. However, by choosing $q = 4$, there is a possibility that he can get more. Hence, the receiver's belief that for $q \neq 3$ the type of the sender is M_H is not intuitive in the Cho–Kreps sense. Proceeding in this manner one can show that pooling at $q = 4$ and $q = 5$ satisfies the intuitive criterion.

Using Milgrom and Roberts (1982), an equilibrium satisfies “economic efficiency” if there exists no other equilibrium at which one type is strictly better off and no type is strictly worse off. Pooling at $q = 5$ does not satisfy this definition because compared to pooling at $q = 4$, both types are worse off. However, pooling at $q = 4$ satisfies the Milgrom–Roberts efficiency criterion.

(b) Consider now the separating equilibrium in which type M_H chooses $q = 2$ and type M_L chooses $q = 6$. In a separating equilibrium, the actions of the incumbent fully reveal the type to the entrant. Thus, on observing $q = 2$, the entrant believes, correctly, that the incumbent is type M_H and, thus, enters, giving the type M_H incumbent a payoff of 168. On observing $q = 6$ the entrant believes (consistent with Bayesian updating) that the type of the incumbent is M_L , so, using Table 12.25 for Treatment I, the entrant stays out, giving the type M_L incumbent a payoff of 592. The participation constraint holds for each type of incumbent.

Let us check for incentive compatibility, i.e., none of the incumbent types should benefit by mimicking the quantity chosen by the other type. If type M_H chooses $q = 6$, then the entrant believes the incumbent to be type M_L and, thus, stays out. This gives type M_H a payoff of $-38 < 168$. So type M_H does not find it worthwhile to mimic the quantity choice of type M_L . Analogously, if type M_L mimics the quantity chosen by type M_H , it is identified (mistakenly) by the entrant as a type M_H , so the entrant enters. The payoff to type M_L in this case is $276 < 592$. Hence, the proposed separating equilibrium is incentive compatible.

The second separating equilibrium in which type M_H chooses $q = 2$ and M_L chooses $q = 7$ can be checked to hold in an analogous manner. Along the lines of the proof of part (a), it is straightforward to check that the first separating equilibrium satisfies the intuitive criterion, while the second does not. ■

Proposition 12.16 *Consider Treatment II.*

- (1) *No pooling equilibrium exists.*
- (2) *The two separating equilibria identified in Treatment I also exist in this case.*
- (3) *There also exist hybrid equilibria in Treatment II. In particular, the following is a hybrid equilibrium. Type M_L chooses $q = 5$. Type M_H plays a mixed strategy, choosing $q = 5$ with probability 0.20 and $q = 2$ with probability 0.80. The decision of the entrant is as follows. On observing $q \neq 5$ the entrant always enters. But when the entrant observes $q = 5$, he enters with probability 0.11 and stays out with probability 0.89.*

Proof: Similar to the proof of Proposition 12.15, thus, it is omitted. The reader is asked to prove this as an exercise. ■

Cooper et al. (1997b) also experimentally test for other equilibrium refinements. The next proposition summarizes the relevant results on refinements that they test; the interested reader can look up Garvin (1993) for the proof.

Proposition 12.17 *Consider Treatment I. Both pooling equilibria in Proposition 12.15 also satisfy the Banks and Sobel (1987) equilibrium refinement of “divinity.” The “perfect sequential equilibrium” of Grossman and Perry (1986) has a unique outcome, namely, pooling at $q = 4$. The “undefeated equilibrium” of Mailath et al. (1993) predicts pooling at $q = 2, 3$, and 4. Noldeke and Samuelson’s (1994) evolutionary model predicts pooling at $q = 4$ as the unique long-run steady state.*

The experimental results for Treatment I are shown in Figure 12.41 for three sessions. Each session was played by 12–16 subjects allocated to the roles of the incumbent and the entrant over

Figure 12.41 Results for Treatment I.

Source: David J. Cooper, Susan Garvin, and John H. Kagel, “Signalling and adaptive learning in an entry limit pricing game.” *The RAND Journal of Economics* 28(4) (Winter, 1997): 662–83. Copyright © 1997, RAND.

three sets of 12 rounds, each set being called a cycle. Subjects are inexperienced in Sessions 1 and 2. Session 3 is conducted with experienced subjects who have prior experience of Treatment I. Each of the histograms shows the percentage of incumbents choosing various levels of quantities. The percentage of entrants who choose to enter is shown as a row of numbers below the histogram beginning with the prefix IN (%).

Inexperienced subjects initially play the full information (or *myopic maximum*) equilibrium. In sessions 1 and 2, in cycle 1, 69% of the choices made by type M_L incumbents coincide with $q = 2$ and 77% of choices made by type M_H incumbents coincide with $q = 4$. As subjects gain experience, in session 3, both types of incumbent subjects gravitate towards the pooling equilibrium in which they choose $q = 4$. However, there is still a substantial fraction of subjects who do not play the pooling equilibrium. Recall from Proposition 12.15 that $q = 4$ corresponds to Milgrom and Robert's (1982) notion of economic efficiency. In cycle 3 of session 3 (constituting the most experienced subjects), the quantity choice of $q = 4$ is made by about 70% of incumbents of type M_H and 92% of the incumbents of type M_L . However, at this pooling equilibrium, only about 6% of the entrants choose IN, the expected equilibrium choice (see Proposition 12.15a).

The separating equilibrium (Proposition 12.15b) is not observed and neither is the pooling equilibrium at $q = 5$ (Proposition 12.15a). Cooper et al. (1997b, p. 670) conclude that: "Indeed, for all of our experiments it is striking how slowly anything resembling a full-blown equilibrium emerges (typically only late in experienced-subject sessions). Even in the best cases, there is a substantial minority of choices (5–10%) that deviate from any given equilibrium."

The experimental results from Treatment II are shown in Figure 12.42. As in Treatment I, in the early periods, each of the incumbent types disproportionately play their full information strategies. Data in the first six periods of play in Treatments I and II are statistically indistinguishable. There are no pooling equilibria in Treatment II (Proposition 12.16). However, there is some tendency for incumbents of type M_H to try to pool with incumbents of type M_L , prior to the emergence of a separating equilibrium. In session 5, the modal choice for all types of incumbents is $q = 4$. By cycle 3 in session 6 (in which subjects have the greatest experience), about half of the incumbents of type M_H and about 80% of incumbents of type M_L play the separating equilibrium (respectively, $q = 2$ and $q = 6$). In response to $q = 2$, 100% of entrants enter, while in response to $q = 6$, about 12% of entrants enter, which is consistent with equilibrium predictions.

The authors explain the data on individual choices by using an adaptive learning model of fictitious play. It does take many rounds of repeated play to converge to equilibrium. Cooper et al. (1997a) consider Treatment II only. They show that the intuitive criterion is clearly violated. An adaptive learning model explains when the intuitive criterion is likely to be satisfied or violated.

The results on equilibrium refinements (Proposition 12.17) are not positive. Cooper et al. (1997a, p. 555) write: "Game theory is at its foundation a hypothesis about how people behave. In particular, it posits that individuals will attempt to anticipate the behavior of others and respond accordingly. This is the soul of game theory, and the experiments indicate that it is alive and well. What may not be so healthy are the legion of assumptions which have been added to the theory in order to get tractable results. In the rush to get theories which give sensible outcomes and are easily employed by theorists, the reality of how people actually behave may have been left behind. We do not suggest that game theory be abandoned, but rather as a descriptive model that it needs to incorporate more fully how people actually behave."

12.6.3 *Finitely repeated games of asymmetric information*

Consider finitely repeated games of one-sided asymmetric information. Suppose, for simplicity, that a player has private information about his two possible types, *strong* and *weak*, in a sense to

Figure 12.42 Results for Treatment II.

Source: David J. Cooper, Susan Garvin, and John H. Kagel, "Signalling and adaptive learning in an entry limit pricing game." *The RAND Journal of Economics* 28(4) (Winter, 1997): 662–83. Copyright © 1997, RAND.

be made precise below. Since the game is finitely repeated, the solution can be found by backward induction. Strategies for each type of each player specify actions for all possible histories of the game. One also needs to specify beliefs of a player on observing out of equilibrium actions.

The equilibrium for such games, due to Kreps and Wilson (1982) and Milgrom and Roberts (1982) (henceforth, KWMR), has generated much interest in economics. The weak type successfully mimics the strong type, initially, by engaging in a costly signal, building up a reputation for being strong. In later periods, the weak type milks its reputation that it has built up in previous periods and reduces the cost of sending a costly signal by randomizing between the costly and a less costly signal.

Consider, for instance, the model of *entry deterrence* that is examined experimentally in Jung et al. (1994). Eight rounds of an entry deterrence game are played by a long-lived incumbent monopolist and a series of short-lived entrants, one for each period. An incumbent monopolist

Table 12.26 Payoff matrix in an entry deterrence game.

Entrant's decision	Monopolist's decision	Payoffs		
		Entrant	Weak monopolist	Strong monopolist
In	Fight	80	70	160
	Accommodate	150	160	70
Out	No choice	95	300	300

Source: Jung et al. (1994).

Table 12.27 Predictions of the equilibrium actions of the weak monopolist and the entrant.

Period	Weak monopolist	Entrant's probability of entering	
	Probability of accommodating	Conditional on entry and fight in previous period	Conditional on no previous entry
1	0.000	0.000	0.000
2	0.000	0.000	0.000
3	0.000	0.000	0.000
4	0.188	0.000	0.000
5	0.346	0.357	1.000
6	0.416	0.357	1.000
7	0.560	0.357	1.000
8	1.000	0.357	1.000

has private information about his two possible types, *weak* (high marginal cost) and *strong* (low marginal cost). The payoffs are shown in Table 12.26. In a one-shot game, a weak monopolist gets a higher payoff from accommodating entry and a strong monopolist gets a higher payoff from fighting entry (in each case because $160 > 70$). Relative to the decision to stay out and get a payoff of 95, it only pays the entrant to enter if the incumbent accommodates ($150 > 95$). Otherwise if the incumbent fights, it is best to stay out ($80 < 95$). The entrant does not know the type of the incumbent but assigns a commonly known prior probability of 0.67 that the type is weak and 0.33 that the type is strong. The predictions are given in Proposition 12.18; one of the exercises asks you to prove it.

Proposition 12.18 *Consider the eight period chain store model of Jung et al. (1994). The predictions of the model, conditional on no accommodation having taken place in any previous round, are given in Table 12.27 (the strong monopolist always prefers to fight, so Table 12.27 only reports the actions of the weak monopolist and the actions of the entrant, conditional on the history of play).*

The weak monopolist fights entry, if it takes place in any of the first three periods; this action prevents the entrant's entry for a while. Entrants play a mixed strategy, and in equilibrium, begin to enter in period 4. From period 4 onwards, the weak monopolist plays a mixed strategy in

which the probability of accommodation increases gradually until it reaches 1 in the last round. The entrant's entry decision is history dependent. Following periods in which there has been entry and fights, the entrants enter with a stationary probability of 0.357. If no previous entry has taken place, then the incumbent monopolist has not had a chance to build his reputation, so entry takes place with probability 1 in periods 5–8. If the weak monopolist does not fight in the first three rounds of play, then the out of equilibrium beliefs of the entrant are that he is a weak type, in which case, all subsequent entrants enter (for the proof of Proposition 12.18, you will need to use these out of equilibrium beliefs).

From Proposition 12.18, standard theory predicts that monopolists will engage in *predatory pricing* (pricing and other practices that deter entry and reduce welfare). The Chicago school has traditionally expressed skepticism about the possibility of predatory pricing. The main source of the skepticism is that the incumbent monopolist cannot forever make losses, thus, entry cannot be stopped in the long run. Unravelling backwards, it should not pay to deter entry in the short run. The possibility of asymmetric information, however, alters the results as shown in Proposition 12.18. In practice, evidence of predatory pricing has been hard to find. Thus, the experimental results of Jung et al. (1994) are important.

Subjects in experiments played between 45–90 rounds of the game. The observed play of the subjects up to round 31 is not very supportive of the equilibrium predictions. For instance, in the initial rounds, weak monopolists accommodate about half the times in the first three periods, although theory predicts that they should be fighting all the time. From rounds 31 onwards, as subjects gain experience with the game, accommodation in the first three rounds was done in only 15% of the plays, while for very experienced subjects it was almost eliminated in these rounds. From round 31 onwards, predatory pricing was found in 80% of the rounds.

There are, however, important departures from the Kreps–Wilson predictions in two important respects. First, the entry rates are not stationary, as predicted. Entry rates increase steadily over the various experimental rounds. Second, while the predicted numbers in the last column of Table 12.27 are higher than those in the penultimate column, the experimental findings are just the opposite. In an alternative approach, Selten (1978) argued that the backward induction argument is more compelling in the last few rounds of the game. So the monopolist might accept the backward induction argument for the last few rounds, while choosing to be aggressive in the initial periods. While this theory makes less precise predictions, it can be a useful device to make sense of the data arising from experiments.

While the data in Jung et al. (1994) violates important aspects of the KWMR predictions, the findings of Camerer and Weigelt (1988) are more supportive of these predictions. Camerer and Weigelt (1988) consider a borrower–lender game in which there is asymmetric information about the type of the borrower. The borrower can be one of two possible types: *normal* (who prefers to default on a loan) and *nice* (who prefers to repay the loan). The structure of the game is similar to the one in Jung et al. (1994) and is also played over eight rounds. The predictions of the model are similar to those in Proposition 12.18 and can be derived using backward induction.

Using the notion of *homemade priors*,⁸⁷ Camerer and Weigelt (1988) conclude that their data broadly supports the Kreps–Wilson predictions. Jung et al. (1997, p. 91) write that: “We give the Kreps and Wilson sequential equilibrium model lower marks than Camerer and Weigelt (1988). . . . Reexamining their data, there are some tendencies to deviate from the Kreps and Wilson sequential equilibrium along the lines found here. In particular, the bankers in the

⁸⁷ In these priors, the lenders think that some proportion of the normal type borrowers will always pay back the loans (i.e., behave just like the nice types).

borrower–lender game, who correspond to the entrants in the chain-store game, lent less as the last period approached, rather than following the stationary strategies required under mixed-strategy play.” It seems that the predictions of the Kreps and Wilson equilibrium have a greater chance of holding under the parameter values employed in Camerer and Weigelt’s borrower–lender game relative to the chainstore game in Jung et al. (1994). Neral and Ochs (1992) show that the results of Camerer and Weigelt are not very robust to changes in parameter values, particularly those related to their homemade priors.

12.6.4 *Signaling in corporate finance*

In actual practice, individual investors in a firm are likely to be less informed about the profitability of the firm as compared to the managers of the firm. Managers of firms with good prospects might then send a costly signal on profitability in order to separate themselves from firms with poorer prospects (Myers and Majluf, 1984).

Suppose that we are interested in explaining excessive levels of debt to equity ratios (leverage) of companies and managers are more informed about the firm’s future profit prospects as compared to investors. We may, heuristically, construct a separating equilibrium in which managers signal their private information by using debt as an instrument, as follows. Only a firm with good prospects may hope to repay a higher level of debt in the future. Hence, a firm with good prospects can, by deciding on a high leverage, separate itself from a type of firm that has bad prospects. Ex-post, when investors observe high leverage, they become informed of the firm’s prospects.

Dividends are sometimes not easy to explain because they just represent a movement from one account (the investors’ share in the firm) to another (investors’ personal bank account), which is taxed. However, under asymmetric information, firms with better prospects may offer greater dividends to signal to investors that current cash flows are healthy.

These sorts of issues are examined by Cadsby et al. (1990, 1998). Consider a firm and its potential investors. The firm has two possible types, indexed by $j = H, L$; types are private information. The firm has initial level of assets, $A_j > 0$, and a project that has a net present value, $B_j > 0$. The cost of the project, $c > 0$, is identical for both types. A type H firm has a relatively higher initial level of assets, so $A_H > A_L$, and a relatively more profitable project, so $B_H > B_L$. We consider Cadsby et al. (1990) first, where signaling is costless. The firm has one of two possible actions. If the firm invests in the project, the end of period value of the firm is $V_j = A_j + B_j - c$, and if it chooses to forgo the project, the end of period value of the firm is $V_j = A_j$.

There is a large pool of risk-neutral investors who are potentially interested in investing in the project. Investors do not know the type of the firm but have prior beliefs that each type is equally likely. Denote by EV_j , the expected value of the firm and by s_j , the share in equity of a type $j = H, L$ firm, that is demanded by an investor in return for the investment. The firm moves first and chooses one of its type-contingent actions, forgo the project, or invest in the project. If the firm forgoes, then the game ends and the firm gets $V_j = A_j$, while investors get nothing. If the firm chooses to invest, it needs to raise the money to pay for the cost c of investing. In this case, a descending value first price auction is conducted among the investors to determine the sole winner who finances the cost of the project, c . Since there is a large pool of risk-neutral and competitive investors, competitive bidding reduces the profits of the investors to zero. Thus, the winning bid, s_j^* , satisfies

$$s_j^* EV_j = c, \quad (12.25)$$

Table 12.28 Type-contingent assets and end of period value of firms.

Experiment	Type L		Type H	
	A_L (Forgo)	V_L (Invest)	A_H (Forgo)	V_H (Invest)
A	250	625	500	1250
B	160	500	620	1000
C	300	750	625	1250
D	80	400	270	600
E	50	375	200	625
F	400	750	800	1250
G	150	480	450	810
H	150	480	450	1050

where the expectation is taken over the type of the firm and the value of the firm is $V_j = A_j + B_j - c$, $j = H, L$. Since the firm knows its type, its profits equal $(1 - s_j^*) V_j$, while the investors get $s_j^* V_j$. A firm of type $j = H, L$ invests if $(1 - s_j^*) V_j \geq A_j$, otherwise it forgoes the investment.

Depending on the parameter values, separating, pooling, and hybrid equilibria can arise in this model. Consider one choice of type-contingent parameter values for A_j , V_j shown in Table 12.28. The first column alphabetically lists the ten sets of experiments, A through J. The first two experiments, A, B, with shaded backgrounds, are the full information benchmarks in which investors know the type of the firm. In all cases, $c = 300$.

The different equilibria that arise for each of the cases in Table 12.28 are given in Table 12.29. The predicted equilibria are listed in the second column and are of the following types: Full information (FI), separating (S), pooling (P), and hybrid or semi-separating (H). The firm has two possible investment actions, forgo or invest. The column labeled Pr(Invest) gives the probability of investment (possibly a mixed strategy). The predicted share of the firm demanded by the investor in equilibrium, s_j^* , for each of the types, $j = H, L$, is also shown.

In a pooling equilibrium, both types of firms either forgo the investment or invest in the project. Investors do not update their beliefs in a pooling equilibrium, thus, using (12.25), $s_L^* = s_H^*$. In a separating equilibrium, one type invests, while the other does not, thus, $s_L^* \neq s_H^*$. For some parameter values, there is a unique equilibrium, while for others, such as those in the experiments E, F, H, and J, there are multiple equilibria.

In the full information equilibrium, in experiments A, B, the type of the firm is known to the investors, hence, using (12.25), $s_j^* = c/V_j$. Using $c = 300$, and the information given in Table 12.28, one can readily compute s_L^*, s_H^* for the first two rows in Table 12.29. For these values of s_j^* , and the values given in Table 12.28, a simple calculation shows that $(1 - s_j^*) V_j > A_j$, $j = H, L$, so both types of firms invest with probability 1 (Pr(Invest) = 1).

Now consider the pooling equilibrium in experiment C. In a pooling equilibrium, prior beliefs are not updated, hence, using (12.25) and Table 12.28, $s_j^* = c/EV_j = \frac{300}{0.5(750) + 0.5(1250)} = 0.3$, $j = H, L$. A firm of type L undertakes the project with probability 1 because $(1 - s_L^*) V_L = 0.7(750) > A_L = 300$. Similarly, a firm of type H invests because $0.7(1250) > 625$.

Table 12.29 Equilibrium predictions of the signaling model in Cadsby et al. (1990).

Experiment	Equilibrium	Type L firm		Type H firm	
		Pr(Invest)	S_L^*	Pr(Invest)	S_H^*
A	FI	1	.480	1	.240
B	FI	1	.600	1	.300

Source: Cadsby et al. (1990).

Consider experiment E in Table 12.28. From Table 12.29, we know that in this case there are three possible equilibria, S, P, and H. Consider, for instance, the separating equilibrium. Let the prior beliefs of investors be such that if the firm invests in the project, it is type L, otherwise, if it forgoes, it is type H. Suppose that a firm of type L chooses to invest and a type H firm chooses to forgo. These choices reveal the types of the firm. Hence, using (12.25), for a type L firm, investors are willing to accept a share in the equity equal to $s_L^* = c/V_L = 300/375 = 0.8$. Hence, the profit of a firm of type L is $(1 - s_L^*)V_L = 0.2(375) = 75.0 > 50$, thus, type L prefers to invest rather than forgo. If firm H were to try to mimic a type L firm, then its profits are $(1 - s_L^*)V_H = 0.2(625) = 125.0 < 200$, hence, incentive compatibility holds, giving rise to a separating equilibrium.⁸⁸

The reader can proceed analogously to construct all other entries in Table 12.29.

We show the results of the experiments in Table 12.30. In the full information cases A and B, there was quick convergence to the predicted equilibrium, hence, the results for these cases are

⁸⁸ By contrast, for experiment E, there is no separating equilibrium in which type H invests and type L forgoes. To see this, let the beliefs of investors be that if the firm invests in the project, it is type H, otherwise, if it forgoes, it is type L. Suppose that a firm of type H choose to invest and a type L firm chooses to forgo. These choices reveal the types of the firm. Hence, using (12.25), for a type H firm, investors are willing to pay a share in the equity equal to $s_H^* = c/V_H = 300/625 = 0.48$. Hence, the profit of a firm of type H is $(1 - s_H^*)V_H = 0.52(625) = 325 > 200$, hence, type H prefers to invest rather than forgo. If firm L were to try to mimic a type H firm, then its profits are $(1 - s_H^*)V_L = 0.52(375) = 195.0 > 50$, so the putative separating equilibrium breaks down.

omitted. For cases C through J, the mean level of s_L and the predicted levels s_L^* are quite close. The other main results can be summarized as follows.

1. When there is a unique predicted equilibrium for an experiment, convergence to that equilibrium takes place in even fewer number of rounds. Convergence was almost instantaneous when the unique equilibrium was pooling (as in C). Convergence took longer when there was a unique separating equilibrium (as in cases G, I).
2. When there is a unique separating equilibrium (as in cases G, I), subjects initially try to play some pooling strategies. However, as they discover in successive rounds that separating is more profitable, actual play converges to a separating equilibrium (in round 6 for G and in round 4 for I).
3. When there are multiple equilibria (as in cases E, F, H), the experimental outcomes converge to the pooling equilibrium quite rapidly (round 2 in E and almost instantaneously in F, H). This occurred irrespective of whether subjects had prior experience of pooling or separating equilibrium.⁸⁹

These results provide good support for the theory. The authors do not report data on “individual” levels of bids, s_i . Strictly speaking, the predictions of theory only apply to these individual decisions, however, the reported results are for the mean levels (see Table 12.30). On the whole, it is surprising that in the light of people failing to match the theoretical predictions in much simpler games, they actually do so remarkably well in these quite complex games. Furthermore, people often violate Bayes’ rule in experiments (see Part 7), which plays a critical role in a Perfect Bayesian equilibrium of signaling games. For these reasons, replicating these experiments, checking for the robustness of the results, looking at data at the disaggregated level, and having a richer action space for firms, is important.

Cadsby et al. (1998) extend their earlier work to introduce the possibility of costly signaling (e.g., advertising). Each of the types of the firm can buy a costly signal. Recall that the profit of

Table 12.30 Actual and predicted results of the signaling model in Cadsby et al. (1990).

Experiment	Type L		Type H		Mean s_L from the data	s_L^* predicted by the model

⁸⁹ The authors offer one possible conjecture for the greater prevalence and salience of the pooling equilibrium. If any of the investors is aggressive enough to anticipate pooling, he will drive the auction price (s_L) down, creating an incentive for firms to pool.

each firm is given by $(1 - s_i^*) V_i$. On the one hand, buying a costly signal reduces the value of the firm, V_i . However, because the costly signal might reveal the type of the firm to the investors, a type H firm might benefit on account of investors bidding a lower share s_H^* . On balance, it might be optimal for a firm to send out a costly signal.

The main aim of the paper is to test for the Cho–Kreps equilibrium dominance criterion (or the intuitive criterion) but also to test if in this more complicated environment signaling equilibria still arise. The results are more negative for the theory in this paper relative to their earlier paper. It is no longer the case that the signaling outcome was obtained for all experiments. Even when subjects reached an equilibrium prediction, the equilibrium was not maintained, i.e., play drifted away from the equilibrium in subsequent periods. The evidence for the intuitive criterion is mixed. Indeed, the data cannot be explained by equilibrium refinements at all but by the myopic short-run gains to type H from revealing its type. In summary, classical signaling equilibrium analysis does reasonably well when signals are not costly, but less well when signals are costly.

12.6.5 *Leader contributions to charitable giving: signaling or reciprocity?*

Evidence suggests that initial public contributions by a relatively big donor (the leader), positively influence subsequent contributions from smaller donors (the followers) (List and Lucking-Reiley, 2002). In a related context, church contributions are found to be higher when contributions are collected by the open basket method (public information) rather than by the closed basket method (Soetevent, 2005). Why is this so? One possibility is that the value of the donations might be private information to big donors, so their contributions may signal to others that such donations are valuable, hence, inducing greater contributions from others.⁹⁰ An alternative explanation is that people may have “other-regarding preferences,” thus, followers reciprocate the contributions of the leader. In this view, a high initial contribution from a leader induces positive reciprocity from the followers.

To fix ideas, consider, as in Potters et al. (2007), a two-player game with a leader (L) and a follower (F). Both players are risk neutral. Contributions to charitable giving, x_i , by each player $i = L, F$, can take two possible values: $x_i = 1$ or $x_i = 0$. The payoffs of the players are given by

$$\pi_i = 1 - x_i + r(x_L + x_F); \quad i = L, F, \quad r > 0, \quad (12.26)$$

where $r \geq 0$, is the per unit return to a player from the total charitable contributions and $r \in \{0, 0.75, 1.5\}$. Under full information, the follower knows the return r . However, under asymmetric information, the follower only knows that the three possible values of r are equiprobable.

The social maximum can be found by choosing x_L, x_F to maximize

$$\pi_L + \pi_F = 2 + (x_L + x_F)(2r - 1). \quad (12.27)$$

Proposition 12.19 *If $r = 0.75$ or 1.5 , then it is socially optimal for each player to contribute the maximum amount, $x_i = 1$. Otherwise, if $r = 0$, it is socially optimal to choose zero contributions, $x_i = 0$.*

⁹⁰ For theoretical models, see Hermlin (1998) and Vesterlund (2003).

Proof: Since the individual choices are binary, $x_i = 0$ or $x_i = 1$, $i = L, F$, we compare the optimum at the two possible values. If $2r - 1 > 0$, or equivalently $r > 0.5$, then, using (12.27), it is optimal to have $x_i = 1$, $i = L, F$. Otherwise, if $2r - 1 \leq 0$, or equivalently $r \leq 0.5$, then the optimal choice is $x_i = 0$, $i = L, F$. ■

Having established the social benchmark, now consider the full information case under privately optimal choices. Let both players simultaneously, or sequentially, decide to make their contribution decision; results are identical for these two cases under full information. In a Nash equilibrium, each player maximizes the objective function, given in (12.26), conditional on the contribution of the other player. Rewriting (12.26) we get,

$$\pi_i(x_i) = 1 + (r - 1)x_i + rx_j; j \neq i, j = L, F. \quad (12.28)$$

We assume that, holding fixed the contributions of player j , player i contributes if $\pi_i(x_i = 1) \geq \pi_i(x_i = 0)$. From (12.28), irrespective of the contribution of the other player, it pays a player to contribute only if $r \geq 1$. Hence, the following result is immediate.

Proposition 12.20 *Under full information, whether players contribute simultaneously or sequentially, it is optimal to contribute if $r = 1.5$ and to not contribute if $r = 0$ or $r = 0.75$.*

Under asymmetric information, nature first draws a value of r , which is observed by the leader but not by the follower; the follower only knows that each value of r is equiprobable. The leader chooses the level of contribution, x_L , which is observed by the follower who then chooses the level of contribution x_F .

Proposition 12.21 *In the unique sequential equilibrium, the leader contributes only when it is socially optimal to do so (i.e., when $r = 0.75, 1.5$). The follower makes the same contribution as the leader. The beliefs of the follower are that if a strictly positive contribution by the leader is observed, then $r = 1.5$, otherwise, $r = 0$.⁹¹*

Proof: We need to check that the stated strategies and beliefs are sequentially rational. First let us check that the strategy of the leader is optimal, given the subsequent strategies along the equilibrium path. Thus, let the leader believe that the follower will match his contribution, i.e., $x_L = x_F$. Then, using (12.28), the payoff of the leader can be written as $\pi_L = 1 + x_L(2r - 1)$. Since $x_L \in \{0, 1\}$, the leader makes a contribution when $2r - 1 \geq 0 \Leftrightarrow r \geq 0.5$, which occurs in the two cases, $r = 0.75, 1.5$. Let $r = 0.75$ or 1.5 . Given the equilibrium strategy of the leader ($x_L = 1$), and the follower's beliefs that require $r = 1.5$, the payoff of the follower, using (12.28), is given by

$$\pi_F = 1 + 1.5 + x_F(1.5 - 1),$$

which is maximized at $x_F = 1$. We leave it for the reader to check that if $x_L = 0$, then $x_F = 0$ is optimal. ■

So far, we have assumed that players care only about their own payoffs. What if players instead have social preferences? In order to incorporate social preferences, Potters et al. (2007) use the following form of Fehr and Schmidt (1999) preferences.

⁹¹ Bayes' rule in these games allows us to put any restrictions on out of equilibrium beliefs; see the game theory Appendix for this claim and for the basics of a sequential equilibrium.

$$U_i(x_i) = \pi_i - \beta_i \max\{\pi_i - \pi_j, 0\}, i = L, F, \quad (12.29)$$

where π_i, π_j are defined in (12.28). In this formulation, players care about their own payoffs as well as about *advantageous inequity*; $\beta_i > 0$ is known as the parameter of advantageous inequity.⁹² Only the full information case is considered under social preferences, so both players know r before they choose their contributions. Under social preferences, holding fixed the contribution of player j , player i contributes if $U_i(x_i = 1) \geq U_i(x_i = 0)$. We shall be particularly interested in the case $r = 0.75$.

Proposition 12.22

- (1) Consider first a simultaneous move game between the leader and follower when they have social preferences. The following are some interesting Nash equilibria.
 - (1a) Both players contribute if $1 - r \leq \beta_L$ and $1 - r \leq \beta_F$. In the special case of $r = 0.75$, this reduces to the condition $0.25 \leq \beta_L$ and $0.25 \leq \beta_F$.
 - (1b) If $r < 1$, then there is also a Nash equilibrium in which both players do not contribute. In particular, this also holds true for the case $r = 0.75$.
- (2) Now consider a sequential game in which the leader chooses x_L first. The follower observes the leader's contribution and then decides on his/her contribution, x_F . In this sequential game, the equilibrium is identical to that in part (1).

Proof: (1a) Suppose that we are interested in finding a Nash equilibrium in donations in which the leader and the follower simultaneously choose their respective contributions. Using (12.26), we get

$$\pi_i - \pi_j = x_j - x_i. \quad (12.30)$$

Suppose that the leader contributes, i.e., $x_L = 1$. Then the utility of the follower from contributing $x_F = 1$ is $U_F = 2r$ (using $x_L = x_F = 1$, (12.28), (12.29), (12.30)). On the other hand, if the follower does not contribute ($x_F = 0$), then from (12.29), (12.30), the follower's utility is $U_F = 1 + r - \beta_F$. Therefore, the follower prefers to match the contribution of the leader if $1 + r - \beta_F \leq 2r$, or, equivalently, if $1 - r \leq \beta_F$. Since $r = 0.75$, the sufficient condition is $0.25 \leq \beta_F$. Given the symmetry of the game, one can check analogously that if the follower contributes, then the leader also contributes if $1 - r \leq \beta_L$.

(1b) Suppose that the leader does not contribute, i.e., $x_L = 0$. The utility of the follower from the matching contribution, $x_F = 0$, is $U_F = 1$. From the non-matching contribution, $x_F = 1$, the utility of the follower is $U_F = 1 + (r - 1)$. Thus, it is optimal not to contribute if $r < 1$. Analogous reasoning applies to the leader if the follower does not contribute. Hence, for $r < 1$, $x_L = 0$ and $x_F = 0$ is also a Nash equilibrium.

(2) The proof follows by backward induction. Conditional on any level of the contributions by the leader, x_L , the payoff of the follower, given in (12.26), is

$$\pi_F(x_F = 1) = r(1 + x_L), \pi_F(x_F = 0) = 1 + rx_L. \quad (12.31)$$

First, let us find an equilibrium in which, having observed $x_L = 1$, the follower also finds it optimal to contribute $x_F = 1$. Using (12.26), (12.29), (12.31), we get $U_F(x_F = 1) = 2r$ and

⁹² Disadvantageous inequity, which is an essential part of Fehr-Schmidt preferences, is ignored here; see Part 2 for more details.

$U_F(x_F = 0) = 1 + r - \beta_F$. Hence, it is optimal for the follower to contribute if $1 - r \leq \beta_F$. Similarly, if the leader does not contribute, $x_L = 0$, then the utility of the follower from contribution and no-contribution is, respectively, $U_F(x_F = 1) = r$ and $U_F(x_F = 0) = 1$. Thus, it is optimal not to contribute if $r \leq 1$. ■

The experiments were run with 192 subjects over four sessions and there were 12 students in a session. Within each session, six pairs of students made decisions over 18 rounds.⁹³ Two kinds of treatments were run, full information and asymmetric information. Within each treatment, simultaneous and sequential move cases are separately run. The results are as follows.

1. The results for leader and follower contribution rates under asymmetric information are shown in Figure 12.43. The total contributions are 50% larger in the sequential move case, relative to the simultaneous move case. It is only in the sequential move case that the leader gets a chance to signal the value of r through his level of contributions. Hence, these results are consistent with the signaling explanation. In the sequential move game, a binomial test reveals that followers are more likely to contribute when leaders contribute. The followers do not exactly match the leader contributions, but there is a high enough match in the contributions to support the predicted equilibrium. When the leader contributes, the follower contributes 80.6% of the time and when the leader does not contribute, the follower also does not contribute 92.2% of the time.
2. Under asymmetric information, the behavior of individual subjects is rational in the following sense. For both simultaneous and sequential treatments, the leaders almost never contribute when $r = 0$ and almost always contribute when $r = 1.5$ (see Proposition 12.21). The most significant difference arises for the case $r = 0.75$. The leadership contributions

Figure 12.43 Contribution rates under asymmetric information.

Source: Potters et al. (2007).

⁹³ Subjects were not shown the functional forms for π and U . Rather, for two abstractly named decisions A and B, corresponding to $x = 0$ and $x = 1$, they were given probabilistic payoffs corresponding to different values of r .

Figure 12.44 Contribution rates under full information.

Source: Potters et al. (2007).

are 15% in the case of simultaneous moves, jumping up to 75% under sequential moves. The contributions of followers also increase in this case.

3. Consider now the case under full information shown in Figure 12.44. In this case, there are no signaling concerns. The classical predictions are given in Proposition 12.20, while the predictions under reciprocity are given in Proposition 12.22. In particular, in a sequential move game, if the follower's reciprocity is high enough (high β_F), then he is more likely to contribute, which also increases the leader's incentive to contribute. This is the main insight that is tested in the empirical results. The contribution rates are quite low when $r = 0$. However, when $r = 0.75$, a quarter of the population contributes, whereas in the absence of reciprocity, nobody should contribute. There is evidence of reciprocal behavior, which is suggestive of social preferences. When the leader contributes (in the sequential case), the follower also contributes in 33.3% of the cases; in the absence of reciprocity, there should be no such effect. That the followers' choices are influenced by those of the leaders is statistically verified using a binomial test. In the sequential case, the leader contributions (27%) are statistically larger than those in the simultaneous move case (16%). However, follower contributions are lower in the sequential case relative to the simultaneous move case. When we take account of the leader and follower contributions, the total contributions in the sequential and the simultaneous cases are not statistically different.

The main difference between the asymmetric and full information cases is this. When reciprocity seems to be present, it does not alter the total amount of contributions under full information when we compare the two cases of simultaneous and sequential contributions. However, under asymmetric information, there are significantly higher contributions in the sequential case. This lends credence to the signaling hypothesis, namely that leader contributions give rise to an increase in overall contributions when the leader has asymmetric information about the returns from contributing.

12.6.6 Multiple signals

Duffy and Feltovich (2002) consider the effect of multiple signals on behavior. They use the term “multiple signals” in the dual sense of “signals” and “messages/actions.” Suppose that a sender and a receiver interact repeatedly, playing a stage game over several rounds. The following three well-known games are considered.

Prisoner's Dilemma (PD)			Stag-Hunt (SH)			Chicken (CH)		
	C	D		C	D		C	D
C	70, 70	10, 80	C	70, 70	10, 55	C	70, 70	50, 80
D	80, 10	40, 40	D	55, 10	55, 55	D	80, 50	40, 40

Payoffs are expressed in points. Each point in the payoff matrix represents a 1% chance of winning \$1. In each of the three games, C stands for cooperation and D for defection. The cooperative outcome is (C, C), while the two coordinated outcomes, or Nash equilibria, are (C, C) and (D, D). In the prisoner's dilemma game (PD) there is a unique Nash equilibrium, (D, D). In the stag-hunt game (SH), there are two pure strategy Nash equilibria, (C, C), (D, D), and a mixed strategy Nash equilibrium in which each player plays C and D with respective probabilities 0.75 and 0.25. In the game of Chicken (CH), there are two pure strategy Nash equilibria, (C, D), (D, C), and a mixed strategy Nash equilibrium in which each player plays C and D with probability 0.5 each.

Three possible treatments are considered. In the *cheap talk only treatment*, the sender can send costless messages to the receiver. In the *observations only treatment*, players can observe the actions of others in the previous round. In the *control treatment*, neither observation of past actions nor cheap talk is allowed. Duffy and Feltovich (2006) introduce two further treatments. In the *words and deeds (WD) treatment*, senders send a cheap talk message to the receivers as an intention of the action that they might play. Receivers also observe the action of the sender in the previous round. The *words, deeds, and lies (WDL) treatment*, is similar except that, in addition, receivers also observe the message/action of the sender in the previous round. Thus, receivers can, by comparing the previous round action and message, check if the sender was lying in the past.

What outcomes do we expect? On the one hand, greater information might enable receivers to make better decisions. However, on the other hand, if multiple signals are *crossed* (e.g., the action in the current round is different from the message in the previous round), then the receiver might have been better off without the additional information. In the converse case, if the message and actions are identical, then signals are said to be *aligned*.

The authors use the framework of Farrell and Rabin (1996) to argue that the three games differ in the perceived truthfulness of messages sent by the sender. In the Farrell–Rabin framework, there are two conditions, which determine this perception. The first condition, *self-commitment*, is that the pair of actions (sender's message, receivers action) should be a Nash equilibrium. The second condition, *self-signaling*, has the following two requirements. (a) When a sender intends to be truthful, he prefers the receiver to play his best response to the message. For instance, in the SH game, the row player may wish the Pareto optimal outcome (C, C) to occur. To ensure this, the row player may send the message C as his intention to play the game. He would prefer the column player to play C, which is his best response. (b) When a sender intends to be deceptive, he does not prefer the receiver to play his best response to the message. For instance, in the PD game, if the sender sends the message C, then he prefers the receiver not to play his best response (because $10 < 70$).

Using this framework, messages in the SH game are most likely to be truthful and believed (they satisfy self-commitment and self-signaling). In comparison, messages sent in the CH game

Table 12.31 Relative frequencies of cooperation, coordination, and efficiency.

Game	Treatment	Cooperation	Coordination	Payoff efficiency	Efficiency gain
PD	WD	0.354 ^{ab}	–	0.230 ^{ab}	0.230 ^{ab}
	WDL	0.391 ^b	–	0.266 ^b	0.266 ^b
	<i>Cheap talk</i>	0.400 ^b	–	0.260 ^b	0.266 ^b
	<i>Observation</i>	0.404 ^b	–	0.266 ^b	0.266 ^b
	<i>Control</i>	0.222 ^a	–	0.113 ^a	0.113 ^a
SH	WD	0.782 ^{ab}	0.798 ^{bc}	0.752 ^{abc}	0.379 ^{abc}
	WDL	0.823 ^b	0.873 ^c	0.828 ^c	0.570 ^c
	<i>Cheap talk</i>	0.835 ^{ab}	0.840 ^c	0.803 ^{bc}	0.508 ^{bc}
	<i>Observation</i>	0.757 ^{ab}	0.667 ^{ab}	0.636 ^{ab}	0.090 ^{ab}
	<i>Control</i>	0.607 ^a	0.513 ^a	0.453 ^a	–0.368 ^a
CH	WD	0.577 ^{ab}	0.507 ^{ab}	0.746 ^{ab}	0.237 ^{ab}
	WDL	0.604 ^{ab}	0.498 ^{ab}	0.770 ^{ab}	0.311 ^{ab}
	<i>Cheap talk</i>	0.564 ^{ab}	0.532 ^b	0.741 ^{ab}	0.223 ^{ab}
	<i>Observation</i>	0.364 ^b	0.438 ^a	0.780 ^b	0.340 ^b
	<i>Control</i>	0.537 ^a	0.475 ^a	0.696 ^a	0.088 ^a

Italicized treatments from Duffy and Feltovich (2002). Within each game and statistic, entries with no superscripts in common are significantly different at the 10% level (two-sided robust rank-order test, session-level data); superscripts earlier in the alphabet correspond to significantly lower values. PD, Prisoners' Dilemma; SH, Stag Hunt; CH, Chicken; WD, Words and Deeds; WDL, Words, Deeds, and Lies.

Source: Duffy and Feltovich (2006).

satisfy self-commitment but not self-signaling, so they are less likely to be truthful or believed. Messages purporting to play C in the PD game satisfy neither self-commitment nor self-signaling, while those purporting to play D satisfy self-commitment but not self-signaling, hence, they are less likely to be believed relative to, say, the SH game.

We define an index of *payoff efficiency* as follows. The outcome with the maximum possible joint payoffs in the game is given an index of 1 and the one with the lowest possible joint payoff is given an index of 0 (for the prisoner's dilemma game, these are respectively (C, C) and (D, D)). The outcome (C, D) in the prisoner's dilemma game has payoff efficiency equal to $\frac{90}{140} = 0.64$. The *efficiency gain* of an outcome is defined as the increase in payoff efficiency relative to the payoff efficiency of the outcome with the lowest joint payoff. Thus, in the prisoner's dilemma, the efficiency gain of the outcome (C, C) is 1.0 and that of the outcome (C, D) is 0.64.

The results from Duffy and Feltovich (2002, 2006) are shown in Table 12.31. The italicized treatments are those from Duffy and Feltovich (2002). The additional, non-italicized, treatments, WD and WDL are from Duffy and Feltovich (2006). The subscripts on the statistics are explained under the table.⁹⁴

⁹⁴ For instance, for any of the games, the statistic corresponding to the control treatment is superscripted with an 'a'. If, say, the superscript on the statistic for the cheap talk treatment is a 'b' (e.g., in column 3, it is 0.400^b for the PD game), then the two statistics are significantly different at the 10% level. When there are double superscripts, it implies that one of the statistics is significantly lower than the other. For instance, the frequency of cooperation in the cheap talk treatment for the SH game is 0.835^{ab}. This implies that the frequency of cooperation in the control treatment (0.607^a) is significantly lower.

Duffy and Feltovich (2002) found that the differences in the levels of cooperation are more pronounced across games, rather than across the information treatments (cheap talk, observation, and control). They also found that when cheap talk was predicted to be credible (using the Farrell–Rabin criterion described above), the level of cooperation in the “cheap talk only” treatment was greater than that in the “observation only” and in the control treatment that allowed neither cheap talk nor observation. In this case, *words spoke louder than actions*. When cheap talk is predicted not to be credible, then it was found that *actions spoke louder than words*. For instance, in Table 12.31, restricting to the Duffy and Feltovich (2002) results, cooperation is much higher with cheap talk in the PD and SH games but lower in the CH game, relative to the other two treatments.

Turning now to the Duffy and Feltovich (2006) findings, relative to the three treatments in Duffy and Feltovich (2002), the WD treatment does not lead to greater cooperation. There is slightly greater cooperation in the WDL treatment. Hence, adding extra information helps somewhat but not a whole lot more. However, WDL still does not improve on the level of cooperation relative to any of the three treatments in Duffy and Feltovich (2002). One possibility is that multiple signals create greater cognitive difficulties of interpreting them.

Could the results be explained by distinguishing cases where the signals are crossed or aligned? Figure 12.45 answers this question. On the vertical axis are relative frequencies of cooperation, coordination, and efficiency. On the horizontal axis are the three games, PD, SH, and CH. The treatments (see key on the right hand side of the figure) are broken up by the two cases of aligned and crossed signals. The figure also shows the data from Duffy and Feltovich (2002).

In the PD and SH games, all three indicators, the levels of cooperation, coordination, and the efficiency gain, are enhanced when signals are aligned rather than crossed. In the aligned case, the level of cooperation is comparable to the three treatments in Duffy and Feltovich (2002). In the crossed case, the level of cooperation is much lower. Thus, it is not the level of information but the content of information that is vital. Results are less clear cut in the CH game.

In addition to the results described above, the individual-level data reveals the following findings. (1) Even when signals are predicted to be uninformative and/or false, they are truthful, and

* : Sig. diff. between aligned and crossed-signal combinations (one-tailed Wilcoxon summed-ranks test, session-level data, $p < 0.10$).
 ‡ : Sig. diff. between aligned and crossed-signal combinations (one-tailed Wilcoxon summed-ranks test, session-level data, $p < 0.05$).

are believed. (2) Overall, the truthfulness of messages varies with the incentive to lie. For instance, lies are more easily caught in the WDL treatment, hence, the senders are more truthful in this treatment. (3) Receivers seem to respond in a manner that is suggestive of payoff maximization and reciprocity.

12.6.7 *Two-sided asymmetric information*

A well-known prediction of classical game theory is that one-sided or two-sided private information may impede trade; these results are summarized in various *no-trade theorems*.⁹⁵ Carillo and Palfrey (2009, 2011) consider novel experiments in two-sided asymmetric information games. Their interest is in considering situations where it is not optimal to engage in some transaction, yet the presence of two-sided asymmetric information may induce trade, contrary to the predictions of classical game theory.

Consider two countries that might go to war. The two countries may keep the status quo (no-war) and enjoy a compromise payoff. Or they may go to war in which the winner gets a higher payoff than the compromise payoff and the loser gets a lower payoff. Yet, on account of two-sided private information, the relative strength of the countries is not mutually known. In the games considered in Carillo and Palfrey (2009), the prediction of a Perfect Bayesian Equilibrium is that both countries should go to war with probability 1 (the analog of the no-trade result). However, the experimental results show that the countries fight with probabilities in the interval [0.5, 0.7]. Thus, there is too much compromise relative to the predictions of theory. Further, and contrary to the predictions of theory, the probability of going to war in the experimental data depends on the magnitude of the compromise payoffs. The results also show limited evidence of any learning by the subjects.

12.7 Public signals and correlated equilibria

Cason and Sharma (2007) consider the following two-player symmetric, strategic form game with multiple Nash equilibria.

	Left (L)	Right (R)
Up (U)	3, 3	48, 9
Down (D)	9, 48	39, 39

Suppose that the monetary payoffs shown in the payoff matrix also represent the respective utilities of the players. This game has two pure strategy Nash equilibria, (D, L), (U, R), and one mixed strategy Nash equilibrium in which the row player plays Up with probability 0.6 and the column player plays Left with probability 0.6.

If the experimenter were to recommend the players to play their part of a Nash equilibrium, say, through a public signal, then, such a recommendation may be expected to be self-enforcing. If it turns out not to be the case, then there are two possibilities. (1) The monetary payoffs in the payoff matrix do not represent utilities of the players. For instance, the players might have social preferences, and, thus, may derive utility from their own monetary payoffs as well as the monetary payoffs of others. (2) The players may doubt the rationality of other players, and, so, believe

⁹⁵ See, for instance, Akerlof (1970) for the case of one-sided asymmetric information and Myerson and Satterthwaite (1983) for the case of two-sided private information.

that other players will not follow their part of the recommended strategy profile. Under these conditions, it may be optimal for a player to ignore the recommendations of the experimenter.

Cason and Sharma (2007) attempt to find out which of these two (or both) possibilities hold. They assign the players to play a *correlated equilibrium* in which the joint payoffs of the players exceed the highest payoffs from any Nash equilibrium. We will only develop the notion of a correlated equilibrium within this simple setup.⁹⁶

Suppose that the players observe some credible public signal of the following form: The probabilities of the strategy profiles (U, L), (U, R), (D, L) and (D, R) are respectively p_{UL} , p_{UR} , p_{DL} , p_{DR} , and $p_{UL} + p_{UR} + p_{DL} + p_{DR} = 1$. In the experiments, the experimenter may credibly and publicly announce these probabilities. The experimenter then randomizes between the four strategy profiles, according to the stated probabilities. Suppose that a particular realization of this randomization is (U, L). The experimenter does not reveal the realization to the players but privately asks each player to play his part of the strategy profile. Players are assumed to use Bayes' rule to form beliefs about the strategies of others.

Suppose, for instance, that the row player is given an instruction to play U. In order to determine whether to comply with the recommendation (play U) or not (play D), the row player needs to form beliefs, using Bayes' rule, about the probability with which the column player will play L. Conditional on the row player given a recommendation to play U, Bayes' rule dictates that the probability of the play of L by the column player is $P(L | U) = \frac{p_{UL}}{p_{UL} + p_{UR}}$. Analogously, one can compute that

$$P(R | U) = \frac{p_{UR}}{p_{UL} + p_{UR}}; P(L | D) = \frac{p_{DL}}{p_{DL} + p_{DR}}; P(R | D) = \frac{p_{DR}}{p_{DL} + p_{DR}}.$$

Then $(p_{UL}, p_{UR}, p_{DL}, p_{DR})$ is a correlated equilibrium if each player plays the assigned recommendation, conditional on the belief that all other players will also follow their recommendations. This requires the satisfaction of the following inequalities.

$$P(L | U) 3 + P(R | U) 48 \geq P(L | U) 9 + P(R | U) 39. \quad (12.32)$$

$$P(L | D) 9 + P(R | D) 39 \geq P(L | D) 3 + P(R | D) 48. \quad (12.33)$$

$$P(U | L) 3 + P(D | L) 48 \geq P(U | L) 9 + P(D | L) 39. \quad (12.34)$$

$$P(U | R) 9 + P(D | R) 39 \geq P(U | R) 3 + P(D | R) 48. \quad (12.35)$$

These inequalities are of the nature of incentive compatibility conditions. For instance, consider the inequality in (12.32). Assuming that (a) the column player plays the recommended strategy, and (b) the row player is given the recommendation to play U, the column player will play L with probability $P(L | U)$ and R with probability $P(R | U)$, irrespective of the strategy of the row player. Thus, (12.32) requires that the row player should get a higher payoff from complying with the recommendation to play U (the LHS), rather than deviating and playing D (the RHS). The inequality in (12.33) requires that the row player prefers to comply with the recommendation to play D rather than to deviate and play U. Inequalities (12.34), (12.35) give analogous conditions for the column player.

The set of all payoffs that can be implemented using a correlated equilibrium are enclosed by the dotted line in Figure 12.46. This is the set of all convex sets of payoffs that can be formed

⁹⁶ For further details on correlated equilibria, we refer the reader to any standard text in game theory, e.g., Fudenberg and Tirole (1991).

Figure 12.46 The set of possible payoffs in a correlated equilibrium.

by using the four inequalities (12.32)–(12.35), the non-negativity conditions on probabilities, and the condition that probabilities sum to one. The Nash equilibrium payoff hull which is shown enclosed by the bold lines is a subset of the set of payoffs that can be obtained in a correlated equilibrium.⁹⁷ The cooperative outcome, (D, D), with the highest joint payoffs (39, 39) (labeled as ‘perfect cooperation’) lies outside the set of correlated equilibrium payoffs. The highest symmetric payoffs that can be obtained in the correlated equilibrium are (31.25, 31.25). This is shown as a point on the outer (northeast) boundary of the set of correlated equilibrium. However, players are indifferent between their pure strategies at this equilibrium, hence, Cason and Sharma (2007) decide to implement a correlated equilibrium just southwest of this point (shown in Figure 12.46). In this equilibrium, each player receives an expected payoff of 30.6, which exceeds the joint payoff from any Nash equilibrium.

The previous literature had found mixed evidence on the implementation of recommended play in a non-correlated equilibrium setting.⁹⁸ However, in a correlated equilibrium setting, Moreno and Wooders (1998) find evidence that is consistent with the play of recommended strategies. Crucially, they allow for non-binding preplay communication, while Cason and Sharma (2007) do not. This factor seems crucial in accounting for the difference in results because Cason and Sharma find that players do not always follow recommendations. Treatments A through F in Cason and Sharma (2007) are described in Table 12.32. Opponents were randomly matched in each of the 60 periods of play.

Treatments A and B consider the effect of recommendations on the strategies chosen by the players. Humans play against robot opponents in treatments C and D. These treatments control for social preferences, as well as beliefs about the rationality of others, that can come into play when humans play against human opponents. Treatments C and D differ with respect to

⁹⁷ The convex hull of the Nash equilibria is formed from the payoffs in the two pure strategy Nash equilibria (9,48), (48,9) as well as the payoff from the mixed strategy Nash equilibrium (21,21).

⁹⁸ See, for instance, Van Huyck et al. (1992), Brandts and MacLeod (1995), Seely et al. (2005).

Table 12.32 A description of the various treatments in Cason and Sharma (2007).

Treatment	Explanation of the treatment	Experience	Subjects
A	Human opponents, no recommendations	None	52
B	Human opponents with recommendations	None	80
C	Robot opponents with recommendations (no one receives robot earnings)	None	31
D	Robot opponents with recommendations (Humans receive robot earnings)	None	26
E	Human opponents with recommendations	Experienced in B	24
F	Human opponents with recommendations	Experienced in C	24

the receipt of robot earnings. If other humans receive robot earnings (as in treatment D), then social preferences might be activated once again. Subjects were told that robots will follow the recommendations without error. Treatments E and F consider the role of experience. These are similar to treatment B, with the exception that the subjects playing the treatment have had prior experience, respectively, in treatments B and C. Furthermore, experimenters elicit the beliefs of subjects about “their expectations of the play of others” and subjects were paid depending on the proximity of their beliefs with the actual play. The beliefs of the players were elicited after the recommendations were made to them. Players then submitted their actions and their beliefs.

In a comparison of treatments A and B, recommendations seem to enhance the play of the cooperative outcome associated with the (D, R) choice, but the significance level is marginal at 10%. However, across all treatments, the recommendations increased the payoffs of the players significantly. This arose not so much by enhancing the play of the cooperative outcome (D, R) as by reducing the play of the worst outcome (U, L).

The percentage of actions consistent with the recommended play are shown in Figure 12.47 for three treatments B, C, and D and for two recommendations: U/L (i.e., U to row player and L to column player) and D/R (D to row player and R to column player). The U/L recommendation is followed to a greater extent than the D/R recommendation. Subjects follow the recommendation more frequently (in a statistical sense) when they play robot as compared to human opponents. The likelihood of following the recommendations is very similar in the two robot treatments, so the results across these two treatments can be pooled. Looking at individual data, 75% of the subjects in the robot treatments followed the recommendations for 90% of the observations. Less than 50% of the subjects followed the recommendations for 90% of the observations when the opponent is a human.

In the two treatments with experienced subjects (E and F), the level of the payoffs and the frequency of following the recommendations are both statistically similar. Hence, these two treatments can also be pooled. Furthermore, the average ratio of actual to recommended payoffs in the

Figure 12.47 Percentage of actions consistent with the recommended play in the various treatments.

Source: *Economic Theory* 33 (2007), 11–27, “Recommended play and correlated equilibria,” Cason, T. N. and Sharma, T. © Springer Verlag with kind permission from Springer Science and Business Media.

experienced versus non-experienced subject treatments are statistically identical. So experience does not seem to alter payoffs.

In the correlated equilibrium that the authors choose to implement (see above), $p_{UL} = 0$. We can use this fact and the elicited beliefs of subjects to check if they believe that their opponents will play the recommended action. Suppose that the recommendation to the row player is to play U. Then, using the relevant formulae above, we can calculate that he should assign probability zero that the opponent will play L ($P(L | U) = 0$) and a probability 1 that the opponent will play R ($P(R | U) = 1$). Analogously if the column player is recommended to play L, then he should assign probability zero to the row player playing U and a probability 1 to the row player playing D.

Results in Figure 12.48, given for periods 31–60, show that the elicited beliefs of players did not always reveal such a pattern. The histogram in the left panel shows that for human opponents, inexperienced subjects had the correct beliefs about their opponents about 77% of the time (when the prediction is 100%). Beliefs get better with experience but only match the predictions when the opponent is a robot. The histogram in the right hand side panel in Figure 12.48 has a predicted height of 0% but actually varies between a height of 25% to 40%, depending on the conditions used. With human opponents, play does not conform to predictions because subjects believe that (human) opponents will not follow the recommendations. Cason and Sharma (2007, p. 26) conclude that: “Our results indicate that recommendations are not sufficient to induce players to switch to any chosen equilibrium. Subjects do not switch because they believe that their opponents will not switch.”

Cason and Sharma (2007) implement a correlated equilibrium in which the payoffs dominate those in a Nash equilibrium. This may potentially confound the coordinating role of recommendations of the mediator with a desire of subjects to improve their payoffs. Motivated by this find-

ing, Duffy and Feltovich (2010) consider experimental evidence on correlated equilibrium in a symmetric game of chicken shown in Figure 12.49.

The following proposition summarizes the various equilibria of the game. The proof is similar to the one we outlined above for the Cason–Sharma paper, so it is relegated to the problem set.

Proposition 12.23 Consider the game of chicken in Figure 12.49.

- There are two pure strategy equilibria (D, C) and (C, D). There is also a mixed strategy equilibrium in which both players play strategy D with probability $2/5$. In the mixed strategy equilibrium, each player’s expected payoff is 5.4.
- Suppose that players could condition their play on a publicly available signal, say, the toss of a coin. Following heads, the row player plays D and the column player plays C. Following tails, the row player plays C and the column player plays D. Each player’s expected payoff in this case is 6, higher than the expected payoff from any Nash equilibrium.
- (Aumann, 1974) Suppose that players condition their choice of strategies on the outcome of three publicly observed random signals, X, Y, Z, each chosen with equal probability. Player 1 (row player) learns only if X was chosen or not, while player 2 (column

player) learns only if Z was chosen or not. Player 1 plays D if the public signal is known to be X and C otherwise. Player 2 plays D if the public signal is known to be Z and C otherwise. These correlated strategies are a mutual best response (a correlated equilibrium) and yield an expected payoff of $6\frac{1}{3}$ to each player.

- (d) Denote by p_{DD} , p_{DC} , p_{CD} , p_{CC} , the probabilities with which a mediator chooses, respectively, the four strategy profiles (D, D) , (D, C) , (C, D) , (C, C) , through some public randomization device. The mediator draws a strategy profile based on the stated probability distribution. However, the mediator does not tell the players which strategy profile was drawn. Players are only, privately, given recommendations to play their part of the strategy profile that is drawn.⁹⁹ Suppose that the following conditions hold.¹⁰⁰

$$2p_{DC} \geq 3p_{DD}; 3p_{CD} \geq 2p_{CC}; 2p_{CD} \geq 3p_{DD}; 3p_{DC} \geq 3p_{CC} \quad (12.36)$$

and

$$p_{DD} + p_{DC} + p_{CD} + p_{CC} = 1. \quad (12.37)$$

Then p_{DD} , p_{DC} , p_{CD} , p_{CC} constitute a correlated equilibrium. ■

Figure 12.50 shows the convex hull of the Nash equilibrium payoffs. This is the triangle labelled A with vertices that correspond to the payoffs from the three Nash equilibria; the two pure strategy Nash equilibria (C, D) and (D, C) with payoffs 3,9 and 9,3 and the mixed strategy equilibrium with payoffs 5.4,5.4. The set of correlated equilibrium payoffs that satisfy (12.36), (12.37) is given by the quadrilateral (union of the regions B_l , A , B_h) with vertices (3, 9), (4.5, 4.5), (9, 3), and $(6\frac{3}{7}, 6\frac{3}{7})$. The highest symmetric correlated equilibrium payoffs are $(6\frac{3}{7}, 6\frac{3}{7})$ and the lowest are (4.5, 4.5).¹⁰¹

Duffy and Feltovich (2010), attempt to implement the following outcomes; the first three are correlated equilibria, while the fourth is not.

1. *Nash-recommendations treatment*: The two pure strategy Nash equilibria (D, C) and (C, D) are recommended with a probability of 0.5 each. The expected payoff of each player is 6 in this case.
2. *Good-recommendations treatment*: Each of the three strategy profiles (D, C) , (C, C) , (C, D) is drawn with a probability of one third ((D, D) is drawn with zero probability) and then a recommendation is made by the mediator. The resulting equilibrium lies in the convex hull of the correlated equilibrium and the expected payoff is $6\frac{1}{3}$ for each player; this payoff exceeds any of the payoffs in the convex hull of the Nash equilibrium payoffs.
3. *Bad-recommendations treatment*: The strategy profiles (D, C) , (C, D) are selected by the mediator with probability 0.4 each and the profile (D, D) is selected with probability 0.2 ((C, C) is selected with probability zero). The expected payoff for each player is 4.8, which is lower than any payoff in the convex hull of the Nash equilibrium payoffs.

⁹⁹ For instance, if the strategy profile (C, D) is drawn, the row player is given a private recommendation to play C and the column player is given a private recommendation to play D .

¹⁰⁰ We assume that either the players are risk neutral or that the numbers in the payoff matrix in the game of chicken are utility values.

¹⁰¹ In general, the set of correlated equilibria contain the set of Nash equilibria. Hence, the convex hull of the set of correlated equilibria contain the convex hull of the set of Nash equilibria. Further, the set of payoffs obtained in the convex hull of Nash equilibria are contained within the set of payoffs obtained in the convex hull of correlated equilibria.

Figure 12.50 Equilibria in the game of chicken in Duffy-Feltovich.

4. *Very good recommendations treatment*: In the final treatment, an equilibrium that is outside the convex hull of the correlated equilibria is selected. In this case, the mediator selects the outcome (C, C) with probability 0.8 and (D, C), (C, D) each with probability 0.1. If players follow the recommendation of the mediator, then the expected payoff of each player is 6.8, which exceeds the highest possible symmetric correlated equilibrium payoffs of $(6\frac{3}{7}, 6\frac{3}{7})$.

A total of 16 experimental sessions were run, 4 for each treatment. Each session had 12 subjects in experiments. Each subject played 20 rounds with the recommendations and 20 rounds without the recommendations, resulting in a total of 7,580 observations. The results are shown in Table 12.33 for the case of no recommendations (under the heading, None) and for the four treatments under recommendations (respectively, under the headings, Nash, Good, Bad, and Very good).

For the case of no recommendations, subjects played without recommendations for 40 rounds. However, in the other cases, they played 20 rounds under the recommendation and 20 rounds without any recommendations. The combined results are also shown. In order to interpret the results in Table 12.33, consider, for instance, the treatment "None" and the combined play over the 40 rounds. In the mixed strategy Nash equilibrium (Proposition 12.23(a)), each player plays D with a probability of $\frac{2}{5}$, so that the joint probability of the play of the strategy profile (D, D) is $(\frac{2}{5})^2 = 0.16$, which appears quite close to the experimentally observed frequency of 0.159. Let us now consider the results in more detail.

1. Consider first the case with no recommendations. In several sessions and time periods, the observed play at the aggregate level is close to the mixed strategy equilibrium. Overall, the authors interpret their findings as supporting a mixed strategy Nash equilibrium, for

Table 12.33 Frequencies of observed outcomes at the aggregate level.

Recommendations	Ordering	Outcome				Average payoff
		(D, D)	(D, C)	(C, D)	(C, C)

- aggregate data, when no recommendations are given. The null hypothesis that behavior is generated by an iid mixed strategy profile is statistically rejected by using a chi-square test.¹⁰²
2. Recommendations matter, although they do so to a different extent in each treatment with recommendations. Overall, a chi-square test rejects the hypothesis that the distribution of outcomes in the no-recommendations and the recommendations treatment (but omitting the Very good recommendations treatment) are identical.
 3. When a correlated equilibrium is recommended to the players (i.e., ignoring the Very good recommendations treatment that lies outside the relevant convex hull of payoffs), play moves in the direction of the recommended equilibrium, relative to the mixed strategy equilibrium. In each case, the frequency of outcomes is very different from the mixed strategy equilibrium.
 4. In the Good-recommendations and the Nash-recommendations treatments, the recommendations were followed 70–75% of the time.
 5. When the recommendation does not arise from a correlated equilibrium, as in the Very good recommendations treatment, subjects learn to ignore the recommendations. Thus, based on this evidence, correlated equilibrium would seem to be a *necessary condition* for recommendations to be followed. This treatment also rules out the possibility that subjects were simply following the recommendations blindly, or to please the experimenter.
 6. Subjects do not follow the recommendations in the Bad-recommendations treatment, which is a correlated equilibrium, but the payoffs are dominated by the convex hull of the Nash equilibrium payoffs. Thus, correlated equilibrium recommendations is not a *sufficient condition* for the recommendations to be followed.

¹⁰² If, however, the outcomes (C, D) and (D, C) are pooled, then play is close to the predictions of the mixed strategy Nash. However, pooling the outcomes (C, D) and (D, C) is inconsistent with a mixed strategy equilibrium in the first place. Such pooling can neither confirm nor reject a mixed strategy equilibrium.

12.8 Strategic complements and strategic substitutes

Suppose that two individuals, or firms, indexed by i, j , are involved in some strategic interaction. They choose respective actions x_i, x_j from their respective action sets $X_i, X_j \subset \mathbb{R}$. The respective payoff functions of the two players are given by $\pi_i(x_i, x_j), \pi_j(x_i, x_j)$, where π_i, π_j are strictly concave and twice continuously differentiable. The Nash equilibrium (x_i^*, x_j^*) satisfies the first order conditions

$$\frac{\partial \pi_i(x_i^*, x_j^*)}{\partial x_i} = 0; \quad \frac{\partial \pi_j(x_i^*, x_j^*)}{\partial x_j} = 0. \quad (12.38)$$

Our assumptions guarantee that the optimal reaction functions of the two players are unique, and these are given, respectively, by $x_i = R_i(x_j)$ and $x_j = R_j(x_i)$.¹⁰³ The slopes of the reaction functions, given by

$$\frac{\partial R_i}{\partial x_j} = \frac{\frac{\partial \pi_i}{\partial x_i \partial x_j}}{-\frac{\partial^2 \pi_i}{\partial^2 x_i}}, \quad \frac{\partial R_j}{\partial x_i} = \frac{\frac{\partial \pi_j}{\partial x_i \partial x_j}}{-\frac{\partial^2 \pi_j}{\partial^2 x_j}}, \quad (12.39)$$

are completely determined by the respective signs of the numerators (the denominators are positive).

Definition 12.3 (*Strategic complements and strategic substitutes; Bulow et al., 1985*)

- (a) The actions of the two players are said to be *strategic complements* (SC) if the reaction functions are upward sloping, i.e. $\frac{\partial \pi_i}{\partial x_i \partial x_j} > 0$ and $\frac{\partial \pi_j}{\partial x_i \partial x_j} > 0$.
- (b) The actions of the players are said to be *strategic substitutes* (SS) if the reaction functions are downward sloping, i.e. $\frac{\partial \pi_i}{\partial x_i \partial x_j} < 0$ and $\frac{\partial \pi_j}{\partial x_i \partial x_j} < 0$.

Thus, actions are SC if an increase in the action by a player increases the marginal payoff to the other player from increasing his/her action. The converse happens under SS. An important implication of SC is that a change in one player's action gives the other player an incentive to move in the same direction, so we should expect to see positively correlated actions. Analogously, under SS, we should expect to observe negative correlation in actions. The concepts of strategic substitutes and strategic complements have great importance in many areas of economics; for instance, multiple equilibria in macroeconomics (Cooper and John, 1988), learning dynamics in games (Milgrom and Roberts, 1991), and supermodularity (Topkis, 1998).

In SC and SS games, because of the mutual dependence of payoffs on actions, *externalities* or *spillovers* arise, which can be positive or negative. In the presence of these externalities, the Nash equilibrium will typically not be Pareto optimal.

Definition 12.4 (*Cooper and John, 1988*): A game has (i) *positive spillovers/externalities* if $\frac{\partial \pi_i}{\partial x_j} > 0, i \neq j$, and (ii) *negative spillovers/externalities* if $\frac{\partial \pi_i}{\partial x_j} < 0, i \neq j$.

¹⁰³ The reaction functions satisfy $\frac{\partial \pi_i(R_i(x_j^*), x_j^*)}{\partial x_i} = 0$ and $\frac{\partial \pi_j(x_i^*, R_j(x_i^*))}{\partial x_j} = 0$.

Proposition 12.24 When $\frac{\partial \pi_i}{\partial x_j} > 0$, the Nash equilibrium will be Pareto dominated by higher actions. On the other hand, when $\frac{\partial \pi_i}{\partial x_j} < 0$, the Nash equilibrium will be dominated by lower actions.

12.8.1 Implications of SS and SC for the degree of cooperation

In Potters and Suetens (2009), pairs of subjects play a finite number of repetitions of a game that exhibits SC, SS, and positive and negative spillovers. They consider the following four treatments. (1) SS with negative externalities (SUBSTneg). (2) SS with positive externalities (SUBSTpos). (3) SC with negative externalities (COMPLneg). (4) SC with positive externalities (COMPLpos).

In the discussion below, we describe only the positive externality games, SUBSTpos and COMPLpos. These games can be converted into a negative externality game by a simple transformation of the variables in the following manner. If $x_i \in [0, m]$ is the decision variable in the positive externality game, then replacing x_i by $m - y_i$ changes this into a negative externality game, where y_i is the decision variable in the negative externality game.

The payoff of player i in the COMPLpos treatment, $\pi_i^{COMPLpos}$, and in the SUBSTpos treatment, $\pi_i^{SUBSTpos}$, is given, respectively, by

$$\pi_i^{COMPLpos}(x_i, x_j) = a + bx_i + cx_j - dx_i^2 + ex_j^2 + fx_ix_j; \quad b, c, d, f > 0, e \geq 0; x_i, x_j \geq 0 \quad (12.40)$$

$$\pi_i^{SUBSTpos} = \alpha + \beta x_i + \gamma x_j - \delta x_i^2 + \epsilon x_j^2 - \xi x_ix_j; \quad \beta, \gamma, \delta, \xi > 0, \epsilon \geq 0; x_i, x_j \geq 0. \quad (12.41)$$

The restrictions in (12.40) ensure that the actions of the two players are SC and that there are positive externalities. Analogously, the restrictions in (12.41) ensure that the actions of the two players are SS and that there are positive externalities. Given the assumptions made, we can use (12.38) and (12.40), (12.41) to find the Nash equilibrium. Similarly, by adding the payoffs of both players, in each case, one can find the joint payoff maximizing choice. The results are summarized in the following proposition; the proof is straightforward and it is omitted.

Proposition 12.25

- (1) Consider first the COMPLpos treatment. The unique, symmetric, Nash equilibrium (N) and the unique, symmetric, joint payoff maximizing choices (JPM) are respectively given by

$$x^N = \frac{b}{2d - f}; \quad x^{JPM} = \frac{b + c}{2(d - e - f)}.$$

- (2) In the SUBSTpos case, the respective unique, symmetric Nash and joint payoff maximizing solutions are given by

$$x^N = \frac{\beta}{2\delta + \xi}; \quad x^{JPM} = \frac{\beta + \gamma}{2(\delta - \epsilon + \xi)}.$$

The following six conditions are imposed across the treatments. (1) Identical Nash equilibrium strategies. (2) Identical Nash equilibrium payoffs. (3) Identical joint payoff maximizing (JPM) choice. (4) Identical JPM payoffs. (5) Identical payoffs from defection. (6) Identical slopes of the best response functions (in absolute value). All these conditions can be satisfied by imposing

Figure 12.51 The best response functions and equilibria in various cases.

suitable restrictions on the parameters in (12.40), (12.41).¹⁰⁴ The Nash and JPM choices are shown in Figure 12.51 (readers should replace indices i, j by 1, 2 in the figure).

A total of 28 subjects (or 14 pairs of subjects) participated in each treatment that was run over 31 rounds. The pairings were maintained through the 31 rounds. At the end of each round, subjects were informed of the actions of their opponent, their earnings, and the earnings of the opponent.

Definition 12.5 The degree of cooperation for pair k in round t of the experiment, ρ_{kt} , is defined as

$$\rho_{kt} = \frac{\bar{x}^{kt} - x^N}{x^{JPM} - x^N},$$

where $\bar{x}^{kt}$ is the average choice of pair k at round t . If $\bar{x}^{kt} = x^N$, $\rho_{kt} = 0$ and if $\bar{x}^{kt} = x^{JPM}$, then $\rho_{kt} = 1$. If $x^{JPM} < \bar{x}^{kt} < x^N$, then $0 < \rho_{kt} < 1$.

¹⁰⁴ The interested reader can check that these restrictions are: $\alpha = a$, $\beta = \frac{b(2d-f)}{2d+f}$, $\gamma = c + \frac{2bf}{2d+f}$, $\delta = \frac{d(2d-f)^2}{(2d+f)^2}$, $\epsilon = e + \frac{2f^3}{(2d+f)^2}$, $\xi = \frac{f(2d-f)^2}{(2d+f)^2}$. Recall also our procedure for transforming a positive externality game into a negative externality game. We require $m = \frac{2b}{2d-f}$. In conjunction, these guarantee the six conditions.

Figure 12.52 Average degree of cooperation in each round for complements and substitutes.

Source: Potters, J. and Suetens, S., "Cooperation in experimental games of strategic complements and substitutes," *Review of Economic Studies* (2009) 3: 1125–47, by permission of Oxford University Press.

The results are as follows.

1. The sign of the externality does not affect the degree of cooperation. Thus, ρ_{kt} is statistically identical in the treatments SUBSTneg and SUBSTpos and in the treatments COMPLneg and COMPLpos. Therefore, the authors pool SUBSTneg and SUBSTpos into SUBST and similarly COMPLneg and COMPLpos into COMPL.
2. The main finding is that cooperation is higher in the complements treatment, COMPL, as compared to the substitutes treatment, SUBST, over all of the 30 rounds; see Figure 12.52. There are also *end-game effects* that are observed in other finitely repeated games (Ledyard, 1995). The endgame effect is larger in the substitutes treatment.
3. Figure 12.52 also shows that play does not converge to the Nash equilibrium of the stage game or to any other outcome (see Definition 12.5 for the conditions required on ρ_{kt}).
4. Recall from the discussion above that in the complements case, the actions of the two players are likely to be positively correlated, while in the substitutes treatment, they are likely to be negatively correlated. This is not observed in the individual data. In both the COMPL and SUBST treatments, the players change their actions in the same direction as the opponent. Social preferences might offer one potential explanation for these results. Suppose that individual players exhibit reciprocity. If one player takes an action directed towards the JPM choice, then the other player does too, motivated by *positive reciprocity*. Analogously, choices directed away from the JPM choice elicit *negative reciprocity*, inducing the opponent to also move away from the JPM choice. The statistical analysis suggests that such results are more pronounced in the case of COMPL as compared to the SUBST treatment.
5. Across both treatments, when both paired players in a round make JPM choices, they tend to stick to these choices in subsequent rounds of the experiment. Call these the "JPM pairs" and the rest as the "non-JPM pairs." Across both treatments, about 40% of the players are JPM pairs. The behavior of these pairs is shown in Figure 12.53. Consider JPM pairs, shown on the right panel of Figure 12.53. The degree of cooperation of these pairs is higher in the COMPL treatment in the first half of the experiment. Also these pairs reach the JPM choice earlier in the COMPL treatment relative to the SUBST treatment. Thus, the complements

Figure 12.53 Average degree of cooperation for non-JPM and JPM pairs.

Source: Potters, J. and Suetens, S., "Cooperation in experimental games of strategic complements and substitutes," *Review of Economic Studies* (2009) 3: 1125–47, by permission of Oxford University Press.

treatment is relatively more conducive to cooperation. Eventually, these pairs reach full cooperation ($\rho_{kt} = 1$) in both treatments. For non-JPM pairs, cooperation is still relatively higher in the COMPL treatment. However, unlike the JPM pairs, they do not achieve the JPM choice in either of the two treatments. Furthermore, the degree of cooperation diverges across the two treatments.

6. Choices of players in price setting experiments are typically SC, while in quantity setting games they are typically SS. The degree of collusion is also typically observed to be higher in the former. The results in this paper, which suggest that the degree of cooperation is likely to be higher in the case of SC is a possible explanation of these experimental findings.

12.8.2 The macroeconomics of nominal inertia

Issues of nominal inertia have been central to modern New Keynesian macroeconomics. A range of theories have been proposed as potential explanations,¹⁰⁵ but they have ignored the impact of behavioral factors. Fehr and Tyran (2008) introduce two behavioral factors with good empirical support: *Money illusion* and *anchoring*, in a model that allows considerations of SC and SS. They find that the extent of behavioral biases is endogenous and depends on the type of strategic interaction, i.e., SC or SS. Behavioral biases are less likely in those strategic environments where they are less costly in terms of forgone payoffs. The Fehr–Tyran findings are inconsistent with the current practice in theoretical macroeconomics; we elaborate below.

The basic structure of the experiment is described in Figure 12.54. Groups of n players are formed and play a pricing game for T time periods. The composition of the group members

¹⁰⁵ See, for instance, Blanchard and Fischer (1989, chapters 8, 9) and Romer (2006, chapter 6).

Figure 12.54 A partial representation of the Fehr–Tyran (2008) experimental setting.

Source: Fehr and Tyron (2008) with permission of The Econometric Society.

was not altered over the T periods. In the first half of the experiment (i.e., $T/2$ time periods), called the pre-shock phase, the money supply was fixed at a level M_0 . In the post-shock phase, which covers the next $T/2$ time periods, a negative monetary shock is implemented that cuts the money supply by a half, so that the new money supply is $M_1 = M_0/2$. The money supply shock is fully anticipated. This is achieved by announcing the shock at the beginning of the post-shock phase and then implementing it. In the experiments, $M_0 = 42$ and $T = 30$. The restart phase is described later.

The *real payoff* of the i th player, v_i , in a group of n players, is given by $v_i = v_i(P_i, \bar{P}_{-i}, M)$, where P_i is the nominal price chosen by the player, $\bar{P}_{-i}$ is the average nominal price chosen by the other $n - 1$ players, and M is the money supply. We assume that n is sufficiently large. It is assumed that v_i is homogeneous of degree zero in $P_i, \bar{P}_{-i}, M$, thus, $v_i(\lambda P_i, \lambda \bar{P}_{-i}, \lambda M) = \lambda^0 v_i$, where $\lambda > 0$. Setting $\lambda = 1/M$ gives

$$v_i = \phi \left(\frac{P_i}{M}, \frac{\bar{P}_{-i}}{M} \right), \text{ where } \phi \left(\frac{P_i}{M}, \frac{\bar{P}_{-i}}{M} \right) = v_i \left(\frac{P_i}{M}, \frac{\bar{P}_{-i}}{M}, 1 \right). \quad (12.42)$$

Half the players in the model are of type x and the remaining half are of type y . The types differ only in their payoffs from the same pair of numbers $P_i, \bar{P}_{-i}$. For player i , denote by $\bar{P}_{-i}^j$ the average price chosen by the other players of type $j = x, y$. Given the composition of the two types of players, and large n , $\bar{P}_{-i} = 0.5\bar{P}_{-i}^x + 0.5\bar{P}_{-i}^y$.

Since there is within-type homogeneity of players, we focus on the symmetric case where all players of type x choose a price $\bar{P}^x$, and all players of type y choose the price $\bar{P}^y$. Thus, the aggregate price level is given by

$$P = 0.5\bar{P}^x + 0.5\bar{P}^y. \quad (12.43)$$

If there are no costs of changing prices (e.g., no macroeconomic frictions or menu costs), then, as in traditional flexible price macroeconomic models, we assume that a proportional change in M leads to the same proportional change in $\bar{P}^x, \bar{P}^y$. Hence, money is neutral. Thus, we get the well-known result that monopolistic competition alone, in the absence of frictions, does not lead to nominal rigidity (Blanchard and Fischer, 1989, Section 8.1).

Holding M fixed, the payoffs of the individuals in (12.42) can be represented in $(P_i, \bar{P}_{-i})$ space. Subjects choose a price $P_i \in \{1, 2, \dots, 30\}$, and are shown a payoff table that gives the payoffs for each pair $(P_i, \bar{P}_{-i})$. The actions $P_i, \bar{P}_{-i}$ can either be strategic complements (the CT treatment) or strategic substitutes (the ST treatment). In any treatment, the equilibrium is identical. For both treatments, CT and ST, in the pre-shock period, $\bar{P}^x = 22$ and $\bar{P}^y = 28$, thus, using (12.43), $P = 25$. For the post shock period, $\bar{P}^x = 11$ and $\bar{P}^y = 14$, so $P = 12.5$.

While choosing their price in any period, players have to form an expectation about the average price of others, $\bar{P}_{-i}^e$. The actual value $\bar{P}_{-i}$ is revealed to players at the end of each round of the experiment. In any round, players had access to all past values of $\bar{P}_{-i}$ as well as their own choices P_i . Since one of the objectives of the paper is to test if money illusion plays an important role, the payoffs are shown to the subjects in nominal terms, $V_i = P v_i$, where v_i is the real payoff of player i . In only one treatment, a control treatment, were payoffs observed by the players in real terms. The payoff matrices of each type of player, are common knowledge and there are no issues of asymmetric information.

The payoff matrices for each of the several cases are very large. However, to get a sense of the game being played and the ease of calculating best replies in the model, we report one payoff matrix, in Figure 12.55, for type y players in the post-shock phase for the substitutes treatment. The selling price is P_i (numbers 1–30 in the first column) and the average price of other firms is $\bar{P}_{-i}$ (numbers 1–30 in the first row). The best reply function for player i for all possible levels of $\bar{P}_{-i}^e$ is shown by the shaded path in the payoff matrix (subjects did not see the shaded best reply path). Along this path, the payoff of player i is 39 throughout.

Corresponding to the payoff matrix for substitutes in the post-shock case shown in Figure 12.55 for type y players, there is an analogous payoff matrix for type x players (not shown) that differs in the payoffs. In equilibrium, type x and type y players choose respective prices 11 and 14, and their respective expectations of the average prices of the other type are 13 and 12. Thus, average price, using (12.43), is 12.5. From Figure 12.55, the best response of a type y player is 14, as claimed. Similarly the best response of a type x player is 11 (using the payoff matrix for type x players that is not shown).

For the case of complements, the equilibrium is identical to the substitutes case, for the post-shock period. In the pre-shock case, by contrast, for complements and substitutes, players of type x and y choose respective prices 22 and 28 (their respective price expectations of the other type are 26 and 24).

For each column in the payoff matrix, there is a unique optimal price for a player and the corresponding payoff is 39. All remaining payoffs in the column are very small numbers, enabling players to quickly spot the optimal value; this rules out the confounds of cognitive complexity. Furthermore, at the end of each period, the average price of other firms is revealed to each player. In light of this, it would be highly unexpected, therefore, if firms did not quickly converge to the equilibrium price in the pre-shock phase when money illusion and anchoring have not yet influenced actions. This intuition turns out to be correct.

At the beginning of period 16, the first period in the post-shock phase, the exogenous drop in money supply is announced publicly. Subjects are given enough time to study the new payoff tables (corresponding to $M_0/2 = 21$) before deciding on their nominal price. There are no informational frictions in the model, which are critical for nominal frictions in standard flexible price neoclassical models exemplified by Lucas (1972). There are also no nominal frictions (such as staggered wages; see Fischer, 1977) that are critical in New Keynesian models.

The *anchoring heuristic* is considered in more detail in Chapter 19. In the context of these experiments, anchoring implies that the equilibrium achieved in the pre-shock phase acts as a *reference*

Source: Fehr and Tyran (2002) with permission of The Econometric Society.

point or *anchor* in the post-shock phase. This could prevent subjects from adequately adjusting their price in the post-shock phase. This constitutes one possible behavioral explanation for nominal rigidity that is typically not considered in mainstream macroeconomics.

A second possible explanation for nominal rigidity is *money illusion*. An increasing amount of evidence shows that money illusion is important in a range of contexts.¹⁰⁶ In the context of the current experiments, money illusion implies that subjects could be more sensitive to changes in nominal payoffs $V_i = P v_i$ rather than real payoffs v_i . Suppose that P and M increase in the same proportion. Then, using (12.42), v_i is unchanged. However, a player who has money illusion may notice that $V_i = P v_i$ has increased, so he would prefer the change. Conversely, after a fall in M , such an individual might adjust P_i insufficiently downwards, fearing a fall in nominal income and, thus, leading to nominal rigidity.

The restart phase (see Figure 12.54) is used to identify if money illusion and anchoring are important. In this phase, the post-shock phase is simply restarted once again. There is evidence that restarts of this sort are not neutral.¹⁰⁷ In the complements case, in the CT-restart-real treatment, subjects were given payoffs in real terms for all three phases (pre-shock, post-shock, and restart). The analogous treatment for substitutes is denoted by ST-restart-real. In the

¹⁰⁶ In a macroeconomic context, Fehr and Tyran (2001) have already shown the presence of money illusion in a price setting game. In a range of other contexts, a significant fraction of individuals demonstrate money illusion. See, for instance, Shafir et al. (1997), Kooreman et al. (2004), Fehr and Tyran (2005, 2007), and Cohen et al. (2005).

¹⁰⁷ In the context of public goods games, a simple restart of the experiment can elicit high levels of cooperation despite the fact that prior to the restart, the cooperation levels had dropped to almost zero, on account of free riding. See, for instance, Andreoni (1988) and Croson (2000).

Figure 12.56 Average nominal price across time in the complements and substitutes treatment.

CT-restart-nominal treatment, subjects are in the complements case and they receive real payoffs in the first two phases (pre-shock, post-shock), but nominal payoffs in the third phase (restart). The corresponding treatment with substitutes is called as ST-restart-nominal.

The results are as follows.

1. Across both types of subjects, x, y , the predicted average equilibrium price for complements and substitutes in the pre-shock phase (first 15 periods) is 25, while in the post-shock phase (periods 16 through 30), it is 12.5. Figure 12.56 shows the pre- and post-shock prices observed in the experiments across the complements treatment (CT) and the substitutes treatment (ST). In the pre-shock phase, in both treatments, and as expected (see the discussion above), price quickly converges to the equilibrium. In the post-shock phase, however, actual prices in both treatments are off (and typically above) the equilibrium price. In the complements case, the actual price is significantly above equilibrium and takes relatively longer to approach it, while in the substitutes treatment prices slightly overshoot the equilibrium price.¹⁰⁸ In each case, there is evidence of nominal rigidity of prices.¹⁰⁹ The strategic environment (complements or substitutes) seems to have an important bearing on the results on nominal rigidity.

¹⁰⁸ In particular, in the CT treatment, for the first eight periods of the post-shock phase, one can reject, at 1%, the hypothesis that the equilibrium prices and the observed average prices are equal. By contrast, in the case of the ST treatment, one cannot statistically reject this hypothesis.

¹⁰⁹ Field evidence on price stickiness is harder to find. Sellers might change a non-price dimension (quantity discounts) or offer underhand discounts, or sales, which might not be reflected in the data from catalogue prices that are often used to check for evidence on price stickiness. For a discussion of these sorts of issues see Blinder et al. (1998). Some of the empirical evidence is also discussed in Romer (2006).

Figure 12.57 Actual average prices and average best replies in the complements and substitutes treatments (Periods 16–18).

Source: Fehr and Tyran (2008) with permission of The Econometric Society.

- The individual choices for type x subjects in period 16, the period in which the anticipated monetary shock takes place, are as follows. In the substitutes case, 72% of the subjects jump immediately to the new equilibrium. But in the complements case, only 25% manage to do so, while 50% choose a price significantly higher than the equilibrium price. The choices of type y subjects are qualitatively similar.
- Subjects were asked about their expectations of the average price chosen by the other players. Thus, one can directly check from the payoff tables if subjects played their best response to the expectations that they held. Subjects played a best response in their nominal price, P_i , conditional on their expectations of the average price, $\bar{P}_{-i}^e$, in the complements treatment and the substitutes treatment (see Figure 12.57).
Thus, the presence of nominal rigidities in the post-shock phase, particularly in the complements treatment, cannot be ascribed to deviations from the best response by players. Rather the differences would then seem to arise from incorrect expectations, $\bar{P}_{-i}^e$. The experimental data indicates that in the pre-shock phase, $\bar{P}_{-i}^e$ is close to the actual price level. However, in the post-shock phase, price expectations are very sticky in the complements treatment, while they align very closely to the equilibrium expectations in the substitutes treatment.
- So what accounts for nominal rigidities? Consider the two treatments CT-restart-real and ST-restart-real. In these treatments, the subjects see payoff tables in real terms in the pre-shock and the post-shock phase. So money illusion is absent. Since there is no need to adjust prices, anchoring is also absent in these treatments. Most subjects conform to the equilibrium predictions towards the end of the post-shock phase in both treatments (in the last ten periods). If the restart-phase results in disequilibrium in this treatment, then factors other than money illusion and anchoring are likely to be contributing to nominal rigidities. However, in the restart-phase, actual and expected prices are instantly in equilibrium. This suggests that, in these experiments, there are no factors other than money illusion and anchoring which could account for nominal rigidities.
- Consider the two treatments CT-restart-nominal and ST-restart-nominal. In these treatments, the subjects were given payoffs in real terms in the pre-shock and the post-shock

phases. In the restart phase they were, however, given payoffs in nominal terms. In the restart phase, the price expectations of subjects are above equilibrium in the complements and the substitutes treatments despite the fact that the same equilibrium should prevail in the restart phase as in the post-shock phase. This is even more surprising because in the last ten periods of the post-shock phase, subjects played out the expected equilibrium. Thus, simply restarting the experiment in terms of nominal payoffs inflates price expectations and actual price levels. This is downward nominal rigidity driven by money illusion. Money illusion was seen to have a much larger effect in the complements case relative to the substitutes case.

6. Consider the treatment CT-real. In this treatment, the payoffs are in real terms in the pre-shock and the post-shock phases. Thus, there is no role for money illusion. There is a statistically significant deviation from equilibrium play in the first four rounds of the post-shock phase. There is no such deviation in the case of the ST-real treatment. Thus, anchoring (to the pre-shock equilibrium) plays a much stronger role in the complements as compared to the substitutes case.
7. Why is equilibrium reached more quickly in the substitutes treatment relative to the complements treatment? Haltiwanger and Waldman (1989), who discussed similar issues, proposed a solution that involved a joint consideration of adaptive and rational players. In order to test this, Fehr and Tyran (2008) ran some simulations. Adaptive players, in these simulations, simply expect the price in the previous period to prevail (perhaps due to money illusion or anchoring). Rational players know the fraction of adaptive players. However, the Haltiwanger and Waldman (1989) explanation is not able to fully explain the experimental findings (although it explains some aspects of it¹¹⁰). One problem is that the same mix of adaptive and rational players that does reasonably well in one treatment does not do well in the other.
8. The last observation in the previous point raises an intriguing possibility. What if the degree of bounded rationality is endogenous and the mix of adaptive and rational players in the two treatments (complements and substitutes) are endogenously distinct? The data suggests that in the complements treatment, the percentage of players who display behavior “close” to adaptive expectations is 45% for type x players and 60% for type y players. In the substitutes treatment, on the other hand, these percentages are, respectively, 6% and 0%. These results are consistent with the view that bounded rationality is relatively more pervasive under complements. Whilst the equilibria are identical in the complements and substitutes treatments, the main difference between the two is the slope of the best reply function in $(P_i, \bar{P}_{-i})$ space. This causes the loss in payoffs from adaptive expectations in the substitutes treatment to be higher than the complements treatment. By implication, subjects in the substitutes treatment stand to gain more by moving from adaptive to rational expectations. Thus, the extent of bounded rationality seems to respond to the cost of making cognitive errors.
9. The implications for existing macroeconomic models of nominal rigidity are profound. Models that invoke informational or contractual frictions or models of purely statistical learning,¹¹¹ do not invoke the cognitive costs of making decisions. Thus, they seem to be

¹¹⁰ For instance, it can explain the greater nominal rigidity in the complements treatment relative to the substitutes treatment.

¹¹¹ For models in the tradition of information asymmetries see Lucas (1972). The new Keynesian literature on contractual asymmetries began with the work of Fischer (1997). For a discussion of statistical learning models, see Evans and Honkapojha (2001).

missing a fundamental explanation of such rigidities based on money illusion and anchoring. Indeed, traditional macroeconomic models are unable to explain these experimental findings. Existing macroeconomic models in which there is a small degree of bounded rationality, such as Akerlof and Yellen (1985), and models of sticky information, such as Mankiw and Reis (2002), are also not fully able to explain the facts.

These comments should give the existing macroeconomic theories a sobering cause for concern. However, the model of Reis (2006), which incorporates a cost of searching for and absorbing information, and of Evans and Ramey (1992, 1998), Brock and Hommes (1997), which relate the formation of rational expectations to cognitive limitations, would seem to be promising in explaining the experimental data.

12.9 A digression on competitive equilibrium experiments

A discussion of the experiments on competitive equilibrium (CE) may appear to be out of place in this chapter. However, there are three justifications for this section. First, the CE is often a limiting case, as the number of participants in strategic situations become very large (e.g., the solution under Cournot competition when the number of firms is large). Second, the CE is often used as a benchmark for comparing the outcomes in many strategic market situations. Third, and intriguingly, the double auction experiments that are used to test the predictions of a CE often claim that the results approximate a CE, even with a very small number of participants (as low as even three); conditions that one may associate with strategic situations.

Economists have developed an elegant theory of *competitive equilibrium*. A vector of the prices of all inputs and all outputs, p^* , is a CE if, given these prices, all economic agents maximize utility/profits and all markets clear. With appropriate dating of goods, this static version can be easily extended to problems that have a time dimension. The existence and uniqueness of such a price vector, p^* , requires strong assumptions (Varian, 1992; Mas-Collel et al., 1995).

An indispensable part of the theory of CE is a fictitious actor, the *Walrasian auctioneer*, who contemplates fictitious out-of-equilibrium trades and then arrives at equilibrium prices. Actual trading then takes place *only* at the equilibrium prices.¹¹² One may imagine that the Walrasian auctioneer starts out with an initial price vector, then invites market participants to truthfully report their intended trades in all markets at that price. If all the excess demands are zero at that initial price, the initial price is the CE price vector, p^* . If the excess demands in some markets are positive (negative), then the auctioneer increases (decreases) the price in those markets. This experimental process goes on until the auctioneer finds a price vector, p^* , at which all excess demands are zero. This is the CE price vector.

Global uniqueness of p^* requires, as a sufficient condition, that all goods be gross substitutes at all prices.¹¹³ Furthermore, we require a large number of atomistic buyers and sellers, none of whom are large enough to influence the actual market outcome. Thus, all individuals are *price takers*. In the classical model, buyers, sellers, and the Walrasian auctioneer, have full information about all relevant aspects. However, because each participant has no effect on the actual outcome, none of the participants can use their information in any strategic manner. Furthermore,

¹¹² In particular, no trades are allowed to take place at the intermediate trial prices that the auctioneer may have experimented and/or iterated with.

¹¹³ Two goods are gross substitutes if an increase in the price of one good leads to an increase in the excess demand for the other.

we require that there be no market frictions or market imperfections, no externalities, and no public goods.

The assumptions behind a CE are unlikely to be met in actual practice. Hence, it is important to test the predictions of the theory in the lab. Edward Chamberlin (1948), one of the pioneers of monopolistic competition, performed a series of seminal experiments to test for a CE. Experimental data gathered from Harvard economics students to test the theory was not even remotely close to the predictions. Vernon Smith (1962) recast these experiments in terms of a double auction format and found support for a CE. Hundreds of experiments using double auctions followed, and found support for a CE.

Gode and Sunder (1993) used the format of the double auction experiments with zero intelligence (ZI) robots, and confirmed the predictions of the CE. In more complex settings, as we shall see, ZI robots do not do as well as humans. The positive results for a CE using ZI robots have raised some fundamental questions. What degree of rationality does the market require on the part of the market participants? Does individual irrationality wash out in the aggregate? Do behavioral biases have any bite in a competitive market equilibrium?

Davis and Holt (1993, p. 167) echo the mainstream view on double auction CE experiments as follows: “In markets organized under double auction trading rules, the predictions of the competitive model appear to be robust . . . Competitive price theory also does a good job of organizing data in some enriched double auction market structures.” In a similar vein, Kagel and Roth (1995, p. 370) write: “The striking competitive tendency of the double auction institution, which has been confirmed by at least a thousand market sessions in a variety of designs, indicates that neither complete information nor large numbers of traders is a necessary condition for convergence to CE outcomes.”

To some readers, the experiments of Chamberlin (1948) that allow buyers and sellers to freely meet and negotiate prices and quantities in an unstructured manner may seem closer to their own visualization of competitive markets. We discuss these issues below. Given excellent survey articles on the subject,¹¹⁴ the aim below is to consider some selected, but seminal, papers only.

12.9.1 *The original market experiments by Chamberlin (1948)*

Chamberlin (1948) performed a series of seminal market experiments with economics students at Harvard. He divided students into an equal number of buyers (B) and sellers (S). Sellers can sell a single unit of a good and buyers have unit demands. Buyers, $j = 1, 2, \dots$ are given cards with a number B_j that equals the buyers' valuation for a single unit. Sellers, $i = 1, 2, \dots$ are given cards marked with a number S_i that equals the cost to the seller of supplying the good. Each buyer and seller has private information about their valuation or cost. The expectation is that buyer j will be willing to pay a price no higher than B_j and seller i will not be willing to accept any price lower than S_i .

In contrast to later experimental practice, Chamberlin allowed the subjects in experiments, in the spirit of actual markets, to mingle with each other and to freely strike bargains with each other. If buyer j encounters a seller i and $S_i < B_j$, then the pair has an opportunity to strike a mutually profitable deal. For instance, if they agree on a price $p : S_i \leq p \leq B_j$, then each gets a non-negative payoff (the buyer's payoff is $B_j - p$ and the seller's payoff is $p - S_i$). The market closes after a certain amount of time. The same experimental market is repeated several times.

¹¹⁴ For the details, the interested reader can look up Davis and Holt (1993) and Volume 1 of the *Handbook of Experimental Economics Results* by Plott and Smith (2008).

The experimental data are shown in Table 12.34. The left hand side panel in Table 12.34 shows the valuations of buyers, arranged in decreasing order, and the cost of sellers, arranged in increasing order. These data are plotted in Figure 12.58. The demand curve, DD, reflects the valuations of the buyers and the supply curve, SS, reflects the costs of sellers. The zig-zag shape arises because sellers have unit supplies and buyers have unit demands. The equilibrium quantity is shown by

Figure 12.58 A plot of the demand and supply curves in Table 12.34.

q^* . The equilibrium price is indeterminate over a range of values. One possible equilibrium price, p^* , is shown in the figure.

From the left hand side panel in Table 12.34, for the first 15 units, shown in a darker background, the cost is lower than the valuation, so there is a possibility of mutually beneficial trades. The prediction of the CE model is $q^* = 15$, and the equilibrium price p^* could be any number between 56 and 58. For the 15th unit, bargaining between the buyer and the seller would ensure a price $p \in \{54, 55, 56, 57, 58\}$. However, given the unit demands and unit supplies, it is not efficient for the buyer with valuation $B_{16} = 56$ to buy. Hence, in equilibrium, $p^* \in \{56, 57, 58\}$.

In Chamberlin's experimental design, subjects mix freely in a room and strike bargains, much as we would expect in many real-world markets. This raises some interesting issues. Consider sellers with costs S_k, S_m and buyers with valuations B_j, B_n , as shown in Figure 12.58. Suppose that the seller with cost S_k (who is not expected to trade in standard equilibrium theory¹¹⁵) meets the buyer with valuation B_j (who is expected to trade in standard equilibrium theory). The buyer's valuation is greater than the seller's cost, so there is scope for mutually advantageous trade. The buyer does not know the valuations of other buyers or the costs of other sellers. If he turns down this opportunity to trade, he might not get another opportunity, thus, he might be willing to strike a bargain with the seller. In an alternative case, if the seller with cost S_m happens to meet a buyer with valuation B_n (who is not supposed to trade in equilibrium theory), then he might strike a bargain for similar reasons. This intuition turns out to be correct as we see below.

¹¹⁵ Such sellers are sometimes referred to as *extramarginal sellers*. Similarly, buyers whose valuations are lower than the competitive equilibrium price are sometimes known as *extramarginal buyers*. The converse of such traders (with costs lower than and valuations higher than the competitive equilibrium price) are sometimes known as *inframarginal traders*.

Figure 12.59 The time path of prices over successive rounds of the experiment.

Source: *Journal of Political Economy*. Chamberlin, Edward H. (1948). "An experimental imperfect market." 56: 95–108. © 1948 University of Chicago Press.

Consider the experimental findings reported in the upper right hand side panel of Table 12.34 from one of the timed sessions. This data describes the buyers' valuations and the sellers' costs from actual trades that took place in the session. Sellers who are in the position of a seller with cost S_k in Figure 12.58 are sellers with costs 58, 62, 64, 72. Buyers who are in the position of a buyer with valuation B_n in Figure 12.58 are buyers with valuations 56, 54, 48, 42. We should not observe any of these market participants trading if the predictions of the CE model were to hold. Yet, we do observe that they trade.

Over 46 repetitions of the experiment, the traded quantity is never below the CE quantity. Further, the actual quantity traded is above the equilibrium quantity in 91.3% of the cases. By contrast, the average price is higher than the equilibrium price 7 times, and lower 39 times.

The typical experimental results are shown in Figure 12.59; the equilibrium price is shown at 57. The data in each round of the experiment is plotted as the curve labeled "Actual Prices." It is clear that there is no tendency for prices to move towards the competitive outcome. Even in the later periods, no apparent convergence is obvious.¹¹⁶ Readers may wish to ponder the following quote, in full, from Chamberlin (1948, p. 102).

My own skepticism as to why actual prices should in any literal sense tend toward equilibrium during the course of a market has been increased not so much by the actual data of the experiment before us which are certainly open to limitations as by failure, upon reflection stimulated by the problem, to find any reason why it should be so. It would appear that, in asserting such a tendency, economists may have been led unconsciously to share their unique knowledge of the equilibrium point with their theoretical creatures, the buyers and sellers, who, of course, in real life have no knowledge of it whatsoever.

Chamberlin (1948), like others after him, allows "out of equilibrium trading," although this is not allowed in theory. However, out of equilibrium trading is needed to substitute for the fictitious

¹¹⁶ As Chamberlin (1948, p.101) notes: "Among the other forty-five examples, the most diverse patterns appear, with no apparently predominant tendencies to be noted."

actor, in the model, the Walrasian auctioneer. The presence of this actor makes theory very difficult to test. Chamberlin's implementation of the market mechanism seems eminently plausible and natural, although it was abandoned.

It is still nevertheless useful to see if one could design institutions that mimic the CE outcome. We consider this next, although we should also test if the proposed institutions are widely observed or not.

12.9.2 Double auction tests of a competitive equilibrium

In a series of papers, beginning with Smith (1962), Vernon Smith used an alternative implementation of a CE, one that used *double auctions* instead. Unlike Chamberlin's setup in which subjects in experiments freely met in order to strike mutually advantageous deals as in most real markets, Smith's subjects only make public offers/asks (in their role as sellers) or public bids (in their role as buyers).

Consider m sellers and n buyers with unit supplies and unit demands. The costs of sellers and the valuations of buyers are not typically public knowledge in double auction experiments. Suppose that one of the sellers moves first and publicly calls out an asking price (or "ask"), a_1 . This can be immediately accepted by a buyer, in which case both parties who are involved in the exchange exit the market and have no further role to play. The remaining parties bid/ask anew. Alternatively, one of the buyers might choose a bid, b_1 . The bid can be immediately accepted by a seller, in which case both parties exit the game and the remaining parties bid/ask anew. If not, then one of the sellers makes another ask, a_2 . This can be followed by fresh rounds of bids and asks, and so on until the time runs out in the experiment.

Proceeding in this manner, we obtain a sequence of asks $a_1, a_2, a_3, \dots$ and a sequence of bids $b_1, b_2, b_3, \dots$ until an object is exchanged. If an object is exchanged at an agreed price p between a buyer who has a valuation v and a seller who has a cost c , then their respective payoffs are $v - p$ and $p - c$. Multilateral public bids distinguish the double auction method from the bilateral private bargaining between individuals on both sides of the market in Chamberlin (1948).

An important component of the double auction experiments is *the market improvement rule*.

Definition 12.6 (*Market improvement rule: Davis and Holt, 1993, p. 128; Kagel and Roth, 1995, p. 369*) *In most auction experiments, non-improving bids/asks are not allowed. So for the sale of any one unit of an object, it is required that $a_1 > a_2 > a_3 > \dots$ and $b_1 < b_2 < b_3 < \dots$*

From Definition 12.6 the asking price of sellers needs to drop over successive asks and the bidding price of the buyers needs to increase over successive bids until an exchange takes place. Table 12.35 gives an illustration of the operation of a double auction during the sale of one unit of a good, taken from Davis and Holt (1993, p. 129). There are four buyers, B1 through B4, and four sellers, S1 through S4. The entire experiment lasts 300 seconds and time is given in seconds in the first column. Seller S2 first announces an ask of \$5, followed by a bid from buyer B4 of \$4.10. The market improvement rule prohibits any subsequent asks above \$5 and any bids below \$4.10. As shown in Table 12.35, subsequent sellers offer decreasing asks and subsequent buyers make increasing bids until, finally, buyer B4 accepts the offer of seller S1 to trade one unit at a price of \$4.30.

The market improvement rule is intended to substitute for a Walrasian auctioneer and it is widely used in double auction experiments with humans and non-human subjects, as in agent-based models. A skeptic may argue that the theory makes no allowance for such a rule and it

Table 12.35 Some data from a double auction experiment reported in Davis and Holt (1993, p. 129).

Time	Bid	Offer
296		S2 offers \$5.00
294	B4 bids \$4.10	
293		S3 offers \$4.50
291	B1 bids \$4.20	
285	B2 bids \$4.21	
284		S1 offers \$4.40
279		S3 offers \$4.39
276		S4 offers \$4.35
271	B2 bids \$4.25	
267	B2 bids \$4.26	
265		S3 offers \$4.34
261		S1 offers \$4.30
254	B4 accepts	

forces trades in the direction of a CE, which is the very phenomenon that it seeks to explain. However, many in the profession consider the results from the double auction experiments to be of fundamental importance.¹¹⁷

In his pioneering work, Smith (1962) used the double auction method, described above, to test for a CE. Each *market period* ends when bids and asks no longer lead to further successful transactions between buyers and sellers. At the end of each market period, say period n , the market is immediately closed and reopened for the next day, which is referred to as period $n + 1$. Each market participant has private information about his/her valuation or cost for the good. A variety of demand and supply curves are considered. The results from one of the 10 “tests,” which corresponds to one such set of demand and supply curves, is shown in Figure 12.60.¹¹⁸ In any test, the demand and supply conditions are held fixed, so that subjects are able to “learn” their way to a CE; however, the supply and demand curves are altered from one test to another.

The demand and supply schedules are shown in the left panel of Figure 12.60. The right panel shows the dynamics of the actual path of prices over the various periods. Buyers have unit demands, given to them on a piece of card. The buyer with the highest valuation in Figure 12.60 has a valuation of \$3.25, and the next highest valuation is \$3.00. So if the price were \$3.00, then, at most, two units would be demanded. These valuations are used to generate the demand curve

¹¹⁷ The following quote from Eckel (2007) is not unrepresentative: “When Vernon tells about this experiment, he maintains he was astonished at the rapid convergence to CE that he observed, and says he had to replicate it a few times, with different shaped demand and supply arrangements, to convince himself it was correct. Experimentalists now know that the institution he implemented, the Oral Double Auction, is about the most powerful institution there could be for inducing convergence to CE. It works like a charm, with groups as small as 3 buyers and sellers, even with low or hypothetical stakes, it reliably converges to equilibrium. Every experimentalist I know conducts this experiment in classrooms in almost every class they teach. It is an unforgettable experience for students. They come away believing that markets (can) work, and that the theory of supply and demand has teeth (or jaws, as Plott would say).”

¹¹⁸ The word “test” in Smith (1962) seems to correspond to an experimental session and each test is comprised of several periods (see Figure 12.60).

Figure 12.60 Price dynamics.

DD. Similarly, sellers are given cards that give the minimum price at which they should be willing to sell a unit, possibly reflecting their costs. This generates the supply curve SS. The minimum price that sellers are willing to accept and the valuation of the buyers is private information. The number of trading periods varies from one experiment to the other. The double auction procedure, described above, is then implemented. The theoretical prediction is an equilibrium price of \$2 and the equilibrium quantity is 6 units.

In Figure 12.60, in the first of five periods, five successful transactions took place, whereas in period 4, seven successful transactions took place. The *parameter of convergence*, α , is defined as $\alpha = \frac{\sigma}{p^*} \times 100$, where σ is the standard deviation of the actual experimental price and p^* is the predicted equilibrium price. The variation in prices, as measured by α , tends to fall in successive periods. While α falls in each period, except for the last few transactions in period 5, a simple eyeball test does not conclusively establish that prices have converged to the equilibrium level p^* . Recall that the various tests differ in the demand/supply curves. In Test 4, for instance, the supply curve is perfectly elastic. In this case, the actual price converges to about \$0.20 above p^* .

The results in Smith (1962) from a range of demand and supply curves are consistent with the competitive market equilibrium. However, one of the predictions of the CE model, the *Walrasian hypothesis*, does not hold.¹¹⁹ Hundreds of subsequent studies that have been done with the basic double auction template provided by Smith (1962) have found similar results.¹²⁰ Features

¹¹⁹ The Walrasian hypothesis implies that the unit price is increasing in excess demands; see Smith (1962, p.116).

¹²⁰ The interested reader may consult the survey by Davis and Holt (1993) for the relevant evidence. Smith (1964) extends his earlier work by looking at prices in various rounds of the experiments when the market institutions are altered. For instance, only sellers may be permitted to announce asks with the buyers passively accepting or rejecting; or the sellers may be permitted to announce asks and the buyers could simultaneously announce bids; or only the buyers may announce bids and the sellers passively accept or reject bids.

of the transition dynamics that lead to the eventual convergence to a CE are still an active area of research (Plott, 2008).

One method of evaluating the efficiency of the observed outcome is to compute a measure of allocative efficiency, E . Define total social surplus as the sum of consumer surplus and producer surplus. Let S_P denote the predicted social surplus under the competitive outcome and S_A the actual social surplus in experimental conditions. Then the allocative efficiency of the observed outcome is $E = (S_A/S_P) \times 100$. The allocative efficiency in double auction experiments with human subjects is very high, typically ranging between 97.3% and 99.4%. The interested reader can see a summary of several studies in Davis and Holt (1993, Table 3.4, p. 136).

List (2004) constructs an experimental design that has shared features with Chamberlin (1948) and Smith (1962). In an artefactual field experiment, he takes experienced traders from the sports cards and collector pin markets. The results are similar, so we consider only sports card dealers. Such traders are either buyers (non-dealers) or sellers (dealers) in their respective markets; these endogenously determined real-life roles are maintained in the artefactual experiments. As in Smith (1962), buyers are given cards with their assigned valuations and sellers are given cards with their assigned marginal costs. Buyers do not find it profitable to pay more than their valuations and sellers do not find it profitable to sell below their marginal costs. The valuations of buyers and the costs of sellers are private information. Typically, there are 12 buyers and 12 sellers in each experimental session that is comprised of five market periods, each period lasting for 10 minutes.

As in Chamberlin (1948), buyers and sellers are allowed to engage in privately optimal exchanges by meeting, bargaining and haggling. The homogeneous commodity that is used in the experiments is multiple copies of a sports card that had no value outside the experiments. A critical feature of the experimental design is in the spirit of Smith (1962) but distinguishes these experiments from the experiments in Chamberlin (1948). Namely, as soon as a buyer and a seller exchanged an object, the price and the contract was publicly announced to all other individuals in the session. It is likely that the most recent exchange price acts as an anchor around which bidding in subsequent rounds takes place.¹²¹ Also, unlike Chamberlin (1948), discussions among groups of sellers and groups of buyers that could lead to a collusive outcome were prohibited.

Three kinds of market demand and supply curves were considered; in each, the equilibrium price was \$13.50 and the equilibrium quantity was 7. In the S12 treatment, the demand and supply curves are symmetric; in the PED12 treatment, the demand curve is perfectly elastic at a price of \$13.50; and in the PES12 treatment, the supply curve is perfectly elastic at a price of \$13.50. The experimental outcomes quickly converge to the predictions of the competitive market outcomes. In the fifth round, in the treatments S12, PED12, PES12, and averaged across all sessions, the respective prices are \$13.12, \$13.15, and \$13.68; the corresponding quantities are 7.3, 6.3, and 6.3.

These convergence results are in stark contrast to the results in Chamberlin (1948) that show no tendency for prices to converge to the competitive equilibrium prices. List (2004) ascribes these results to the role of experience among traders. The more experienced the traders, the greater the rents that they earn in the experimental exchanges, conditional on trade taking place. By contrast, when the experiments are run with children, convergence to a competitive equilibrium does not take place. These conclusions are open to alternative interpretations. However, the value of this study is that it demonstrates that a double auction is just one method of achieving consistency with a competitive outcome. A second method is the provision of information to each participant following each successful exchange in these experiments.

¹²¹ For details on the *anchoring heuristic*, see Chapter 19.

12.9.3 Agent-based models of competitive double auction markets

There has been growing interest in *agent-based computational economics* (ACE). Duffy (2006, p. 951) provides a useful set of characteristics of this approach: “agent-based computational economic (ACE) researchers consider decentralized, dynamic environments with populations of evolving, heterogeneous, boundedly rational agents who interact with one another, typically locally. These models do not give rise to closed-form solutions, and so results are obtained using simulations. ACE researchers are interested in the aggregate outcomes or norms of behavior that emerge and are sustained over time, as the artificial agents make decisions and react to the consequences of those decisions.”

An important application of ACE to double auctions is provided by Gode and Sunder (1993).¹²² They were interested in finding if the convergence properties of double auction experiments on CE with human subjects could also be obtained with non-human subjects, such as zero intelligence (ZI) robots. The conjecture was that the rules of the double auction experiments, such as the market improvement rule, and not the rationality of human subjects, is responsible for the supposed convergence results with human subjects.

ZI robots, unlike human subjects, bid randomly from an appropriate distribution of asks or bids. A robot buyer, j , with valuation B_j is allowed to bid randomly, any number in the interval $[0, B_j]$. A robot seller, k , with cost S_k , asks randomly any price in the interval $[S_k, m]$, where m is the maximum over all buyer valuations. Crucially, the ZI robots follow the market improvement rule given in Definition 12.6, which plays an important role in the observed success of the double auction market experiments. ZI robots, defined in this way, are said to respect the budget constraint, because they do not trade at a loss. We call these constrained robots ZI-C traders. In a control treatment, all buyer and seller robots could bid randomly from the interval $[0, m]$. Since, these traders do not respect the budget constraint and will sometimes make losses, they are called the ZI-U traders.

The price dynamics are shown in Figure 12.61. The left panel shows the demand and supply schedules with a CE price prediction of 80 and a quantity prediction of 24. The right panel shows the results over six periods of the experiment with ZI-U and ZI-C robots, and human subjects; each period has several market rounds. Human subjects stay fairly close to the predictions of the theory. The ZI-C subjects show greater fluctuation around the equilibrium prediction than human subjects, however, the variation in prices declines over successive market periods.

One has to be careful in interpreting this decreased variation in prices for ZI-C subjects, because, by definition, robot subjects do not engage in learning. The reason for this reduction in variance is that the higher valuation/lower cost units tend to be traded first, which is a feature that is in-built into the market improvement rule. The greatest variation is found in the case of ZI-U robot traders who show no tendency to converge to the equilibrium predictions. The allocative efficiency, E (defined above), for ZI-C robots is 98.7%, slightly higher than the corresponding figure for human subjects of 97.6%.¹²³

¹²² The precursor to the Gode and Sunder (1993) paper is the paper by Hurwicz et al. (1975). The interested reader can explore this literature further by consulting Tesfatsion and Judd (2006).

¹²³ Readers who wish to follow up the extensive literature may consult Duffy (2006).

12.9.4 *Evaluating the experimental evidence on competitive markets*

It is not possible to observe the behavior of the fictitious player in economic theory, the Walrasian auctioneer, who is critical in achieving a CE. This makes it difficult to falsify the theory. Experimenters are left with the open question of what proxy to use for the Walrasian auctioneer in their experiments. Chamberlin (1948) allowed buyers and sellers to freely bargain with each other and agree on mutually beneficial trades. Smith (1962) chose a double auction setting in which the bilateral dealings in Chamberlin are replaced with public bids and asks. Chamberlin's results reject the Walrasian competitive outcome, while Smith's results support it. The subsequent literature has followed Smith's double auction experimental method.¹²⁴ Furthermore, a CE requires

¹²⁴ For instance, Miller et al. (1977) extend Smith's (1962) work to an intertemporal, two season market. On p. 299, they open with the following quote: "However, it is now well established by many experimental replications that knowledge of market supply and demand is not a necessary and may not be a sufficient condition for classical

that there should be no “out of equilibrium trading.” All trades should only be carried out at the equilibrium price which is arrived at by the Walrasian auctioneer. However, in all experiments, out of equilibrium trading is crucial and essential.

One interpretation of the experimental literature in this area is that its main interest lies in discovering if there exist institutions that mimic the outcome of CE. This is of interest in its own right, insofar as a CE possesses desirable efficiency properties. The double auction setting, augmented with the market improvement rule, is one such institution. Let us call this the *augmented double auction institution*.

The augmented double auction institution achieves nearly 100% allocative efficiency. However, despite its similarity to trading in stock markets, it begs the question of why do we not observe it more often in practice. For instance, regulatory and antitrust agencies desiring a competitive, efficient outcome should simply announce and implement the augmented double auction for all cases where they suspect a non-competitive outcome. But they typically don't. One possible explanation is that there could be important transaction costs, or other important frictions associated with this institution that are not modeled in experiments. Furthermore, the auction or stock market trading situation need not be typical. For instance, there may be practical difficulties in bringing all participants in a transaction to the table every time an exchange takes place.

The market improvement rule seems critical to the success of the double auction setting, both in the human and the robot setting. By constraining movements in bids and asks (see description above), one may wonder if it nudges the results in the direction of the predictions of the competitive model. Indeed, zero intelligence robots also arrive at the competitive outcome when a market improvement rule is imposed on them. On the other hand, a strength of the augmented double auction results is that even with a minimum degree of rationality (as with zero intelligence robots) one typically obtains the desirable competitive outcome, which is a particular strength of this mechanism.

The static double auction setting is quite special. The equivalence of results generated with ZI robots and humans can break down in a more complex double auction setting. Furthermore, in both human and robot treatments, prices might not converge to the CE prices. Van Boening and Wilcox (1996) relaxed the assumption of fixed costs for sellers and introduced *avoidable costs*. These are costs that are actually incurred only if an exchange takes place. The seller's entry decision is more complicated here. They have to guess the identity of the other sellers who might also enter (because costs are avoidable if they defer entry). In this more complicated setting, the efficiency of the observed outcome for human subjects is significantly lower than the competitive outcome. Furthermore, the performance of ZI robots is even worse than human subjects.

Miller (2008) considers the performance of ZI robots in the two-season setup introduced by Miller et al. (1977). In these experiments, the subjects have to make an informed decision on how many units to carry forward from one season to the next, which requires a degree of cognitive sophistication. Predictably, ZI robots fail to converge to the CE. Brewer et al. (2002) consider the possibility that the demand and supply curves are *continuously refreshed*. By this it is meant that they are altered from one trading period to another. In this setting, ZI-C robots chose very variable prices that do not converge to the CE. These results caution against drawing the common conclusion that a CE can easily be obtained in lab experiments.

competitive equilibria to be achieved when a stationary market is organized under auction rules.” A similar report of the evidence is given in Davis and Holt (1993) and Kagel and Roth (1995).

CHAPTER 13

Models of Behavioral Game Theory

13.1 Introduction

Consider a perfect Bayesian Nash equilibrium (PBNE) in a dynamic, extensive form game.¹ Roughly speaking, a profile of strategies and beliefs is a PBNE if for each player at each decision node, two main conditions hold. First, conditional on what has happened so far in the game, players play a best response, conditional on their beliefs about other players and the subsequent equilibrium strategies of the players. Second, the beliefs of players about the strategies of other players are formed using Bayes' rule, and equilibrium actions and beliefs are consistent with each other. Simpler games, such as static games of full information, and static games of incomplete information, require appropriate simplifications of a PBNE, respectively, a Nash equilibrium and a Bayesian Nash equilibrium.

Chapter 12 showed that the Nash equilibrium concept and its refinements in more complex games fail to fully account for the experimental evidence, particularly from the early rounds of games. A natural response is to attempt to relax one or both conditions of a PBNE. In particular, this has led to the development of two main behavioral alternatives.

The first of these alternatives, *quantal response equilibrium* (QRE), is considered in Section 13.2. In a QRE, the first condition of a PBNE is relaxed. As in *stochastic utility models*, players play noisy best replies, conditional on their beliefs about the strategies or types of others. The noise in best replies may arise from privately observed payoff shocks or taste shocks. However, players correctly anticipate the noisy best replies of others. Noisy best replies do not imply random play. Rather, the actions of players that give a higher expected payoff are played with a higher probability. A QRE is a fixed point in the strategies and the beliefs of the players.

We consider QRE in normal form games (McKelvey and Palfrey, 1995), and, briefly, in extensive form games (McKelvey and Palfrey, 1998). In many cases, the predictions of QRE are in better accord with the findings of experimental games, as compared to a PBNE. In particular, a QRE can account for the effect of changes in the magnitude of payoffs on the chosen strategies when a Nash equilibrium predicts no such effect. We consider two successful empirical applications. The first is due to McKelvey et al. (2000) and a second is an application to Basu's traveller's dilemma game, due to Capra et al. (1999).

¹ See the appendix on game theory if you are rusty with this concept.

Haile et al. (2008) showed that a QRE does not impose falsifiable restrictions if the noise with which players play their strategies is not independently and identically distributed. We outline their objections, and the response of Goeree et al. (2005) who proposed the *regular quantal response equilibrium* (RQRE).

It would appear that the cognitive requirements for a QRE that require computing a fixed point in “actions” and “beliefs about the noisy play of others” are quite high. Relaxing the second feature of a PBNE is likely to be less cognitively taxing. In this case, players’ beliefs are not required to be consistent with the actions of other players, yet all players play a best response to their, possibly mistaken, beliefs. Within this class of models, *level- k models*, considered in Section 13.3, provide the leading behavioral alternative to a Nash equilibrium and its refinements. Level- k models were initially introduced by Stahl and Wilson (1994, 1995) and Nagel (1995) to explain certain experimental findings that were difficult to reconcile with existing theories.

In level- k models, players have a *hierarchy of beliefs*. Level-0 players (or type $L0$) are non-strategic, and in many applications they choose uniformly randomly over the set of available actions. However, when the underlying actions are framed in a non-neutral manner or have different degrees of salience, then this need not be the case. Level- k , $k \geq 1$ players (or types Lk , $k = 1, 2, \dots$) assume that all other players are of type $Lk - 1$. Type $L0$ players need not physically exist. At a minimum, they serve as a model of other players in the minds of type $L1$ players. Since each type best responds to the optimal actions of the immediately lower type in a recursive manner, type $L0$ is the *anchoring type* and the specification of its actions is often critical to the results. The beliefs of players are not assumed to be in equilibrium, so level- k models would seem to apply particularly to new and unfamiliar situations, to games that one plays infrequently, and particularly, to data from the early rounds of experiments. Arguably, the domain of such decisions is rich, varied, and important (e.g., marriage, divorce, purchase of consumer durables, house purchases, decisions on pension plans, and mortgage/insurance decisions).

The inability of level- k models to specify the optimal actions of type $L0$ players may be considered to be a drawback by some. However, this problem is no different from the specification of a reference point in prospect theory, or the specification of a prior in Bayesian models, or the specification of a utility function in a model. The assumptions that one makes about type $L0$ players can be tested for their validity, particularly in out of sample data. The evidence on the physical existence of type $L0$ players is mixed; Sections 13.4.5 and 13.4.6 specifically discuss this evidence, although further evidence is scattered in many places in the chapter.

Section 13.3.2 considers a well-known application of level- k models, the *p -beauty contest* (Nagel, 1995). In the p -beauty contest, participants simultaneously make a guess in an interval $[0, 100]$; the winning guess is closest to p times the average guess. When $p < 1$, the Nash equilibrium is the lower limit of that interval, 0, and when $p > 1$ the Nash equilibrium is the upper limit, 100. The level- k model makes very precise predictions for this game. Let $p = \frac{2}{3}$, and assume that type $L0$ players choose uniformly randomly over $[0, 100]$. Then, the level- k prediction is that we should observe spikes in guesses at the numbers $50(\frac{2}{3})^k$ for $k = 1, 2, 3, \dots$. The thrust of the experimental findings for data from early rounds of experiments is that one rarely observes the Nash outcome, and one does observe spikes in the data at the points predicted by the level- k model. These findings hold even for subjects whom one would expect to have high cognitive abilities.²

Section 13.3.3 considers the *cognitive hierarchy model* (CH), which is closely related to the level- k model (Camerer et al., 2004a). In CH models, each type Lk player, $k \geq 1$ assumes that there

² See for instance, Stahl and Wilson (1994, 1995), Nagel (1995), Ho et al. (1998), Bosh-Domènech et al. (2002), Camerer (2003a,b).

is a non-degenerate distribution of all lower types of players, $Lk - 1, Lk - 2, \dots, L0$. Players form the correct inferences about the distribution of lower types, normalized by the truncation of the distribution at level $Lk - 1$. Typically, the underlying distribution of players is a Poisson distribution, which is a one parameter family of distributions, allowing for a tractable estimation of such models. In a CH model, the rationality of the players increases as k increases. In most games, CH and level- k models make similar predictions. More work is needed to successfully discriminate between these two models (Crawford et al., 2013).

Section 13.4 considers further applications of level- k and CH models. When there are multiple equilibria in coordination games, classical game theory proposes several refinements, such as salience of labels, payoff dominance, and risk dominance, to explain the choice among multiple equilibria. Section 13.4.1 considers the salience of labels in 2×2 coordination games with multiple equilibria (Crawford et al., 2008). Label salience, in the sense of Schelling (1960), helps one to reconcile experimental data when one chooses symmetric games. However, in asymmetric games, payoff asymmetries may conflict with label salience. Indeed in such cases, label salience alone is unable to predict experimental choices. By contrast, a level- k model makes predictions that are in better accord with the evidence relative to classical game theory.

Section 13.4.2 considers the role of communication in enhancing coordination in a Battle of Sexes (BOS) game (Crawford, 2007). Section 13.4.3 considers a stag-hunt game in which payoff dominance and risk dominance are traditionally used to choose among multiple equilibria (Crawford, 2007). Several messages emerge, although they are sensitive to the specification of type $L0$ players. The level of coordination in level- k models is often higher than that under a Nash equilibrium. Communication can enhance the level of coordination in level- k models, even when it is not predicted to do so in classical game theory. Risk dominance and payoff dominance play no role in level- k models unlike in classical game theory. Coordination, when it occurs, is entirely accidental.

Section 13.4.4 considers the *market entry game* in which there is a market of fixed integer size, say $d > 0$, and there are $N > d$ potential entrants who can each supply one unit (Selten and Güth, 1982). If $n \leq d$ entrants enter, then they all have a payoff of 1. Otherwise, if $n > d$ entrants enter, then all entrants get zero. The Nash equilibrium is that $n = d$ entrants should enter. Most experiments show that, with some learning, the predictions of the Nash equilibrium hold, a finding that Kahneman (1988) found to be “magical”. This was often held up as an example of the ability of classical game theory to make successful predictions (Sundali et al., 1995). However, it turns out that CH models can explain this magical finding equally well (Camerer et al., 2004a; Crawford et al., 2013). The emerging field evidence supports an explanation based on level- k /CH models (Goldfarb and Yang, 2009; Goldfarb and Xiao, 2011).

Empirical evidence for level- k models is considered in Section 13.4.5 (Costa-Gomes et al., 2001; Costa-Gomes and Crawford, 2006). These papers examine the *choice data* of the subjects as well as the *search and lookup data* collected using the mouselab software.³ The authors allow for the presence of a large number of possible types of players, including non-level- k players. However, once the choice and the lookup data are combined, the most common types are the level- k types, $L1, L2$, and $L3$. Type $L0$ players are rare.⁴ Some evidence is also found for subjects who play the Nash equilibrium and those who use simple heuristics. One such simple heuristic is to carry out one round of iterated dominance, and then play a best response on the assumption that opponents

³ See Section 12.5.4 in Chapter 12 for a description of the relevant method.

⁴ This finding is replicated in several of the other papers considered in this chapter; for instance, see Crawford and Iriberri (2007b) in an auction context.

randomize uniformly over their strategies. There is a fair bit of stability of types across similar games (but see Hargreaves et al. (2014) and the discussion below).

Georganas et al. (2012) find that for one class of games there is stability of types, but for the other class in their experiments the level- k types are not stable. They conjecture that (i) the level- k heuristic may be activated in some games and not in others, but it is not clear what causes this activation, and (ii) the likely source of the difference in their results from earlier ones is that in Costa-Gomes et al. (2001) and Costa-Gomes and Crawford (2006) the instructions are too detailed, and subjects may have been primed to play best responses due to the number and nature of the practice rounds.

Clearly, the issue of priming of subjects prior to an experiment by playing best response games with them is an important one for experimental economists. Perhaps it may be considered to be a proxy for achieving greater external validity in the experiments. Nevertheless, this issue has also been picked up by several other emerging papers who avoid such priming of subjects. We consider some of these papers in Section 13.4.6 under the title “Do non-strategic players really exist?”⁵ The message arising from these papers is that type $L0$ players, and those who just make non-strategic choices (such as choosing dominant actions in p-beauty contest games), need not just be an artifact in the minds of level $L1$ players. Rather, such non-strategic players seem to comprise a significant fraction of the players—around 40% in some studies. Furthermore, there is significant heterogeneity in the choices of these players. Clearly, this area is very new and requires further research before a fuller picture emerges.

In classical game theory, and in many behavioral models, players derive utility from the strategies or actions of all players. However, in many contexts, players may also derive utility *directly* from the beliefs about the choices and actions of others. For instance, people may have beliefs about the beliefs of others about their actions, and they may dislike falling short of these beliefs (*guilt*). This, in turn, may influence their choice of action. The standard framework cannot be adapted by simply adding the psychological payoffs to the material payoffs, because beliefs themselves are endogenous. These considerations require the development of new techniques that is embodied in *psychological game theory*. *Psychological games* and the relevant equilibrium concepts are considered in Section 13.5.

The seminal contribution in psychological games is Geanakoplos et al. (1989). In order to build intuition for more complicated classes of games, we outline this contribution in Section 13.5.1 for one-stage games. Recall that in Part 2 of the book, we considered the empirical evidence for the role of reciprocity and intentions in influencing outcomes. A formal treatment of these issues requires psychological game theory. Drawing on the work of Geanakoplos et al. (1989), the seminal application to reciprocity, based on a normal form two-player game, is Rabin (1993). While Rabin’s model is the first to formalize issues of intentions and reciprocity, it is not designed for sequential games that are of considerable importance in modeling issues of intentions and reciprocity.⁶

One drawback of the framework proposed by Geanakoplos et al. (1989) is that the beliefs of players are *initial beliefs* even when the underlying game is a sequential game. In sequential games, the actions of players at any node may reveal their intentions, hence, the beliefs of other players about choices and beliefs may change as the game unfolds through subsequent nodes. Further-

⁵ Some of the literature considered in this section includes: Costa-Gomes and Weizsäcker (2008), Agranov et al. (2012), de Sousa et al. (2013), and Burchardi and Penczynski (2014).

⁶ For instance, Rabin’s model can explain rejections in ultimatum games; however, the model is consistent with many other equilibria as well, including overfair offers (e.g., proposer offers more than 50%), which are generally not observed.

more, in this framework, players derive utility solely from their own beliefs and payoffs depend only on the set of strategies that lead to a terminal node, and not the plans that players may have had.

In Section 13.5.2 we consider the more general framework of Battigalli and Dufwenberg (2009) that takes account of these objections. In Section 13.5.3, we give an application of this general framework to a consideration of reciprocity in sequential games, and introduce the notion of a *sequential reciprocity equilibrium* (Dufwenberg and Kirchsteiger, 2004). This allows for a better fit of the predictions with the relevant evidence. For instance, while Rabin's model predicts unconditional cooperation in the sequential prisoner's dilemma game, a sequential reciprocity equilibrium makes the plausible prediction of conditional cooperation in the same situation. We also consider some of the evidence for this framework from public goods games (Dufwenberg et al., 2011).

Dufwenberg and Kirchsteiger (2004) were mainly concerned with the modeling of reciprocity. In Section 13.5.4, we combine the role of reciprocity with considerations of social preferences in sequential games (Falk and Fischbacher, 2006). This more general framework has even better explanatory power. For instance, it can explain the experimental results arising from the ultimatum game, the dictator game, the gift exchange game, the public goods game, and the prisoner's dilemma game.

Section 13.5.5 considers the role of *guilt* in games (Battigalli and Dufwenberg, 2007). We consider a range of examples and evidence that illustrate the important role of guilt: from public goods games (Dufwenberg et al., 2011), to *promises* and *partnerships* (Charness and Dufwenberg, 2006). A growing number of empirical papers support a positive correlation between the degree of cooperative actions of players and their *second order beliefs*.⁷ This is consistent with players exhibiting *guilt aversion*. We also consider the recent work of Khalmetski et al. (2015) who reconcile the negative findings of Ellingsen et al. (2010) for guilt aversion with earlier work that reports positive findings.

Section 13.6 considers some aspects of the important work of Gintis (2009).⁸ He argues for retaining the rationality assumption in economics, i.e., humans have a complete and transitive preference relation between the relevant choices. His starting point is that there are no plausible *epistemic foundations* for the assumption of *common knowledge* of rationality in classical game theory. Hence, the very plausibility of a Nash equilibrium based on the epistemic conditions (Aumann and Brandenburger, 1995) is in doubt.⁹ It is possible that *social norms* and *conventions* may serve to bring about common priors and ensure common knowledge about an event. However, Gintis argues that it is a mistake to think of Nash equilibria as social norms (a common argument given by many game theorists) for two reasons. First, the epistemic conditions required for a Nash equilibrium are too stringent to be plausible. Second, many social norms are, in fact, not Nash equilibria.

Imagine a *choreographer* who coordinates human behavior. First, Gintis argues that social norms and conventions play the role of a choreographer. The foundation for this argument goes

⁷ First order beliefs are beliefs about the likely actions of others. Second order beliefs are beliefs about first order beliefs of others.

⁸ Our focus is mainly on Gintis's 2009 book but we encourage the reader to follow up the references in the book that form the basis of his arguments, for a more well-rounded understanding of the issues, as well as a better appreciation of the contribution by Herbert Gintis.

⁹ Aumann and Brandenburger (1995) showed that in two-player games, mutual knowledge of payoffs and of rationality is sufficient for a Nash equilibrium. However, for three or more players, this mutual knowledge assumption must be supplemented by common knowledge of conjectures.

back to Aumann (1987) who showed that under common priors Bayesian rationality guarantees that in any epistemic game economic agents play a correlated equilibrium. A second insight is to assign the role of creating the common priors for the choreographer. A necessary condition is that humans should be predisposed to following the recommendations of the choreographer to play a correlated equilibrium if they can do no better than by following the recommendations. Evolutionary arguments are then used to argue that such predispositions must exist.

Section 13.7 considers a range of other behavioral game theory models. These models often rely on plausible arguments that are often, but not always, underpinned by some form of psychological evidence. However, the psychological underpinnings of many of these models need to be better established. We consider existing evidence for these models but further empirical testing needs to be carried out to establish their relevance.

Section 13.7.1 considers *analogy-based expectations equilibrium* (ABEE) (Jehiel, 2005). In an analogy-based model, players have an information partition of the set of nodes of a game at which other players move. Each of these information partitions is known as an *analogy class*. On account of cognitive limitations, players assign the average action of the opponent to all the nodes in an analogy class and best respond to these average beliefs. Players need not know the payoffs of other players, nor the analogy classes of others. This lightens the cognitive burden on players from playing the game. However, at the moment we do not have a good account of how players construct analogy classes.

In Section 13.7.2 we consider the *subjective heterogeneous quantal response equilibrium* (SQRE) (Rogers et al., 2009). The QRE and the CH models relax different features of a Nash equilibrium. The QRE relaxes the best response feature and level- k /CH models relax the feature of mutually consistent beliefs. An SQRE, on the other hand, has the ambitious agenda of combining insights from both models and to show how these models are special cases of a more general overarching model.

Section 13.7.3 introduces the concept of a χ -*cursed equilibrium* (Eyster and Rabin, 2005), which applies to finite Bayesian games. In this model, χ -*cursed* players believe that with probability $\chi \in [0, 1]$, all the types of an opponent play the average optimal action, and with probability $1 - \chi$, the opponent's types play their type-contingent optimal actions. Thus, with probability χ , players do not show full awareness of the correlation between the types and the optimal actions of players. A player is fully cursed if $\chi = 1$, and the benchmark case of a Bayesian Nash equilibrium obtains when $\chi = 0$.

For finite Bayesian games, a χ -cursed equilibrium always exists. The main application of a χ -cursed equilibrium that we consider is to auctions in Section 13.8.3. For games of full information, the χ -cursed equilibrium reduces to a standard Nash equilibrium, which is often rejected by the data for new games and for early rounds of play in experimental games. The psychological underpinnings for the cursed equilibrium model are less clear than some of the other behavioral models, but the similarity in some settings with the ABEE, a model with arguably better psychological foundations, is encouraging.

Section 13.7.4 considers *evidential reasoning* and *evidential games* (al-Nowaihi and Dhami, 2015). This model applies to static games of full and incomplete information, although, in principle, it can be extended to dynamic games. Suppose that players choose their strategies simultaneously in full information or incomplete information settings. Players are typically uncertain about the actions that other players will choose in static games, perhaps because it is a new game/situation, or it is played infrequently, or the cognitive limitations of players may prevent the deductive reasoning needed for a Nash equilibrium. A great deal of evidence from psychology indicates that in such cases, players assign *diagnostic significance* to their own actions in making

inferences about the actions of other like-minded players. For instance, players who intend to cooperate in a prisoner's dilemma game, assign very high probability that others will cooperate. Voters who intend to vote for Democrats (resp. Republicans) in US elections assign very high probability that other voters will vote for Democrats (resp. Republicans) despite sharing identical public information on polls. A corrupt official may, likewise, overestimate the probability that others are corrupt, again taking his own actions as diagnostic of the actions of others.

Each player then best responds to his *evidential beliefs* about others, by solving essentially a decision theoretic representation of the underlying strategic situation. This affords enormous cognitive simplification of a complex underlying situation. Evidential games provide a general framework within which to think of many other belief formation processes such as level- k models, when restricted to static games. This line of work may be thought of as providing a *heuristics* and *biases* approach to strategic interaction, much like a similar approach in decision theory due to Daniel Kahneman and Amos Tversky that helped explain the evidence much better (see Part 7). There should be no presumption that evidential reasoning is rational, in the same way that judgment heuristics are not judged on their satisfaction of the relevant axioms of rationality. However, it provides a fast and frugal method of dealing with an uncertain situation, which is a typical feature of good heuristics. The relevant issue is not the a-priori rationality of such heuristics, but the conformity of empirical evidence with such modes of reasoning.

Section 13.7.5 considers the model of *noisy introspection* (Goeree and Holt, 2004). In a QRE, recall that players play a noisy best response but their beliefs are mutually consistent and each player takes account of the noise with which the other players choose their actions. Models of noisy introspection relax the mutual consistency of beliefs by relying on iterated conjectures in a noisy version of the standard notion of rationalizability. Finally, Section 13.7.6 gives a brief note on other models that include *team reasoning* (Bacharach, 1999, 2006) and *strong Stackelberg reasoning* (Colman et al., 2014).

Section 13.8 considers auction settings in which bidders bid for a single unit of an object. The evidence indicates that the standard predictions of auction theory are often violated by experiments. For instance, the actual bids of bidders are often different from their predicted bids in first and second price auctions, and the revenue equivalence theorem often does not hold. Particular interest has focused on the explanation of a *winner's curse* in common value auctions. Consider an object that has a common value for each bidder but each bidder receives a private signal of the value. The bidder with the most favorable signal wins the object but finds, ex-post, that the bid was too high relative to the common value; this is known as the winner's curse. We look at explanations of the winner's curse using two kinds of theoretical models—level- k models and the χ -cursed equilibrium. We also consider the empirical evidence for these alternative explanations.

13.2 Quantal response equilibrium (QRE)

In a *quantal response equilibrium* (QRE), players do not play best replies, but play noisy best replies, given their beliefs about the strategies of the opponents. All players have accurate beliefs about the noisy play of their opponents. QRE has the desirable feature that more rewarding strategies are played with relatively greater probabilities; in particular the best reply is played with the greatest probability. There are several possible reasons why players might play in this manner. Their payoffs might be subject to privately observed random shocks. Hence, other players may observe the play of a probabilistic best response. Yet another reason has its roots in the refinement literature in which players play their strategies with some noise (Van Damme, 1987).

One implication of the probabilistic choice of strategies in a QRE is that kinks, if any, in the best reply functions of players are smoothed. A second implication is that since all strategies are played with strictly positive probability, the vexed problem in classical game theory of assigning beliefs to “out of equilibrium paths of play” is avoided. For instance, in signaling games, issues arising from the failure of Bayes’ rule to assign probabilities to nodes that are not on the equilibrium path of play, do not arise.

13.2.1 QRE in normal form games

We first consider QRE in normal form games, as in McKelvey and Palfrey (1995), followed by the application of QRE to extensive form games.

Suppose that there are n players. The pure strategy set of player i is given by $S_i = \{s_{i1}, s_{i2}, \dots, s_{in_i}\}$, where n_i is the cardinality of the set. To minimize notation, we denote a particular member of the set S_i by s_i . Thus, any pure strategy profile for the n players is denoted by $s = \{s_1, s_2, \dots, s_n\} \in S = \times_i S_i$. The pure strategy set of all players other than player i is denoted by S_{-i} , with the typical element denoted by s_{-i} .

Let Σ_i be the set of all probability distributions over the set S_i , with typical element σ_i . We will often denote the probability with which player i plays pure strategy j by σ_{ij} . A mixed strategy profile of the n players is denoted by $\sigma = \{\sigma_1, \sigma_2, \dots, \sigma_n\}$, where σ is a member of the set $\Sigma = \times_i \Sigma_i$. We will sometimes denote the mixed strategy profile of the game by $\sigma = (\sigma_i, \sigma_{-i})$, where $\sigma_i \in \Sigma_i$ and $\sigma_{-i} \in \times_{j \neq i} \Sigma_j$.

The von Neumann–Morgenstern utility of player i from the pure strategy profile $s = (s_i, s_{-i})$ is given by $u_i(s) = u_i(s_i, s_{-i}) : S \rightarrow \mathbb{R}$. The normal form of the game is denoted by $G = \{n, S_1, \dots, S_n, u_1, \dots, u_n\}$. Consider the mixed strategy profile σ , where $\sigma(s)$ gives the probability with which the pure strategy profile s is played. Then the expected payoff of player i is given by

$$u_i(\sigma) = \sum_{s \in S} \sigma(s) u_i(s). \quad (13.1)$$

Consider player i and begin with some mixed strategy profile of the game, $\sigma = (\sigma_i, \sigma_{-i})$. Denote the mean utility of player i when he plays the pure strategy s_{ij} and others play the mixed strategy vector σ_{-i} by $\bar{u}_{ij}(\sigma) = u_i(s_{ij}, \sigma_{-i})$; this is found by applying (13.1). Let $\bar{u}_i(\sigma) = \{\bar{u}_{i1}, \bar{u}_{i2}, \dots, \bar{u}_{in_i}\}$, so that $\bar{u}(\sigma) = \{\bar{u}_1, \bar{u}_2, \dots, \bar{u}_n\}$. QRE introduces additive payoff shocks (as in *stochastic utility models*), so that the *true utility* of player i from $\sigma = (s_{ij}, \sigma_{-i})$ is given by

$$v_{ij}(\sigma) = \bar{u}_{ij}(\sigma) + \epsilon_{ij}, \quad j = 1, 2, \dots, n_i. \quad (13.2)$$

$E\epsilon_{ij} = 0$, where the expectation is taken over all pure strategies of player i ; this holds for all i . The vector of shocks $\epsilon_i = (\epsilon_{i1}, \epsilon_{i2}, \dots, \epsilon_{in_i}) \in \mathbb{R}^{n_i}$ has a joint probability density $f(\epsilon_i)$ such that the marginal distribution $f(\epsilon_{ij})$ exists for all j . Such an f is said to be *admissible*. These shocks may also arise from mistakes in implementing choices. The vector of payoffs of player i arising from his various pure strategies, when others play σ_{-i} is given by

$$v_i(\sigma) = (v_{i1}(\sigma), v_{i2}(\sigma), \dots, v_{in_i}(\sigma)) \in \mathbb{R}^{n_i}.$$

The behavioral assumption made in QRE is that player i plays action s_{ij} only if it gives a better payoff relative to the other available actions, i.e., if

$$v_{ij}(s_{ij}, \sigma_{-i}) \geq v_{ik}(s_{ik}, \sigma_{-i}) \text{ for all } s_{ik} \in S_i. \quad (13.3)$$

Given σ , denote the set of vectors, $\varepsilon_i \in \mathbb{R}^{n_i}$, for which (13.3) holds, by Φ_{ij} .

$$\Phi_{ij} = \{\varepsilon_i \in \mathbb{R}^{n_i} : v_{ij}(s_{ij}, \sigma_{-i}) \geq v_{ik}(s_{ik}, \sigma_{-i}) \text{ for all } s_{ik} \in S_i\}. \quad (13.4)$$

Substituting (13.2) in (13.4) we get,

$$\Phi_{ij}(\bar{u}_i(\sigma)) = \{\varepsilon_i \in \mathbb{R}^{n_i} : \bar{u}_{ij}(\sigma) + \varepsilon_{ij} \geq \bar{u}_{ik}(\sigma) + \varepsilon_{ik} \text{ for all } s_{ik} \in S_i\}. \quad (13.5)$$

The probability that $\varepsilon_i \in \Phi_{ij}(\bar{u}_i(\sigma))$ is given by $\pi_{ij}(\bar{u}_i(\sigma))$ such that

$$\pi_{ij}(\bar{u}_i(\sigma)) = \int_{\Phi_{ij}(\bar{u}_i(\sigma))} f(\varepsilon_i) d\varepsilon_i. \quad (13.6)$$

Thus, for a given σ , the pure strategies of player i , $(s_{i1}, s_{i2}, \dots, s_{in_i})$, are played with respective probabilities $\pi_i(\sigma) = (\pi_{i1}(\sigma), \pi_{i2}(\sigma), \dots, \pi_{in_i}(\sigma))$. In turn, these probabilities are induced by the probability distribution of the error term ε_i . Analogous expressions can be found for the play of pure strategies of the other players. Given σ , denote the vector of such probabilities by $\pi(\sigma) = (\pi_1(\sigma), \pi_2(\sigma), \dots, \pi_n(\sigma))$; this vector gives the probability with which each player plays each of the pure strategies.

Definition 13.7 (*Quantal response equilibrium*): A QRE, σ^* , is a fixed point of the mapping $\pi(\sigma^*) = \sigma^*$. Alternatively, for all players, $i = 1, 2, \dots, n$ and for all strategies $j = 1, 2, \dots, n_i$, we must have $\sigma_{ij} = \pi_{ij}(\bar{u}_i(\sigma))$.

In words, this is what happens. Each player decides to play all his pure strategies with *choice probabilities* conditional on his *beliefs* about the probabilistic play of others. A QRE arises when all the choice probabilities and the beliefs coincide for all players. Hence, the idea is very similar to a rational expectations equilibrium. To reiterate, each individual plays his noisy best response in a QRE, taking full account of the errors made by the opponents that are reflected in their probabilistic play of pure strategies.

The function $\pi_i(\bar{u}_i(\sigma)) = (\pi_{i1}, \pi_{i2}, \dots, \pi_{in_i})$ is known as a *quantal response function*. The function $\pi = (\pi_1, \pi_2, \dots, \pi_n)$ is defined over a compact interval and each π_i is continuous. Thus, it follows from Brouwer's fixed point theorem that the fixed point in Definition 13.7 exists. From (13.5), the set $\Phi_{ij}(\bar{u}_i(\sigma))$ expands for larger values of $\bar{u}_{ij}$, hence, from (13.6), π_{ij} is a non-decreasing function of $\bar{u}_{ij}$. Thus, if the mean payoff from a pure strategy increases, the probability with which it is played cannot decrease.

If every ε_{ij} is an independent draw from an extreme value distribution,¹⁰ then the choice probabilities take the *logit form*,¹¹ i.e.,

$$\pi_{ij}(\bar{u}_i(\sigma)) = \frac{\exp(\lambda \bar{u}_{ij}(\sigma))}{\sum_{k=1}^{n_i} \exp(\lambda \bar{u}_{ik}(\sigma))}. \quad (13.7)$$

¹⁰ The extreme value distribution has a cumulative distribution function given by $F(\varepsilon) = \exp[-\exp(-\lambda\varepsilon)]$. The mean of the distribution is given by $E\varepsilon = \gamma/\lambda$ where $\gamma \approx 0.577$ is Euler's constant.

¹¹ For a derivation, see Appendix B in Part 5.

Figure 13.1 Two-player matching pennies game.

The logit density has a single parameter λ . From observed values of σ , the parameter λ can be estimated by maximum likelihood methods. λ is inversely proportional to the variance of the errors. As $\lambda \rightarrow \infty$ the variance of the shocks goes to zero and behavior approaches a Nash equilibrium. On the other hand, when $\lambda = 0$, people choose randomly among their pure strategies. Thus, the fitted values of λ can inform us about the degree of noise in the game.

QRE has often been successful in explaining behavior in experimental games where the Nash equilibrium predictions have been unsuccessful. We shall review some of this evidence below from different kinds of games such as auction games, bargaining games, and coordination games. A strong case for the QRE as an alternative to Nash equilibrium is made by Camerer et al. (2004b). “Quantal response equilibrium (QRE), a statistical generalization of Nash, almost always explains the deviations from Nash and should replace Nash as the static benchmark to which other models are routinely compared.”

Consider the two-player matching pennies game shown in Figure 13.1. There is no pure strategy Nash equilibrium in this game. In most versions of the matching pennies game, $x = 1$, but here we allow for the effects of different levels of stakes. Let us first compute the mixed strategy Nash equilibrium (MSE) of the game. Let the column player play R with probability π_R and the row player play T with probability π_T . The row player prefers to play T over B if and only if

$$x\pi_R - (1 - \pi_R) \geq -\pi_R + (1 - \pi_R) \Leftrightarrow \pi_R \geq \frac{2}{3+x}, \quad (13.8)$$

which, for $x = 1$, requires that $\pi_R \geq 1/2$. The column player prefers to play L over R if and only if

$$\pi_T - (1 - \pi_T) \geq -\pi_T + (1 - \pi_T) \Leftrightarrow \pi_T \geq \frac{1}{2}. \quad (13.9)$$

Each of the players is indifferent among the respective pure strategies, if

$$\pi_T^* = \frac{1}{2}; \pi_R^* = \frac{2}{3+x}, \quad (13.10)$$

which gives the MSE.

Let us now compute the logit QRE using (13.7). For expositional purposes, consider the row and column players, respectively, as players 1 and 2. Given that the column player plays R with probability π_R , the respective expected payoffs to the row player from playing the two pure strategies, T, B , are

$$\bar{u}_{1T}(\pi_R) = x\pi_R - (1 - \pi_R) \text{ and } \bar{u}_{1B}(\pi_R) = -\pi_R + (1 - \pi_R). \quad (13.11)$$

Similarly, conditional on the row player playing T with probability π_T , the respective expected payoff of the column player from the strategies L, R , are

Figure 13.2 QRE and Nash equilibrium for the cases $x = 1$ and $x = 3$.

$$\bar{u}_{2L}(\pi_T) = \pi_T - (1 - \pi_T) \text{ and } \bar{u}_{2R}(\pi_T) = -\pi_T + (1 - \pi_T). \quad (13.12)$$

Given (13.11), (13.12), and using (13.7), the respective probabilities with which the row and the column players play strategies, T, R , in a logit QRE are given by:

$$\pi_T = \frac{\exp(\lambda \bar{u}_{1T}(\pi_R))}{\exp(\lambda \bar{u}_{1T}(\pi_R)) + \exp(\lambda \bar{u}_{1B}(\pi_R))}, \quad (13.13)$$

$$\pi_R = \frac{\exp(\lambda \bar{u}_{2R}(\pi_T))}{\exp(\lambda \bar{u}_{2R}(\pi_T)) + \exp(\lambda \bar{u}_{2L}(\pi_T))}. \quad (13.14)$$

The solution to (13.13), (13.14) gives the QRE: π_T^{qre}, π_R^{qre} .

In Figure 13.2, the best reply functions are shown as the continuous step functions; their intersection gives the MSE in (13.10). Two cases are shown, $x = 1$ and $x = 3$. The MSE for the case $x = 1$ is shown at point A, where $\pi_T^* = \pi_R^* = \frac{1}{2}$. When x increases from $x = 1$ to $x = 3$, the best reply function for the column player does not shift, but that for the row player shifts to the left (shown as the dotted step function). In the new Nash equilibrium, shown at point B, $\pi_T^* = \frac{1}{2}, \pi_R^* = \frac{1}{3}$. An increase in x does not alter the probability, π_T^* , with which the row player plays T . This is a testable restriction of an MSE.

The logit probabilities under QRE, derived from (13.13), (13.14), are shown as the smooth curves. For any non-degenerate choice of the opponent's mixed strategy, each player plays both strategies with non-zero probabilities. The row (column) player's quantal best reply starts in the southwest (northwest) corner of the unit square and ends in the northeast (southeast) corner. The initial QRE, corresponding to $x = 1$ is shown at point A, as $\pi_T^{qre} = \pi_R^{qre} = 0.5$ (check that this holds for any λ).

When x increases to $x = 3$, the quantal reply function for the row player (shown as the dotted curve) shifts left, while that of the column player is unaffected; since the payoff from T increases,

it is played with a higher probability. In the new QRE, shown at point C, $\pi_R^{qre} < 0.5$, while $\pi_T^{qre} > 0.5$; this is a “better response” by both players. Hence, the prediction of the QRE is different from the Nash prediction. As x increases the QRE changes, but there is no change in a Nash equilibrium. This, *own-payoff effect* on observed probabilities of the play of strategies is observed (Ochs, 1995; McKelvey et al., 2000; Goeree et al., 2003); which is consistent with QRE but not Nash.

It is likely that the degree of errors people make, as captured in the parameter λ , varies across people. McKelvey et al. (2000) confirm this to be the case. They find that a heterogeneous QRE model, HQRE (see Section 13.7.2), accounts much better for the data and outperforms a Nash equilibrium. They consider the three games, A, B, and C shown in Figure 13.3.

The generic game is Game A. Game B is derived from A by multiplying the payoffs of the column player by 4. Game C is derived from A by multiplying the payoffs of all players by 4. Since the Nash equilibrium is invariant to positive affine transformations of the payoffs, the Nash equilibrium in all three games is identical.¹² Suppose that the row player plays U with probability p and the column player plays L with probability q . In the unique Nash equilibrium of the game, $(p^*, q^*) = (0.5, 0.10)$.

In contrast to the Nash equilibrium, the QRE is not invariant to affine transformations of payoffs. Figure 13.4 shows values of (p, q) in a logit QRE for games A, B, C when we vary λ (subscripts on p, q denote the game played). When $\lambda = 0$, the mixing probabilities in a QRE, p, q , correspond to random choice. One may conjecture that as players gain experience, the variance of errors with which they play their strategies decreases (or, λ increases). As λ increases, p first increases then decreases before converging towards the Nash equilibrium value of 0.5. Thus, unlike a Nash equilibrium, the prediction of QRE is that the row player will first overplay U, before converging to the Nash prediction. The behavior of q in Figure 13.4, in contrast to the behavior of p , exhibits no hump-shaped profiles. Rather, starting from random choice at $\lambda = 0$, q gradually moves downwards towards the Nash prediction of 0.10.

The three games differ with respect to the speed with which the behavior converges to the Nash equilibrium. Games with the highest payoffs are more conducive to quicker convergence. Thus, the speed of convergence is highest in Game C, followed, respectively, by Games B and A (McKelvey et al., 2000, p. 526).¹³ In particular, for any λ , it is true that $0.5 = p^* < p_B < p_A$ and $0.5 = p^* < p_B < p_C$.

¹² If (σ_i, σ_{-i}) is a Nash equilibrium then for all i we have $u(\sigma_i, \sigma_{-i}) \geq u(\sigma'_i, \sigma_{-i})$ for all possible mixed strategies σ'_i of player i . Define $v = a + bu$, where $b > 0$. Then we also have $v(\sigma_i, \sigma_{-i}) \geq v(\sigma'_i, \sigma_{-i})$. For instance, Game B is derived from Game A by letting $a = 0$ and $b = 4$ for the column player.

¹³ The difference between the speed of convergence between Games B and C is not entirely transparent from looking at Figure 13.4.

Figure 13.4 Predictions of the quantal response equilibrium for games A, B, and C for various values of λ .

Source: Reprinted from *Journal of Economic Behavior and Organization* 42: 523–48. McKelvey, R., Palfrey, T., and Weber, R., "The effects of payoff magnitude and heterogeneity on behavior in 2×2 games with mixed strategy equilibria." Copyright © 2000, with permission from Elsevier.

Since a Nash equilibrium corresponds to no errors ($\lambda \rightarrow \infty$), one may view the movement from left to right as a process of learning. Indeed, one purpose of these experiments is to check if the errors with which people play their strategies diminish with experience.

In the first instance, three candidate models are pitted against each other in explaining the data. (1) Random play (i.e., $p = q = 0.5$), (2) QRE, and (3) Noisy Nash model (NNM). In the NNM, players play a linear combination of random play and Nash play. Thus, the row and the column players play the respective strategies, $\hat{p} = (1 - \gamma)0.5 + \gamma p^*$ and $\hat{q} = (1 - \gamma)0.5 + \gamma q^*$, $\gamma \in [0, 1]$. In all cases, $\hat{p} = 0.5$ because $p^* = 0.5$, but as γ increases, $\hat{q}$ falls from a maximum value of 0.5 to $q^* = 0.10$. For a fixed value of γ , the NNM makes identical predictions for all three games, A, B, and C.

For the aggregate data in the experiments, we get $(p, q) = (0.643, 0.241)$ for Game A; $(p, q) = (0.630, 0.244)$ for Game B; and $(p, q) = (0.594, 0.257)$ for Game C. Thus, the Nash equilibrium is not supported by the data from any of the games. Random play is rejected for all games. In all games, the row player overplays U and the column player overplays L (relative to a Nash), which is consistent with the predictions of a QRE. Affine transformations in payoffs not only create departures from the Nash predictions but create inter-game differences in strategies. For instance, the play of D by the row player is statistically different between games C and A, and between games C and B. There are no trends over time in the estimated values of λ , ruling out any role for learning.¹⁴ Based on a likelihood ratio test, NNM beats random play and Nash, and for games A and C it also beats QRE, although for game B, QRE does best.

The choices of the row and the column players at the individual level exhibit significant heterogeneity, suggesting that the value of λ across the players is variable. Thus, the analysis carried out on the basis of a fixed λ across the players is based on a mis-specified model. In the second

¹⁴ Eight sessions were run. In each session, subjects played two games against anonymous opponents. Each game was played over 50 rounds.

part of the paper, the authors allow for heterogeneity across players in λ (heterogenous quantal response equilibrium, HQRE).¹⁵ The HQRE fits the data for all games much better than QRE and performs better than NNM for all games that are considered.

13.2.2 QRE in extensive form games

McKelvey and Palfrey (1998) extended the concept of QRE to extensive form games. We shall only give a heuristic treatment of this topic, and one example. Consider an extensive form game in which the set of information sets is given by H . Pick any arbitrary information set, $h \in H$ and let A_h be the set of actions available to a player at that information set. As in normal form games, we assume that each player plays with some noise, so each possible action at each information set is played probabilistically. For any action $a_{hj} \in A_h$, we wish to calculate the expected payoff of the player, $\bar{u}_{hj}$ (this calculation will be explicit in the example, below). Since players play their actions with noise, the “true” utility from action a_{hj} is given by

$$v_{hj} = \bar{u}_{hj} + \varepsilon_{hj},$$

where ε_{hj} is the noise associated with action a_{hj} . Our behavioral assumption is that the player who moves at the information set A_h , chooses action a_{hj} , if and only if

$$v_{hj} \geq v_{hk} \text{ for all } a_{hk} \in A_h. \quad (13.15)$$

In the logit form, the probability of playing strategy $a_{hj} \in A_h$ is given by

$$\pi_{hj} = \frac{\exp(\lambda \bar{u}_{hj})}{\sum_{a_{hk} \in A_h} \exp(\lambda \bar{u}_{hk})}. \quad (13.16)$$

The RHS of (13.16) depends on beliefs because it involves the calculation of expected payoffs from various actions. The LHS of (13.16), on the other hand, is the actual probability with which the player chooses action a_{hj} . In a QRE, beliefs and choice probabilities coincide.

Consider, as an example, the bilateral crises game in Signorino (1999). There are two countries, 1 and 2. Each country has two actions at each of its decision nodes, fight (F) or not fight (N). The sequence of moves is shown in the extensive form representation of the game in Figure 13.5. The final outcomes at each of the terminal nodes are represented by acronyms (payoffs are suppressed). For instance, if 1 and 2 both choose N, then the outcome is the status quo (SQ). If 1 does not fight at any node but 2 fights, then the outcome is that player 1 capitulates (C1). If player 2 initiates a fight and 1 sequentially decides to fight, the outcome is a player 2 initiated war (W2). C2 and W1 are defined in an analogous manner. Define the utility of player $i = 1, 2$ from outcome $j = \text{SQ, C1, C2, W1, W2}$, by u_{ij} .

Figure 13.5 also shows the probabilities with which each player plays his pure strategies. For instance, the probability that player 1 fights at the initial node is p_1 (thus, the probability that he does not fight is $1 - p_1$). If player 1 does not fight then player 2 fights with probability q_2 followed by player 1 who fights with probability p_4 . If player 1 fights at the initial node, then player 2 fights with probability q_3 .

¹⁵ This was achieved by assuming that the distribution of λ is lognormal across the players. Maximum likelihood was then used to estimate the mean and the variance of the normal distribution.

Figure 13.5 The bilateral crises game.

Source: Signorino, C. S. (1999) "Strategic interaction and the statistical analysis of international conflict." *American Political Science Review*, 93(2): 279–97, reproduced with permission from Cambridge University Press.

Using (13.16), the logit choice probabilities are recursively given by the following set of equations.

$$q_3 = \frac{\exp(\lambda u_{2W_1})}{\exp(\lambda u_{2W_1}) + \exp(\lambda u_{2C_2})} \quad (13.17)$$

$$p_4 = \frac{\exp(\lambda u_{1W_2})}{\exp(\lambda u_{1W_2}) + \exp(\lambda u_{1C_1})} \quad (13.18)$$

$$q_2 = \frac{\exp(\lambda [p_4 u_{2W_2} + (1 - p_4) u_{2C_1}])}{\exp(\lambda [p_4 u_{2W_2} + (1 - p_4) u_{2C_1}]) + \exp(\lambda u_{2SQ})} \quad (13.19)$$

$$p_1 = \frac{\exp(\lambda [q_3 u_{1W_1} + (1 - q_3) u_{1C_2}])}{\exp(\lambda [q_3 u_{1W_1} + (1 - q_3) u_{1C_2}]) + \exp(\lambda [q_2 [p_4 u_{1W_2} + (1 - p_4) u_{1C_1}] + (1 - q_2) u_{1SQ}])} \quad (13.20)$$

A QRE of the bilateral crises game is the set of values $(p_1^{qre}(\lambda), q_2^{qre}(\lambda), p_4^{qre}(\lambda), q_3^{qre}(\lambda))$ in which the choices and the beliefs of the players are mutually consistent. Once the equilibrium choice probabilities are computed, then we can directly compute the probability of each outcome by observing the path of play. For instance, the probability of the status quo equals $(1 - p_1^{qre}(\lambda)) (1 - q_2^{qre}(\lambda))$ and the probability of war initiated by player 1 equals $p_1^{qre}(\lambda) q_3^{qre}(\lambda)$. Thus, the total probability of war is

$$p_W(\lambda) = p_1^{qre}(\lambda) q_3^{qre}(\lambda) + (1 - p_1^{qre}(\lambda)) q_2^{qre}(\lambda) p_4^{qre}(\lambda). \quad (13.21)$$

The size of λ reflects errors made by the players. Players choose randomly if $\lambda = 0$, and as $\lambda \rightarrow \infty$ they are fully rational in the sense of making no errors and complying with the Nash predictions. Given the observed probabilities of play of the pure strategies, λ can be estimated using maximum likelihood techniques. For instance, suppose that we have N data points on whether wars occurred. Let d_i be a dummy variable for the i th observation that takes a value 1 if a war occurred, and 0 otherwise. The likelihood function is

$$L(\lambda) = \prod_{i=1}^N p_W^{d_i}(\lambda) [1 - p_W(\lambda)]^{1-d_i}.$$

The likelihood function can now be maximized with respect to λ to get the estimated value of λ . Since an increase in λ is associated with a decrease in errors in decision making, experiments repeated over time can be used to check if λ increases, which would indicate learning.

One application of these ideas is to the theory of *information cascades*. In such models, nature first chooses some state of the world that is not revealed to a sequence of T players. The players then choose some action in a sequential manner. Each player takes some action, based on a private signal about the state of the world that might have been initially chosen by nature. The signals of the players are uncorrelated with each other. At the time of choosing an action, each player observes the history of the game, i.e., the actions of the sequentially preceding players, but not their signals. An *information cascade* is said to take place when after some set of players have chosen their actions, each subsequent player rationally ignores their own private signal, so learning completely ceases (Banerjee, 1992; Bikhchandani et al., 1992).

When players cease to learn in this manner, there are potentially serious welfare consequences, e.g., bank runs, mass hysteria, and stock market bubbles. Information cascades are distinguished from *herd behavior* in that while the actions of the players might be observationally equivalent, under herd behavior, players do not necessarily ignore their private information.¹⁶ Using experimental data, Goeree et al. (2007) show that when cascades are predicted in 100% of the sequences, i.e., behavior is conformable to a Nash equilibrium, they only observe cascades in less than 7% of the sequences (out of 116 possible sequences). Kübler and Weizsäcker (2004) also report negative findings, similar to these. A QRE model is able to explain the experimental findings by placing restrictions on the inferences of subsequent players if a deviation from a cascade occurs. In a QRE, learning continues to take place even after an information cascade has taken place.

13.2.3 Does the QRE impose falsifiable restrictions?

Haile et al. (2008) show that unless one makes specific assumptions on the distribution of the errors, QRE imposes no falsifiable restrictions. If the errors ε_{ij} (associated with the pure strategy j of player i) are independently and identically distributed then there are no problems for QRE. However, in the absence of such information, the results from QRE need to be interpreted with caution. We demonstrate this result by using examples from Goeree et al. (2005) who responded to the working paper version of Haile et al. (2008). While the focus of Haile et al. (2008) is on strategic interaction, the pedagogical merit of the examples in Goeree et al. (2005) is that they focus on a single decision maker (player 1) playing a game against nature.

Suppose that a single decision maker has two strategies s_{11} and s_{12} ; the respective mean payoffs from these strategies are $\bar{u}_{11} = 1$ and $\bar{u}_{12} = 2$. Under the setup of the QRE, the actual payoffs are given by $v_{1j} = \bar{u}_{1j} + \varepsilon_{1j}$, $j = 1, 2$. Thus, the probability that strategy s_{11} is chosen is $\pi_{11} = \Pr[v_{11} \geq v_{12}] \Leftrightarrow \Pr[1 + \varepsilon_{11} \geq 2 + \varepsilon_{12}]$. Thus,

$$\pi_{11} = \Pr[\varepsilon_{11} - \varepsilon_{12} \geq 1] \text{ and } \pi_{12} = 1 - \pi_{11}. \quad (13.22)$$

The joint density of $\varepsilon_{11}, \varepsilon_{12}$ is given by $f(\varepsilon_{11}, \varepsilon_{12})$. Let us now drop the assumption that $\varepsilon_{11}, \varepsilon_{12}$ are independently and identically distributed. There are two cases to consider.

¹⁶ So essentially, information cascades imply herding but the converse is not true. See Smith and Sørensen (2000) for this distinction. Boğaçhan and Kariv (2004) implement this distinction in their experimental design.

1. ε_{11} and ε_{12} are independently but not identically distributed.
2. ε_{11} and ε_{12} are identically but not independently distributed.

It can be shown that in either of these two cases, for any $p \in (0, 1)$, we can find some $f(\varepsilon_{11}, \varepsilon_{12})$ such that $\pi_{11} = p$ and $\pi_{12} = 1 - p$. Since we started off with an arbitrary $p \in (0, 1)$, in these cases, QRE is not falsifiable and any observed frequency of play of the two strategies can be rationalized.

Consider the first case where ε_{11} and ε_{12} are independently but not identically distributed. Suppose that an experimenter observes that the frequency of play of strategy s_{11} is p . He then imposes the following distributional assumptions. (i) ε_{11} takes a value 2 with probability p and a value $\frac{-2p}{1-p}$ with probability $1-p$. (ii) ε_{12} takes a value 0 with probability 1. Under these assumptions it follows that

$$\pi_{11} = \Pr[\varepsilon_{11} - \varepsilon_{12} \geq 1] = p,$$

which gives a perfect fit of QRE with the evidence.

Now consider the second case of identical but not independent marginal distributions. Suppose that ε_{12} is distributed uniformly over $\left[0, \frac{2}{1-p}\right]$. The marginal distribution of ε_{11} is not independent. It takes the following form.

$$\varepsilon_{11} = \begin{cases} \varepsilon_{12} + 2 & \text{when } \varepsilon_{12} \in \left[0, \frac{2}{1-p} - 2\right], \\ \varepsilon_{12} + 2 - \frac{2}{1-p} & \text{otherwise.} \end{cases}$$

It follows that the condition $\varepsilon_{11} - \varepsilon_{12} \geq 1$ holds only over the interval $\left[0, \frac{2}{1-p} - 2\right]$, where the marginal distributions of ε_{11} and ε_{12} are both uniform. Thus,

$$\Pr[\varepsilon_{11} - \varepsilon_{12} \geq 1] = \Pr\left[\varepsilon_{12} \leq \frac{2}{1-p} - 2\right] = p.$$

Thus, if an experimenter observes the frequency of play of strategy s_{11} to be p and if he had the freedom to choose the distributions of $\varepsilon_{11}, \varepsilon_{12}$ in the manner described above, then QRE would give a perfect fit with the data. These observations hold for an arbitrary number of players and strategies (Haile et al., 2008).

In light of this critique, researchers who wish to use the QRE have at least two options. First, they could continue to assume that the ε_{ij} are independently and identically distributed. Second, they might wish to use a variant of the QRE, the *regular QRE*, which was proposed by Goeree et al. (2005). The regular QRE makes no assumptions about the distribution of errors but, rather, gives an axiomatic foundation for the QRE, based on a set of plausible axioms, as we now describe.

From (13.6), we know that π_{ij} is a function of $\bar{u}_i = (\bar{u}_{i1}(\sigma), \dots, \bar{u}_{ij}(\sigma), \dots, \bar{u}_{in_i}(\sigma))$.

Definition 13.8 (*Regular quantal response function*; Goeree et al. 2005) *The regular quantal response function satisfies the following axioms for all $\bar{u}_i(\sigma) \in \mathbb{R}^{n_i}$.*

1. *Interiority:* $\pi_{ij}(\bar{u}_i(\sigma)) > 0$ for all i, j .
2. *Continuity:* $\pi_{ij}(\bar{u}_i(\sigma))$ is continuous and differentiable in $\bar{u}_i(\sigma)$.

3. *Responsiveness*: $\frac{\partial \pi_{ik}(\bar{u}_i(\sigma))}{\partial \bar{u}_{ik}(\sigma)} > 0$, $k = 1, 2, \dots, n_i$.
4. *Monotonicity*: If $\bar{u}_{ij}(\sigma) > \bar{u}_{ik}(\sigma)$, then $\pi_{ij} > \pi_{ik}$ for all i, j, k .¹⁷

Interiority implies that all pure strategies are played with strictly positive probability. Continuity is a purely technical restriction, which ensures that slight changes in mean payoffs do not lead to jumps in the probability with which the associated strategies are played. Responsiveness requires that strategies whose expected payoff increases are played with a greater probability. Monotonicity requires that strategies whose mean payoffs are higher are also played with a higher probability. Responsiveness and monotonicity appear to be very similar but they are distinct; one of the exercises gives an example that demonstrates their difference. A regular QRE requires that the probabilities with which players play their pure strategies satisfy Definition 13.8 and the beliefs and choices of players coincide.

Definition 13.9 (Regular QRE): Suppose that π_{ij} is regular (Definition 13.8). A regular QRE arises for all players, $i = 1, 2, \dots, n$ and all strategies $j = 1, 2, \dots, n_i$ if $\sigma_{ij} = \pi_{ij}(\bar{u}_i(\sigma))$.

A regular quantal response function preserves continuity of $\pi_{ij}(\bar{u}_i(\sigma))$, hence, Brouwer's fixed point theorem can be used to ensure the existence of a regular QRE.

13.2.4 An application of QRE to the traveller's dilemma game

Consider Basu's (1994) *traveller's dilemma game*. In this game, an airline loses two identical pieces of luggage of two distinct travellers, who are returning from a holiday from an identical destination. It is public knowledge that each piece of luggage has an identical value,¹⁸ but the exact value is private knowledge to the travellers. The airline is concerned that the passengers might make an excessive claim. Hence, it makes the following announcement to the two travellers: "We know that the bags have identical contents, and we will entertain any claim between \$80 and \$200, but you will each be reimbursed an amount that equals the minimum of the two claims submitted. If the two claims differ, we will also pay a reward of \$R to the person making the smaller claim and we will deduct a penalty of \$R from the reimbursement to the person making the larger claim."

The unique Nash equilibrium of this game is for each individual to make an identical claim of \$80. To prove this, assume to the contrary that travellers 1 and 2 make respective claims x_1, x_2 such that $x_2 > 80$. Assume risk neutrality and $0 < \varepsilon < R$. If $x_1 = x_2 + \varepsilon > x_2$, then the payoff of traveller 1 is $x_2 - R$. If traveller 1 makes a claim $x_1 = x_2 - \varepsilon < x_2$, then his payoff is $x_2 - \varepsilon + R > x_2 - R$. Thus, it is a strictly dominant strategy to make a lower claim than the other player. This argument applies symmetrically to player 2. Iteratively deleting strictly dominated strategies in this manner, in the unique Nash equilibrium, $x_1 = x_2 = 80$, independent of the penalty R . This is the unique rationalizable equilibrium outcome.

However, one's intuition may suggest that as R becomes small, the travellers will attempt to make the maximum possible claims. Capra et al. (1999) conduct lab experiments to see if the outcome is affected by the penalty, R . In their experiments, the values of the items and the penalties are denominated in cents (so, e.g., \$80 is replaced by 80 cents).¹⁹

¹⁷ Goeree et al. (2005) show that *interchangeability* is a sufficient condition for monotonicity. Interchangeability, in turn, implies that the joint distribution of errors $f_i(\varepsilon_{i1}, \varepsilon_{i2}, \dots, \varepsilon_{in_i})$ for player i is invariant to permutations of the ε_{ij} terms. This implies that the marginal distributions are identical and so are covariances and conditional moments.

¹⁸ Perhaps each traveller has been able to produce a witness who was present when the luggage was packed and based on an estimate, the value of the two pieces of lost luggage is deemed identical.

¹⁹ Groups of 9–12 economics students were recruited to play a series of traveller's dilemma games. They were given a \$6 participation fee and could earn \$24–\$44 for a session.

Figure 13.6 Claims, over time, for various values of R .

Source: Capra et al. (1999) with permission from the American Economic Association.

The experimental findings are as follows.

1. The behavior of the subjects was heavily influenced by the penalty, R , as shown in Figure 13.6. For low values of R , behavior diverged significantly from the Nash equilibrium and no evidence of convergence was found. For instance, for low reward/penalty rates ($R = 5$ and $R = 10$), the average claim was 180, close to the maximum possible claim of 200. In the two intermediate cases ($R = 25$ and $R = 20$), the average claims were respectively, 120 and 145. For high penalty rates ($R = 50$ and $R = 80$), behavior did converge towards the Nash equilibrium. Thus, unless the reward/penalty is high enough, behavior departs from a Nash equilibrium.
2. The authors also find that *learning direction theory* (making adjustments in the current period that are a best response to the play of the opponent in the previous period) explains to an extent the current actions of players. However, it cannot account for the effect of R on the pattern of play.
3. A natural candidate explanation is QRE. We have seen several examples above, in which changes in the magnitude of the payoffs is predicted, under QRE, to alter the probabilities with which players play their strategies, even when the Nash equilibrium predicts no such effect. Indeed, the *responsiveness axiom* in Definition 13.8 includes this feature as an essential element of the regular quantal response function. When R is low, then errors that players make under a QRE are less costly in terms of payoffs, hence, players make higher claims with greater probability. The authors implement a learning model in which players update their beliefs about the opponent by observing their actions each period in a manner that is consistent with *fictitious play*.²⁰ A logit model is used to compute the probabilities of making various claims, as in (13.16); the maximum likelihood estimate of the noise parameter is $\lambda = 0.092$. In Figure 13.7, we show the average claims in each treatment (dots),

²⁰ See Part 5 of the book for models of fictitious play.

Figure 13.7 Average claims, logit predictions, and the Nash prediction in the traveller's dilemma game.

the Nash prediction (the horizontal dotted line at 80) and the logit equilibrium prediction (dark continuous curve). The logit prediction clearly explains the data much better than the Nash equilibrium.

13.3 Level- k and cognitive hierarchy models

Compared to a Nash equilibrium, in a QRE one relaxes the assumption that players play best replies with probability one. In a second class of models, however, players play their best replies with probability one but the beliefs and choices of players need not be mutually consistent. This is arguably less cognitively challenging, relative to computing a fixed point in beliefs and actions. During the early rounds of play in experiments when players play a new game against other players whose choices they are uncertain of, there is no reason why their beliefs should be consistent with the actions of other players. Hence, this class of models is likely to be more successful in explaining behavior in these situations. In this section we consider two closely related models in this class—the *level- k model* and the *cognitive hierarchy model*.

13.3.1 The level- k model

In order to explain the structure of level- k models, consider a set of players in some game. Players are heterogeneous and can be grouped into types (or levels) such as $L_0, L_1, L_2, \dots, L_K$ and a typical type/level is written as type/level $L_k, k = 0, 1, \dots, K$. Here the term “types” bears no relation to the ordinary usage of this term in neoclassical economics (e.g., types in adverse selection problems). Only players of type L_0 are *non-strategic*, in the sense that they do not play a best response to the actions of any other type. Typically, but not necessarily, type L_0 players are assumed to randomize over the set of available actions. In level- k models, for all $k = 1, 2, \dots, K$, type L_k players play a best response to the belief that all other players are of type L_{k-1} .

One generalization of the level- k model is the *cognitive hierarchy model* (CH) of Camerer et al. (2004). In the CH model, for types $k = 1, 2, \dots, K$, a type Lk player assumes that there is a distribution (typically Poisson) of all the lower type players $Lk - 1, Lk - 2, \dots, L0$. Each type then plays a best response to the distribution of lower types. The CH model is considered below in Section 13.3.3. For the moment, we restrict ourselves to the level- k model.

We may refer to type $L0$ as the *anchoring type*. The motivation for this terminology lies in the hierarchical structure of the model. The computation of the best response for type Lk players, $k \geq 1$ requires finding the best response of type $Lk - 1$ players, which in turn requires finding the best response of type $Lk - 2$ players, and so on until we arrive at type $L0$ players. Thus type $L1$ players directly anchor on type $L0$ players, while all other types of players do so indirectly. There might, of course, be no non-strategic $L0$ types in the population. Type $L0$ players could be entirely fictitious and exist only as models of other players in the minds of type $L1$ players. The exact specification of type $L0$ is important in applications.

The frequencies of the various types of players can be estimated from the data. A great deal of initial work found that the proportion of type $L0$ players is very small but some of the emerging empirical evidence estimates a higher fraction of such players. The broad message of the results is that the greatest proportion of players is of type $L1$, a somewhat smaller fraction is $L2$ players, and a relatively small fraction is of type $L3$. Types higher than $L3$ are rare. Since iterated beliefs are truncated at fairly low integer value in most experimental results ($k \leq 3$), these non-equilibrium models also seem to address the criticism of circularity of traditional game theoretic equilibrium concepts. For instance, Selten (1998) wrote: “Basic concepts in game theory are often circular in the sense that they are based on definitions by implicit properties...Boundedly rational strategic reasoning seems to avoid circular concepts. It directly results in a procedure by which a problem solution is found.”²¹

A well-known finding from many experimental games is that the initial response of players may be different from their later responses. Furthermore, in the presence of multiple equilibria, the choice of strategies in the initial rounds often determine which equilibrium outcome will be reached (see Section 12.4.9). One motivation for level- k models is that they can potentially inform us about the initial pattern of play, and the choice among multiple equilibria.

Critics argue that level- k models may allow for too much flexibility in the specification of the actions of types $L0$. One possible response to this criticism is to consider the fit of out-of-sample data under the relevant assumptions made on the behavior of type $L0$ players. Another response is to invoke various notions of *portability*. In the context of the level- k model, this involves the application of the level- k model to similar problems and checking to see if the predictive success in one problem carries over to a comparable problem. This is the strategy employed by Crawford and Iriberri (2007a) in the context of the hide-and-seek game that we outline in the problem set, below. They determine that O'Neill's (1987) card matching game and a related game in Rapoport and Boebel (1992) are similar to the hide-and-seek game. They find that when they apply the level- k model to these related games, the actions of type $L0$ are non-strategic. The similarity of the behavior of type $L0$ players across related games provides some, albeit imperfect, degree of confidence in the robustness of the results.²²

²¹ However, Selten may not consider level- k models to be models of bounded rationality since these models involve explicit optimization in order to compute best replies; see, Harstad and Selten (2013).

²² See also the discussion on portability across games in the context of the paper by Hargreaves Heap et al. (2014) in the introductory chapter.

Another possible criticism of the level- k models is that, they do not allow for the possibility of learning. In level- k models, since the beliefs of players are not in equilibrium, why should players continue to hold on to these beliefs in repeated play? There are several responses. First, the objective of level- k models is to explain the behavior of players in the early rounds of the experiments (Crawford et al., 2013).²³ Second, the real-world is not stationary, unlike the typical experimental environment in repeated play, hence, real world learning may be quite difficult in some cases. Third, not all learning experiments result in rational expectations in beliefs (see Part 5).

13.3.2 The p -beauty contest

The basic idea of the p -beauty contest game is outlined in John Maynard Keynes (1936, pp. 155–6):

professional traders may be likened to those newspaper competitions in which the competitors have to pick out the six prettiest faces from a hundred photographs, the prize being awarded to the competitor whose choice most nearly corresponds to the average preferences of the competitors as a whole . . . It is not a case of choosing those which, to the best of one's judgement, are really the prettiest, nor even those which average opinion genuinely thinks the prettiest. We have reached the third degree where we devote our intelligences to anticipating what average opinion expects the average opinion to be. And there are some, I believe, who practise the fourth, fifth and higher degrees.

The quote is highly suggestive of a level- k model. Keynes also seems to think that people predominantly classify as types $L0$ to $L3$ with higher types being rarer; this is in agreement with the experimental evidence from a range of games.

The outcome in p -beauty contest games depends on whether the equilibrium can be achieved in a finite or infinite number of steps. We follow Ho et al. (1998) in describing both cases. There are n participants. Participant $i = 1, 2, \dots, n$ is asked to choose a number, x_i , from some closed interval $[a, b]$. Denote the simple average of the guesses by $\bar{x} = \sum_{i=1}^n x_i$, and define the number $y = p\bar{x}$, where $p \geq 0$. The winners are those individuals whose guess is closest to y . Formally, the winners belong to the set

$$W = \{i : |y - x_i| \leq |y - x_j|; j = 1, 2, \dots, n\}. \quad (13.23)$$

The total prize money is equal to $n\pi$ where $\pi > 0$.²⁴ If the set W consists of $m \geq 1$ winners, then each winner receives a prize equal to $n\pi/m$. Notice the similarity of this setup with Keynes's example. To win, one must guess "the average opinion about the average guess."

The equilibrium outcome in the p -beauty contest depends on whether $p < 1$ or $p > 1$, as shown in the next proposition.

²³ In the real world, players often make decisions on a fairly irregular basis, e.g., household decisions on pension plans, marriage, number of children, purchase of consumer durables such as cars, and partly illiquid assets such as houses. Thus, learning opportunities are not unlimited. Similarly, many decisions of firms are also of a very irregular nature that afford little learning opportunities, such as merger decisions, bidding in an auction for bandwidth rights, and fundamental corporate restructuring. Arguably, irregular and infrequent decisions might account for a large part of economic activity.

²⁴ In most experiments, the reward does not depend on the number of participants. However, Ho et al. (1998) were interested in testing for the effect of group size.

Proposition 13.26 Suppose that there are n participants in the p -beauty contest and each chooses a number $x_i \in [a, b]$. The set of winners satisfies (13.23). (i) When $p < 1$, the Nash equilibrium outcome is $x_i = a$ for all i . (ii) When $p > 1$, the Nash equilibrium outcome is $x_i = b$ for all i .

Proof: Since all individuals are identical we can restrict attention to symmetric equilibria.

(i) Let $p < 1$. Suppose that for all i , $x_i = x$, so $\bar{x} = x$. There are two possibilities. First, $x = a$, so $y = pa$. In this case, since $p < 1$ no player can improve his payoff by choosing a smaller number, so we are done. However, if $x > a$, then unilateral deviations by players can improve payoffs. Suppose that player i chooses a guess $x' = x - \epsilon \geq a$, where $\epsilon > 0$ is a small number, and all other players choose a guess x . Then, $y = p \left[\frac{(n-1)x}{n} + \frac{x'}{n} \right]$. Reducing his guess by ϵ , player i induces a reduction in y of $\frac{\epsilon p}{n} < \epsilon$. Hence, the guess of player i is closest to the new value of y , making him the unique winner. Thus, the unique symmetric equilibrium is one where $x_i = a$, $i = 1, 2, \dots, n$. (ii) The proof is analogous to (i) so it is omitted. ■

In experiments, it is often the case that subjects do not take account of the effect of their actions on the average action. Proposition 13.26 continues to hold in this case as well.

Next, we consider the predictions of the level- k model. Suppose that there are n players in the p -beauty contest, where n is very large, and each player ignores the effect of his guess on the average guess. Each player chooses a number $x_i \in [a, b]$. The set of winners satisfies (13.23). All players are level- k thinkers, so they belong to types $L_0, L_1, L_2, \dots$

Suppose that $[a, b] = [0, 100]$, and $p = 2/3$. Suppose that type L_0 players choose uniformly randomly over $[0, 100]$. Type L_1 players believe that all other players are type L_0 , whose average choice is 50, so, they believe that $y = 50(\frac{2}{3}) = 33.33$, which is also their optimal guess. Type L_2 players believe that all others are type L_1 , so $y = 50(\frac{2}{3})^2 = 22.22$, which is also their optimal guess. In general, type L_k players guess the number $50(\frac{2}{3})^k$. Hence, if these types of players are present in the data we should expect to observe spikes at the numbers $50(\frac{2}{3})^k$, $k = 1, 2, \dots$. Type L_∞ players will choose a guess of 0 that coincides with a Nash equilibrium.

Now suppose that $[a, b] = [0, 100]$, $p > 1$, and continue to assume that type L_0 players choose uniformly randomly over $[0, 100]$. If $50p > 100$, then type L_1 players will win for sure if they guess 100, so this is their optimal guess; all higher types will also optimally choose to guess 100. If $50p < 100$, then type L_1 players will choose the guess $50p$. Type L_2 players believe that all others are type L_1 players, so they choose the guess $\min[50p^2, 100]$. If $\min[50p^2, 100] = 100$, then all higher types will also choose to guess 100. Similarly, type L_3 players will choose $\min[50p^3, 100]$ and if $\min[50p^3, 100] = 100$, then all higher types also choose to guess 100. Continuing with this recursion, type L_∞ will choose the guess 100, which is also the Nash equilibrium. Hence, the sequence of guesses will be $50, 50p, 50p^2, \dots, 100$.

In the earliest test of the p -beauty contest, Nagel (1995) found that for $[a, b] = [0, 100]$ and $p = 2/3$, the mean guess with a subject pool of 14–16 German students was 35. There were spikes in the data at the choices 50, 33, 22, which identified level 0, 1, and 2 thinkers, and the respective percentage of such types in her dataset was 13, 44, and 39. Figure 13.8 shows a histogram of choices from Nagel's data for the case $p = 2/3$ (she also reports results for other values of p such as $1/2$ and $4/3$).

Ho et al. (1998) extend Nagel's results. To illustrate their experimental findings, consider two games.

1. An infinite threshold game IT in which $a = 0$, $b = 100$, $p = 0.7$; this is denoted by $IT([0, 100], 0.7, n)$. The highest number that a type L_0 may choose is 100. Hence, given

Figure 13.8 Results for the p -beauty contest game when $p = 2/3$.

Source: Nagel (1995) with permission from the American Economic Association.

$p = 0.7$, type $L1$ will not choose a number between $(70, 100]$, type $L2$ will not choose a number between $(49, 100]$, type $L3$ will not choose a number between $(34, 100]$ and so on. In general type Lk will not choose a number between $(0.7^k 100, 100]$. The Nash equilibrium choice of 0 is achieved as $0.7^k \rightarrow 0$, i.e., by type $L\infty$, and requires an infinite number of steps of iterated dominance.

2. A finite threshold game FT in which $a = 100$, $b = 200$, $p = 1.3$; this is denoted by $FT([100, 200], 1.3, n)$. The lowest number that a type $L0$ may choose is 0. Hence, given $p = 1.3$, type $L1$ never chooses a guess from the interval $[100, 130)$, type $L2$ never chooses to guess from the interval $[100, 169)$, type $L3$ never chooses to guess from the interval $[100, 219)$. But since $219 > 200$ the optimal guess of type $L3$ and all higher types is 200. Hence, we need only three rounds of iterated deletion of dominated strategies to achieve the equilibrium.

Ho et al. (1998) give results for a range of values of p , such as 0.7, 0.9, 1.1, 1.3. Some of their findings can be summarized as follows.²⁵

First, based on first round data, the choices made by the players are clustered around the midpoint of the interval $[a, b]$. For the case $p < 1$, across all conditions (i.e., varying the size of the interval $[a, b]$ and the number of participants, n), the respective percentages of types $L0, L1, L2, L3$ were 16, 21, 13, 50. The corresponding numbers for the case $p > 1$ are 22, 31, 13, 34. Hence, all the players in the sample can be accounted for by types $L0$ to $L3$; in particular, there are not types $L4$ or above. By contrast, for any p , we obtain the Nash equilibrium prediction for type $L\infty$. Choices converge towards equilibrium only over time. However, this does not prove that players attain higher levels of iterated rationality. Rather it could simply be due to learning effects. A learning model that is estimated by the authors confirms this. In this model, there are two main types of

²⁵ See also Camerer (2003a) for a nice exposition of these findings.

Figure 13.9 Results for the p-beauty contest using diverse subject pools with $p = 2/3$, $a = 0$, $b = 100$.

players: Level-0 players who simply adapt to past play and level-1 players who best respond to the play of level-0 players.

Second, choices are closer to equilibrium in finite threshold games, and converge faster to equilibrium relative to infinite threshold games. This is due possibly to the higher degree of rationality required in the latter. These differences are statistically significant. Larger groups ($n = 7$ rather than $n = 3$) make choices that are closer to equilibrium.

Third, we report in Figure 13.9, taken from Camerer (2003b), the choices made by Caltech graduates, portfolio managers, and economics Ph.D.s for the case $p = 2/3$, $a = 0$, $b = 100$. Most people would impute a high degree of cognitive ability to this group (and possibly rationality too). Yet these special groups show significant spikes around the numbers 50, 33, 22 that are also consistent with level- k subjects.

Fourth, experienced and inexperienced subjects demonstrate similar choices in the first round of the experiments, but the choices of the former converge more quickly to equilibrium. Experienced subjects must have played a similar game in the past. For instance players who play the IT game could have played the FT game before and vice versa.

Bosch-Domènech et al. (2002) compare the results of p-beauty contest games from two different kinds of experiments. (1) Experiments with lab subjects. (2) Three different sets of experiments with newspaper subjects carried out separately in 1997 by Thaler; Bosch-Domènech and Nagel; and Selten and Nagel. The newspaper experiments are treated by the authors as field experiments in which one has far less control over the subject pool. Two kinds of data are considered: choice data, i.e., actual guesses made by players in the experiments and data arising from unstructured comments of the participants to justify the choices that they make. The main observations are as follows. The results from choice and comments data from the independent newspaper experiments are similar and show spikes at 50, 33, and 22 that are consistent with level- k subjects.

The subjects in experiments in the lab are typically not allowed to communicate with each other. However, some of the newspaper subjects attempted to form coalitions but it did not affect the results (see, however, the findings of Burchardi and Penczynski (2014), below). The frequency of equilibrium choices is highest among theorists in the lab (15%), followed by newspaper subjects (6%) and undergraduate lab subjects (1%). The most successful newspaper subjects (in terms of winning the prize) were those who chose to run their own experiments and chose to submit numbers close to the winning numbers in their private experiments. The authors comment (p. 1698) that “To our shame, we were taught the very lesson that we, experimentalists, are trying to teach our fellow economists: when in doubt, run experiments.”

Grosskopf and Nagel (2008) introduce the two-person p -beauty contest game for $p = 2/3$. The solution to this game is even less cognitively challenging than a n -player game, $n \geq 3$. The reason is that if the winning number is the one which is closer to $p < 1$ times the average, then the smaller number always wins, irrespective of the size of the larger number chosen. For this reason, it is cognitively easier to spot that choosing the number zero is a weakly dominant strategy.

Two distinct subject pools were chosen. First, students who did not have a prior exposure to the p -beauty contest. Second, professionals (including game theorists) at conferences where this paper was presented; four of these five conferences were economics conferences. The results are as follows. Professionals do better than students in choosing the Nash outcome (36.2% versus 9.85%). However, another way of looking at this result is that about 90% of the students and about 63% of professionals play weakly dominated strategies (i.e., a choice that is not equal to zero). Professionals choose zero more often (in a statistically significant sense) in the two-player game than in the $n > 2$ player game (data for the $n > 2$ comes from Bosch-Doménech et al., 2002), hence, they benefit relatively more from a reduction in the cognitive requirements of a two-player game. However, there is no statistical difference in the cumulative density functions of choices of students and professionals in the cases $n = 2$ and $n > 2$.

Breitmoser (2012) questions the suitability of a level- k approach for the p -beauty contest. He argues for an explanation of the data that is based on quantal response equilibrium (see Section 13.2) and models of noisy introspection (see Section 13.7.5). His main point is that by ignoring the effect of one's own guess on the average guess, the predictions of level- k models are mis-specified. However, it appears to be the case, in most experiments, that subjects ignore the effects of their own actions on the average. Thus, the predictions in the standard level- k model are made under the joint hypothesis that subjects follow level- k models and use the heuristic of ignoring the effects of their actions on the average.²⁶ The empirical tests that we report in Section 13.4.5, for instance, by Costa-Gomes et al. (2001) and Costa-Gomes and Crawford (2006) assume that subjects follow this heuristic. Yet, they find strong support for level- k models.

13.3.3 The cognitive hierarchy model (CH)

Camerer et al. (2004a) generalize the level- k model by assuming that each type Lk player, $k = 1, 2, \dots$ believes that other players belong to a distribution of lower types $Lk - 1, Lk - 2, \dots, L0$. This is the *cognitive hierarchy model* (CH). The authors give two motivations for the CH model. First, as k increases, the expectations of each type in the level- k model may appear increasingly irrational because they ignore the presence of an increasingly larger number of types, while in the CH model, they appear increasingly rational. Second, the predictions of the CH model appear

²⁶ I am grateful to Vincent Crawford for clarifying these issues in a personal communication.

as precise as those of the level- k model in a large class of games, but in some, such as the entry game, they appear to be better. However, in a recent survey, Crawford et al. (2013) write that:²⁷

It would be of interest to discriminate between level- k and CH models, but so far no study has clearly separated their predicted decisions. But most level- k estimates that make adequate allowance for errors assign $L0$ a much lower frequency than CH estimates do, often zero. Thus a CH model's Poisson constraint will often be binding, and a level- k model, which imposes no such restriction, will fit better (see however Camerer, Ho, and Chong 2004, Section II.B; and Chong, Camerer, and Ho 2005).

We now explain the CH model in more detail. Suppose that players are exclusively of types Lk with $k = 0, 1, 2, \dots$ and there is a distribution $f(k)$ of these types. In the CH model, a type Lk player believes that all other players are of types $Lk - 1, Lk - 2, \dots, L0$. Given the evidence on cognitive limits, it is plausible to assume that the fraction of higher types is lower relative to the fraction of lower types. One way of capturing this is to assume that the ratio $f(k)/f(k - 1)$ declines at a rate that is proportional to k . This property is satisfied by the Poisson distribution,²⁸

$$f(k) = \frac{e^{-\tau} \tau^k}{k!}; k = 0, 1, 2, \dots, \quad (13.24)$$

which is a one-parameter family of distributions such that the mean and variance are given by τ .

The belief of type Lk players about the proportion of players of a lower type Lh ($h < k$) is denoted by $g_k(h)$ and is given by the following normalized distribution

$$g_k(h) = \frac{f(h)}{\sum_{l=0}^{k-1} f(l)}. \quad (13.25)$$

Thus, players use the correct distribution f in forming beliefs about the fractions of players who perform relatively lower steps of thinking. As k becomes larger, $\sum_{l=0}^{k-1} f(l)$ approaches 1, so the gap between $g_k(h)$ and $f(h)$ diminishes. In this sense, higher types have increasingly rational expectations about others.

Denote by s_k^j , strategy j of a type Lk player and by s_h^l the strategy of an opponent, which gives the strategy profile (s_k^j, s_h^l) . Suppose that a player of type Lk has J_k pure strategies. Denote by $p(s_h^l)$ the probability that a player of type Lh , $h < k$, chooses the strategy s_h^l . Players of type $L0$ are assumed to randomize uniformly over their strategies, hence, the probability that any player of type $L0$ chooses strategy s_0^j is denoted by

$$p(s_0^j) = 1/J_0. \quad (13.26)$$

A player of type Lk knows that the opponent who plays s_h^l is likely to be a type Lh player, $h < k$, with probability $g_k(h)$. In turn, a type Lh player plays s_h^l with probability $p(s_h^l)$. Thus, in the mind of a player of type Lk , the probability of the strategy profile (s_k^j, s_h^l) is given by

²⁷ In the quote we have omitted an explanatory footnote.

²⁸ Crawford et al. (2013, p. 15) point out that while the Poisson distribution is not very restrictive in some domains, it is quite restrictive in others.

$$P_k(s_h^l) = \sum_{h=0}^{k-1} g_k(h) p(s_h^l). \quad (13.27)$$

The expected payoff of a player of type Lk from the strategy profile (s_k^j, s_h^l) is given by

$$E\pi_k(s_k^j, s_h^l) = \sum_{s_h^l \in S_{-k}} \pi_k(s_k^j, s_h^l) P_k(s_h^l), \quad (13.28)$$

where $\pi_k(s_k^j, s_h^l)$ is the payoff of player k and S_{-k} is the set of pure strategies of the opponent.

Players are assumed to best respond, conditional on their (non-equilibrium) beliefs. Thus, if $s_k^* \in \arg \max E\pi_k(s_k^j, s_h^l)$, then $p(s_k^*) = 1$. The model is solved recursively. From (13.26), the strategy of type $L0$ players is given by $p(s_0^j)$. Using this data, we can solve for g_1 and P_1 , which enables us to solve for the optimal strategy of type $L1$ players. Given the optimal strategies of types $L0$ and $L1$ we compute g_2 and P_2 that allows us to solve for the optimal strategy of type $L2$ players and so on.

Consider the class of dominance solvable games. The prediction of the CH model with a Poisson $f(k)$ when the single parameter of the Poisson distribution $\tau \rightarrow \infty$ is identical to the Nash equilibrium. This prediction is reached by finite deletion of dominated strategies. To see this, use (13.24) to write:

$$\frac{f(k-1)}{f(k-j)} = \frac{(k-j)!}{(k-1)!} \tau^{j-1}, j \geq 1. \quad (13.29)$$

Consider a type Lk player. As $\tau \rightarrow \infty$, type Lk imagines that all other types are type $Lk-1$. In this case, the model becomes essentially the simpler level- k model. We show in Section 13.4.4 that the outcome of a dominance solvable game with level- k players is identical to the Nash equilibrium outcome.

In coordination games such as the stag-hunt game, the CH model gives important insights into the effects of group size. It turns out that when group size increases, the likelihood that the inefficient risk dominant equilibrium gets played increases. This is able to explain the empirical results of Huyck et al. (1990); see one of the exercises at the end of the chapter.

From (13.29), an increase in τ , for any player of type Lk , increases the relative proportion of higher types among the set of types $Lk-j$, $j \geq 1$. The parameter τ can be estimated from the data. In p-beauty contest games, collating results over several studies, Camerer et al. (2004a) report mean and median values of τ equal to, respectively, 1.30 and 1.61. These values are supportive of a CH model; recall that level- k models, by contrast, would require much higher values of τ . Also, subject pools that comprise individuals with greater analytical skills or greater education are also characterized by higher values of τ . An increase in stakes also increases the estimated value of τ .

Camerer et al. (2004a) consider early round data, with no feedback, for a very large number of games (33 matrix games and 22 games that have a mixed strategy equilibrium). They pit the predictions of a Poisson CH model and the Nash equilibrium against each other. The two main findings are as follows. First, when the Nash predictions are good approximations, the CH model is almost as accurate. Second, when the Nash predictions are poor approximations of the experimental results, then the predictions of the CH model are usually more accurate (Crawford et al. (2013)).

Table 13.1 Game 8 from Costa-Gomes et al. (2001).

	L	R	Data	Nash	CH
T	45, 66	82, 31	.92	1	.82
TM	22, 14	57, 55	0	0	.06
BM	30, 42	28, 37	0	0	.06
B	15, 60	61, 88	.08	0	.06
Data	.64	.36			
Nash	1	0			
CH	.55	.45			

Source: Camerer et al. (2004a).

Consider, for instance, the results given by Camerer et al. (2004a) for game 8 from Costa-Gomes et al. (2001) in Table 13.1. This is a two-player normal form game in which the players simultaneously choose their strategies. The unique Nash equilibrium of the game in pure strategies is (T,L). The experimental data, reported in the right hand side and the lower panels shows that most row players (92%) play T, but 36% of the column players do not play their part of the Nash profile, L, preferring instead to play the alternative strategy R. Suppose that $\tau = 1.7$ which is not unrepresentative of the estimates (Camerer et al. (2004a)). Then, from (13.24), we get that

$$f(0) = \frac{e^{-1.7}(1.7)^0}{0!} \approx 0.18; f(1) = \frac{e^{-1.7}(1.7)^1}{1!} \approx 0.31; f(2) = \frac{e^{-1.7}(1.7)^2}{2!} \approx 0.26. \quad (13.30)$$

Column players of type $L1$ believe that they are facing type $L0$ row players who randomize equally between their strategies T, TM, BM, B. Hence, the expected payoffs of a type $L1$ column player from playing L and R, respectively, are 45.5 and 52.75, so, they play R. Now consider type $L1$ row players who believe that they are facing type $L0$ column players who randomize equally among L and R. Since T is a dominant strategy, it is also the best reply for type $L1$ row players.

Row and column players of type $L2$ in the CH model believe that they face a heterogeneous population of type $L0$ and type $L1$ opponents. Using (13.25), (13.30), the normalized fractions of opponents in the mind of a type $L2$ player are

$$g_2(0) = \frac{0.18}{0.18 + 0.31} = 0.36; g_2(1) = 1 - g_2(0) = 0.64. \quad (13.31)$$

Thus, the payoffs of a column player of type $L2$ from the two strategies, L and R are respectively

$$\begin{aligned} L : 0.36 \left(\frac{66 + 14 + 42 + 60}{4} \right) + 0.64(66) &= 58.62. \\ R : 0.36 \left(\frac{31 + 55 + 37 + 88}{4} \right) + 0.64(31) &= 38.83. \end{aligned}$$

Thus, it is optimal for a column player of type $L2$ to play L. Playing L is also optimal for any column player of type Lk , $k \geq 3$. Row players of any type Lk , $k \geq 1$ find it optimal to play the strictly dominant strategy T. Since type $L0$ column players randomize equally between L and R,

so half of them choose R. Also, as shown above, all type $L1$ column players also play R. All other types of column players play L. Using (13.30), the total fraction of column players who play the strategy R is $\frac{1}{2}(0.18) + 0.31 = 0.40$. This is close to the findings of the experimental data that 36% of the column players play R.

Type $L0$ row players play T with probability 0.25. Since $f(0) \approx 0.18$ and all other types of row players play T under a Poisson CH, a fraction 95.5% of the players are predicted to play T. The experimental finding of 92% of the players playing T is in line with this prediction. Thus, in this illustrative example, where Nash predicts well (for row players), the CH model predicts equally well and where Nash does not predict well (for column players), the prediction of the CH model is superior. An exercise at the end of this chapter gives another example from Game 4 of Binmore et al. (2001) that illustrates a similar point.

13.4 Applications of level- k and CH models

In this section we consider further applications of level- k models.

13.4.1 *Is the power of focal points limited?*

Conventional game theory does not allow for the names of strategies or labels on decisions to have “salience.” Indeed, the equilibrium of the game is independent of the names that one might choose for various strategies. Schelling (1960) argued that some actions and labels could be more salient than others and may facilitate coordination in games. We have considered the evidence on these issues in the previous chapter. In Schelling’s experiments, two subjects were simultaneously asked to choose a place where they would meet the other subject in New York. No communication was allowed between the subjects. If the choices of the two subjects coincided, then they both received an identical positive payoff. Otherwise they both received zero. Despite the very large number of places that one could name in New York, a common choice was the Grand Central Station. This allowed for a high rate of coordination in a game where, ex-ante, one might have expected a low rate of coordination. Hence, in this context, the choice of Grand Central Station has particular salience; such a salient choice may also be termed as a *focal point*.

Crawford et al. (2008) use level- k models to examine 2×2 coordination games with symmetric and asymmetric payoffs. In asymmetric 2×2 coordination games, individual players may derive a greater payoff from one of the strategies relative to the others, hence, such a strategy is said to exhibit *payoff salience*. However, it is quite likely that another strategy may exhibit *label salience* that conflicts with *payoff salience*. So what outcome do we expect? The main aim is to show that when payoff salience opposes label salience, then even minute asymmetries in the game could significantly reduce the power of focal points.

In a pilot study with unpaid subjects in experiments, the authors first used a 2×2 coordination game called Chicago Skyscrapers. This was similar to the idea in Schelling’s work; each player simultaneously chooses a meeting point with the other player, a common choice is rewarded and no communication is allowed. The difference is that players were given a restricted, easier, choice; each player had to choose between the Sears Tower (a salient Chicago landmark) and a less salient building across the road, the AT&T building. The payoff matrices are shown in Figure 13.10. Player 1 is the row player and player 2 is the column player. The choices made by the subjects are shown in brackets next to each strategy.

Symmetric game			Slightly asymmetric game			Moderately asymmetric game		
	Sears (90%)	AT&T (10%)		Sears (58%)	AT&T (42%)		Sears (47%)	AT&T (53%)
Sears (90%)	100, 100	0, 0	Sears (61%)	100, 101	0, 0	Sears (61%)	100, 110	0, 0
AT&T (10%)	0, 0	100, 100	AT&T (39%)	0, 0	100, 100	AT&T (39%)	0, 0	110, 100

Figure 13.10 The non-incentivized Chicago skyscrapers game in Crawford et al. (2008). With permission from American Economic Association.

Symmetric game			Slight asymmetries		
	X (76%)	Y		X (28%)	Y
X (76%)	5, 5	0, 0	X (78%)	5, 5.1	0, 0
Y	0, 0	5, 5	Y	0, 0	5.1, 5

Moderate asymmetries			Large asymmetries		
	X (61%)	Y		X (60%)	Y
X (33%)	5, 6	0, 0	X (36%)	5, 10	0, 0
Y	0, 0	6, 5	Y	0, 0	10, 5

Figure 13.11 Results with incentivized experiments in Crawford et al. (2008). With permission from American Economic Association.

For the symmetric game, the results are consistent with Schelling's insights; 90% of the row and the column players choose the salient strategy, Sears Tower. Thus, in 81% of the cases, successful coordination on the Sears Tower takes place. However, the power of focal points becomes weaker as the degree of asymmetry in the game increases, which also increases the tension between payoff and label salience. In the slightly asymmetric and the moderately asymmetric games, coordination is achieved on the Sears Tower, respectively, in 35.4% and 23.5% of the cases.

The authors then conducted incentivized experiments in which Sears and AT&T were replaced, respectively, with the alphabets X and Y. The expectation is that X is more salient than Y. As the authors say (p. 1446): "We anticipated that X would be more salient than Y, because X marks the spot and X precedes Y in the alphabet." The nature of the results was identical to the Chicago Skyscrapers game; Figure 13.11 which also shows the percentage of row and column players choosing the action X, shown in brackets.

The results suggest the following conclusions. First, the choices made in the symmetric game suggest that X is a salient action, but to a lesser extent as compared to the Sears Tower in the Chicago Skyscrapers game. Second, under slight payoff asymmetries most subjects prefer the payoff salient action of their opponent. However, as the degree of asymmetry increased, subjects switched to favoring their own payoff salient action. This is reflected in the coordination rates across games. Let the coordination rate in a game be the joint play of the strategy profiles (X, X)

and (Y, Y). In the symmetric game, the coordination rate is $(0.76)^2 + (0.24)^2 = 64\%$. However, in the asymmetric games, the coordination rates are lower but increase as the degree of asymmetry successively increases (respectively, 38%, 46%, and 47%). This pattern of coordination is the reverse from the Chicago skyscrapers games (where it fell rather than increased).

These stylized facts cannot be explained using the QRE because there is no concept of the salience of a payoff label in that theory. Crawford et al. (2008) give an explanation in terms of the level- k model. They make the plausible assumption that the behavior of type $L0$ players may differ in the symmetric and the asymmetric games, in the following manner.

A1 If the coordination game is symmetric, then type $L0$ players choose the “label salient action” with probability $p \geq 0.5$.

In the slightly asymmetric game in Figure 13.11 the payoff salient actions are Y for the row player and X for the column player. The behavior of type $L0$ players with respect to their payoff salient actions is given in the next assumption.

A2 If the coordination game is asymmetric, then type $L0$ players choose the “payoff salient action” with probability $p \geq 0.5$. Using the slightly asymmetric and the moderately asymmetric games, define

$$\underline{p} = \frac{5.1}{5.1 + 5} = 0.505; \quad \bar{p} = \frac{6}{6 + 5} = 0.545. \quad (13.32)$$

Assumption A2 requires that

$$\underline{p} < p < \bar{p}, \quad (13.33)$$

i.e., the payoff bias of type $L0$ players in the asymmetric games is quite modest.

We first show that Schelling’s insight about focal points holds perfectly in the symmetric coordination game.

Proposition 13.27 *Under assumption A1, all row and column players choose X in the symmetric coordination game.*

Proof: Consider the symmetric coordination game shown in Figure 13.11. Using assumption A1, all row and column players who are type $L0$ choose the label salient action X with a probability $p > 0.5$. All type $L1$ players choose a best response to the play of type $L0$ players. Their expected payoff from choosing X is greater than that from choosing Y (since $5p > 5(1-p)$), so they choose X with probability 1. Hence, by an analogous argument, all types Lk , $k \geq 2$ of row and column players also play X with probability 1. ■

Proposition 13.28 *Consider the slightly asymmetric game in Figure 13.11 and suppose that assumption A2 holds. Row and column players of type $L1$ choose their partner’s payoff salient actions, respectively X, Y. Row and column players of type $L2$ choose their own payoff salient action, respectively Y, X.*

Proof: From assumption A2, we know that row and column players of type $L0$ play their payoff salient actions (Y for row player and X for column player) with probability p that is given in (13.33). Thus, the expected payoff from playing X for row players of type $L1$ is relatively greater

because $5p > 5.1(1 - p) \Leftrightarrow p > \underline{p}$, which holds from (13.33). An analogous argument shows that the expected payoff of column players of type $L1$ from playing their partner's payoff salient action, Y , is relatively greater. Players of type $L2$ play their best replies, conditional on the behavior of type $L1$ players. Row players of type $L2$ know that column players of type $L1$ play Y to which the best response is their own payoff salient action, Y . Similarly, column players of type $L2$ know that row players of type $L1$ play X , to which the best response is their own payoff salient action X . ■

The results for the games with moderate and large asymmetries are similar, so, we derive the results for the game with moderate asymmetries only.

Proposition 13.29 *Consider the moderately asymmetric game under assumption A2. Players of type $L1$ play their own payoff salient action (row players play Y and column players play X). Players of type $L2$ play the payoff salient action of their opponents (row players play X , column players play Y).*

Proof: From assumption A2, players of type $L0$ play their payoff salient actions with probability p given in (13.33). Conditional on these beliefs, players of type $L1$ play as follows. Row players of type $L1$ prefer to play Y because $5p < 6(1 - p) \Leftrightarrow p < \bar{p}$, which is true from (13.33). By the same reasoning, column players of type $L1$ optimally play X . Since row players of type $L1$ play Y , the best reply of column players of type $L2$ is to play Y . By an analogous reasoning, the best reply of a row player of type $L2$ is X . ■

Crawford et al. (2008), show that under assumptions A1, A2, the qualitative results of the level- k model match their experimental data. They also show that for plausible distributions of the frequencies of the various types, the model can also closely replicate the quantitative findings from the experimental data.

13.4.2 *Coordination and communication with boundedly rational players*

There has been an interest in the role that communication can play in affecting the degree of coordination in games where coordination failures are a possibility.²⁹ The development of language is regarded by biologists and anthropologists as one of the critical features of human evolution. Perhaps it allowed primitive man to coordinate individual actions, in important collective actions such as hunting.

Two essential components of human communication and language are the ability to listen and speak. In the context of the coordination games typically considered in economics, *listening* often involves an attempt to figure out the intentions of the other players and *speaking* typically involves an attempt to influence the beliefs/actions of others. The literature on cheap talk games (e.g., Crawford and Sobel (1982); Farrell (1987, 1988)) makes progress in this direction.

Farrell (1987), for instance, focuses on problems of coordination in the Battle of Sexes (BOS) game. The robustness of these results was checked in a more extended class of games by Rabin (1994). A central concern of this endeavor was to check if coordination could be increased in the BOS game by *preplay communication*. Preplay communication took the form of cheap talk, i.e., messages that were non-binding and also costless. One or both players could engage in cheap talk; this is respectively known as *one-way* and *two-way* communication. While the language-content of the underlying messages was not specified, which might be objected to by anthropologists and

²⁹ See for instance, Ellingsen and Östling (2010) and Crawford (2007), Crawford (2003).

	H	D
H	0, 0	a, 1
D	1, a	0, 0

Figure 13.12 Battle of Sexes game in Crawford (2007); $a > 1$.

sociologists, it was taken as given that a preexisting common language made the messages unambiguous. This literature considers specific game theoretic equilibria and also identifies the set of rationalizable strategies. An important finding is that rationalizable preplay communication does not ensure either coordination or a Pareto-efficient equilibrium, although such communication may enhance coordination.

Following Crawford (2007) we now apply the level- k model to the Battle of Sexes (BOS) game shown in Figure 13.12. There are two strategies for each player, H and D. The respective payoffs of the row and the column players are shown in Figure 13.12, where $a > 1$.

THE OUTCOME UNDER CLASSICAL GAME THEORY

The unique symmetric equilibrium for the BOS game is in mixed strategies. Each player plays H with probability $p = a/(1 + a)$. Coordination occurs when either of the two outcomes, (H,D) or (D,H) are played. Given the equilibrium mixed strategy profile, these two outcomes occur with an identical probability of $p(1 - p)$, hence, the expected coordination rate, in equilibrium, is $2p(1 - p)$. Substituting for p gives the expected coordination rate,

$$\rho(a) = \frac{2a}{(1 + a)^2}. \quad (13.34)$$

A simple calculation gives rise to the following remark.

Remark 13.2 *The coordination rate, $\rho(a)$, is maximized at $a = 1$ and the maximum coordination rate is given by $\rho_{\max} = 0.5$. Since, $\lim_{a \rightarrow \infty} \rho(a) = 0$ the payoff from each pure strategy in the mixed strategy profile is $a/(1 + a)$.*

THE OUTCOME UNDER A LEVEL-K MODEL WITH NO COMMUNICATION

Crawford (2007) assumes that there are four types of level- k players $L1, L2, L3, L4$. The anchoring type $L0$ is not physically present, however, it exists in the mind of type $L1$ as a model of what other players are like. Type $L1$ believes that type $L0$ players randomize uniformly over their pure strategies.

Proposition 13.30 *Consider the BOS game in Figure 13.12. The matrix of equilibrium actions in a level- k model with no communication is shown in Table 13.2.*

Proof: Conditional on the behavior of type $L0$ players, type $L1$ players receive a higher payoff from playing H rather than D (because $a > 1$). Conditional on the strategy of type $L1$ players, type $L2$ players play their best response, D. Analogously, conditional on the strategy of type $L2$ players, type $L3$ players choose H. Similarly, type $L4$ players play their best response, D, to the strategy

Table 13.2 Equilibrium actions in a level- k model without communication.

Types	L1	L2	L3	L4
L1	H, H	H, D	H, H	H, D
L2	D, H	D, D	D, H	D, D
L3	H, H	H, D	H, H	H, D
L4	D, H	D, D	D, H	D, D

of type $L3$ players. The resulting strategy profiles of types $L1, L2, L3, L4$ in pairwise interaction are shown in Table 13.2. For instance, the strategy profile in the (3,2)th cell of the matrix, (H,D), shows that if a type $L3$ row player plays against a type $L2$ column player, then they play their respective optimal strategies H and D. ■

Recall our assumption in this section that type $L0$ players exist only in the minds of type $L1$ players as a model of other players. The extent of cooperation, thus, depends on the frequency of types $L1, L2, L3, L4$. From Proposition 13.30, the two cooperative outcomes (H,D) or (D,H) are possible only if a type $L1$ or $L3$ player plays against an opponent of type $L2$ or $L4$ (i.e., an odd numbered type plays against an even numbered type of player). Denote the composite frequency of types $L1$ and $L3$ by λ and the composite frequency of types $L2$ and $L4$ by $1 - \lambda$. The probability that $L1$ or $L3$ row players meet $L2$ or $L4$ column players is $\lambda(1 - \lambda)$. Similarly the probability of the complementary event that $L2$ or $L4$ row players meet $L1$ or $L3$ column players is also $\lambda(1 - \lambda)$. Hence, the total probability of cooperation is

$$\hat{\rho}(\lambda) = 2\lambda(1 - \lambda). \quad (13.35)$$

Remark 13.3 $\hat{\rho}$ is maximized at $\lambda = 0.5$, and the maximum value of coordination is $\hat{\rho}_{\max} = 0.5$. This gives the maximum coordination rate under a level- k model.

Using Remarks 13.2 and 13.3, we can compare the coordination rates, respectively, in the mixed strategy Nash equilibrium and in the level- k model. Since $\rho(1) = \rho_{\max} = 0.5$, $a > 1$, and $\rho'(a) < 0$, it follows that $\rho(a) < 0.5$ for all $a > 1$. Thus, $\hat{\rho}(0.5) = \hat{\rho}_{\max} > \rho(a)$ for all $a > 1$. Thus, $\lambda = 0.5$ is a sufficient condition for the coordination rate in a level- k model to be relatively greater than in the mixed strategy Nash equilibrium. Furthermore, since, $\rho'(a) < 0$, $\lim_{a \rightarrow \infty} \rho(a) = 0$ and $\hat{\rho}$ is independent of a , thus, as the degree of asymmetry in the game increases, the gaps in the coordination rates under the level- k model and the mixed strategy Nash equilibrium continue to widen. Players using the level- k model do not coordinate on the basis of risk dominance or payoff dominance. Coordination, when it happens, is entirely accidental. Since level- k players use a non-equilibrium model, ex-post, they are often surprised by the outcome.

THE OUTCOME UNDER A LEVEL- k MODEL WITH TWO-WAY COMMUNICATION

Suppose that there is a preexisting language that is common knowledge. In this language suppose that the message h sent by any player means “I intend to play H,” while the message d means “I intend to play D.” Let r denote the random message $0.5h + 0.5d$. There are two stages. In the first stage, players exchange messages that are chosen simultaneously. In the second stage, players choose actions, H, D, conditional on having received the message in the first stage. Let R denote the random strategy, $0.5H + 0.5D$. There could conceivably be many rounds of communication

Table 13.3 Optimal choice of messages and actions in the two-stage game with communication.

Types (messages)	L_1 (r)	L_2 (h)	L_3 (d)	L_4 (h)
L_1 (r)	R, R	D, H	H, D	D, H
L_2 (h)	H, D	H, H	H, D	H, H
L_3 (d)	D, H	D, H	D, D	D, H
L_4 (h)	H, D	H, H	H, D	H, H

followed by the second stage choice of actions, as, for instance, in Farrell (1987). Here, we allow for only one round of communication followed by the second stage choice of actions.

We make the following assumptions in the model with communication:

- C1: Type L_0 players choose each of the available actions with equal probability (random choice). Having observed the outcome of this randomization, they always send a truthful message (h if they realized action is H and d if the realized action is D). Such players completely ignore the message received by other players when choosing their actions.
- C2: As is standard in level- k models, in stage 2, players of each type choose their best reply, conditional on beliefs about the strategies of lower types, formed after observing the first stage messages. Players do not, however, revise their beliefs about the types of other players even if the message is unexpected.
- C3: When the expected payoff from truthtelling and lying is identical, then subjects tell the truth, i.e., they have a preference for truthtelling.

Proposition 13.31 *The matrix of optimal actions and messages in a level- k model with one round of communications is shown in Table 13.3. The optimal messages (either h or d) for each type are shown immediately following the type designation and the actions can be read off from the individual cells in the matrix.*

Proof: Type L_1 players (first row and first column) believe that the opponents are exclusively type L_0 players. Given assumption C1, type L_0 players are equally likely to choose the action H or D, and their messages truthfully reflect their actions in stage 2. However, when they choose their message, type L_1 players do not know the message chosen by type L_0 , which is equally likely to be h or d. Type L_1 players also know that their message will be completely ignored by type L_0 players, so truthful and untruthful messages give the same payoff. Thus, since they are equally likely to play H or D subsequently, assumption C3 (preference for truthtelling) ensures that they send a truthful message, i.e., message r.

In the second stage, believing that the messages are sent by truthful type L_0 players, type L_1 players best respond by playing H if the message is d and D if the message is h. Thus, when a type L_1 player plays against an opponent who is a type L_1 player, all four outcomes, i.e., HH, HD, DH, DD are equally possible; this is reflected in the (1,1)th cell in Table 13.3. In all other entries in row 1 and column 1 in Table 13.3, type L_1 plays a best response to the observed message of the opponent (H if message is d and D if the message is h).

Type L_2 players believe that all other players are of type L_1 who will randomize equally between the two messages. They also believe (correctly) that type L_1 players consider the messages they receive to be a truthful representation of the play of the opponent in stage 2. Since $a > 1$, type L_2 players always choose message h and action H. Type L_1 players will choose action D after observing the message h. Hence, type L_2 players always achieve their desired payoff of $a > 1$ against type

$L1$ players (but not necessarily against other types of players). This explains the optimal message, h , and the strategy choice of such players: H in the second row and H in the second column in Table 13.3.

Consider now type $L3$ players who believe that all other players are of type $L2$. We know that type $L2$ players always announce the message h and play the strategy H . The best response of type $L3$ players is to announce d (since $C3$ holds) and play action D . Analogously, type $L4$ players truthfully announce h and play the action H . This explains all the elements in Table 13.3. ■

Comparing Propositions 13.30, 13.31 we can draw out the implications of communication.

1. Other than type $L1$, communication alters the actions of all other types. In the absence of communication, type $L1$ has a unique best reply, namely, H . However, in the presence of communication, type $L1$ always best responds to the observed first stage message, which is believed to be sent by a truthful type $L0$ opponent. Type $L2$ effectively plays the role of a Stackelberg leader to the perceived type $L1$ opponent. Thus, type $L2$ sends message h , and plays H ensuring a payoff of $a > 1$. Contrast this with the play of D by type $L2$ in the absence of communication.
2. Consider the pairing in which a type $L1$ player encounters a type $L1$ opponent. In the absence of communication, the outcome is (H, H) , which gives each player a payoff of zero. However, in the presence of communication, all four outcomes are equally possible (see Table 13.3). Hence, at least half the times, these pairings end up with a coordinated outcome, although it is purely by chance.
3. Consider the pairing in which a type $L1$ player encounters a type $L3$ opponent. In the absence of communication, the outcome is (H, H) , and each player gets a payoff of zero. In the presence of communication, the outcome is one of the two coordinated outcomes, i.e., either (D, H) or (H, D) . The secret behind the improved outcome is the listening skills of type $L1$ (who is best responding to a perceived type $L0$ opponent).

Suppose that the proportions of type $L1, L2, L3, L4$ players are, respectively, $\rho_1 = 0.4, \rho_2 = 0.3, \rho_3 = 0.2, \rho_4 = 0.1$; this is consistent with data from similar games. These assumptions imply that the composite frequency of types $L1$ and $L3$ is $\lambda = 0.60$. Thus, using (13.35), the cooperation rate under no communication is $2(.60)(.40) = 0.48$.

Taking account of observations 2, 3, above, we can now compare the overall coordination rates with and without communication. In the pairing $L1, L1$ that takes place with probability $\rho_1^2 = .16$, the coordination rate goes up from 0 to $1/2$, while in the pairing $L1, L3$ or $L3, L1$ (which has probability $2\rho_1\rho_3 = 0.16$) it goes up from zero to one. Hence, the total increase in the probability of coordination is $\frac{1}{2}\rho_1^2 + 2\rho_1\rho_3 = 0.24$, so the new coordination rate is 0.72 . An important aspect of the coordination rates in the level- k model is that they do not depend on how asymmetric the game is, i.e., on the size of the parameter a in the payoff-matrix.

13.4.3 *Risk dominance and payoff dominance in sender-receiver games*

Consider the two-player stag-hunt game shown in Figure 13.13. Two players simultaneously choose actions H and L that have the connotations of “high” and “low” effort levels. Think of action H (hunting stag) as involving high and cooperative effort with a partner, while action L (hunting hare) involves low effort, no cooperation with a partner, but also lower payoffs. Uncoordinated outcomes hurt the player who undertakes action H .

	H	L
H	9, 9	0, 8
L	8, 0	7, 7

Figure 13.13 A stag-hunt game.

There are two pure strategy Nash equilibria in the game: (H, H) and (L, L). The strategy profile (H, H) is the payoff dominant equilibrium, and it is also Pareto optimal, while (L, L) is the risk dominant equilibrium.³⁰ The payoff from choosing H is high for a player if the opponent also chooses H. However, if the opponent chooses L, then choosing H is risky. Hence, in such games there is a basic conflict between the safer strategy, L, which gives lower coordinated payoffs and the riskier strategy, H, which gives higher coordinated payoffs.

In this section we make four assumptions, SH1 to SH4.

SH1: Each player is a level- k player, $L0, L1, L2, \dots$. A player of type Lk believes that all other players are of type $Lk - 1$, $k = 1, 2, \dots$. Type $L0$ chooses uniformly over the two actions in the stag-hunt game, H, L and chooses truthful messages. The actual frequency of type $L0$ players is zero. They exist only in the minds of players of type $L1$ as a model of the type of other players.

THE BENCHMARK CASE OF NO-COMMUNICATION

Consider first the benchmark case of no-communication. Given assumption SH1, type $L1$ players prefer action L over action H because $0.5(8) + 0.5(7) > 0.5(9)$. Type $L2$ players believe that the opponents are of type $L1$, hence, they choose their best reply, L. Proceeding in an analogous manner, all higher types also choose L. Since the frequency of type $L0$ players is zero (assumption SH1), in any pairing of players, the risk dominant equilibrium (L, L) is chosen. This provides firmer foundations for the concept of a risk dominant equilibrium.

Psychologists such as Colman et al. (2014) raise two concerns with the results under no-communication. First, the prediction (L, L) fails to explain why in experimental games there is so much coordination on the outcome (H, H). They cite Colman and Stirk (1998), who find that 79% of players play the strategy H in the stag-hunt game. Second, Colman et al. worry about the asymmetry in the theory because players “never credit their co-players with the same level of strategic sophistication as themselves.” We shall see below that the outcome (H,H) is predicted to arise in level- k models once we allow for the possibility of communication. Further, the empirical evidence does provide good support for level- k models in a range of other games; we shall review some of the evidence below.

THE POSSIBILITY OF ONE-WAY COMMUNICATION

What outcome can we expect if we introduce the possibility of preplay communication in which players can simultaneously send costless messages? We shall only consider one-way communication below.

SH2: There is some preexisting language in which the messages h and l , respectively, are commonly known to mean that the player intends to play the strategies H and L.

³⁰ These concepts are discussed in the appendix on game theory.

One possibility, suggested by Farrell (1988), is that each player can send a message h which is self-committing. However, such a message is not incentive compatible. A player who intends to play L may also have an incentive to send the message, h . Communication can be one-way or two-way. The evidence on the role of communication in enhancing cooperation is mixed. For instance, Cooper et al. (1992) find that two-way communication is conducive for the play of (H, H) , but one-way communication is ineffective. Charness (2000), on the other hand, finds that one-way communication is effective in promoting the play of (H, H) .

Under one-way communication, in the preplay round, a sender chooses a message from the set $\{h, l\}$ that is observed by the receiver. The receiver does not choose to send any message. This is followed by the simultaneous choice of actions from the set $\{H, L\}$.

SH3: When indifferent between two actions, players of all types have a slight preference to tell the truth.

SH4: If any player of type L_k , $k > 1$, receives an unexpected message, then it assumes that the opponent is a truthful player of type L_0 .³¹

Proposition 13.32 *Consider the stag-hunt game in Figure 13.13 with one-way communication and suppose that assumptions SH1–SH4 hold.*

- (a) *The outcome is the payoff dominant equilibrium, (H, H) , in the following two cases.*
 - (i) *When two players of type L_k , $k \geq 2$ play the stag-hunt game.*
 - (ii) *When a type L_1 receiver meets a sender of any type L_k , $k \geq 2$.*
- (b) *When a type L_1 sender plays against a receiver of type L_k , $k \geq 1$ the risk dominant equilibrium (L, L) is played.*

Proof: We need to consider the strategy of each type of player, separately in the role of a sender and a receiver. From assumption SH1, a type L_0 sender randomizes among H , L , and truthfully chooses the message that corresponds to the action intended. Type L_0 players are unaffected by the message of the sender.

Consider a type L_1 sender. He believes the receiver is of type L_0 . Since type L_0 players randomize uniformly over actions, ex-ante type L_1 players have a preference to play L over H . Since type L_0 receivers are unaffected by the message and players have a slight preference to tell the truth, type L_1 senders send the honest message, l , and plays L in the second stage. Type L_1 receivers believe that they are facing an honest type L_0 sender, so responds to the message h by playing H and to the message l by playing L .

Type L_2 senders believe that the receiver is a type L_1 player. Given the strategy of type L_1 receivers, it is optimal for a type L_2 sender to send the message h and play the action H ; this results in the payoff dominant equilibrium (H, H) . Type L_2 receivers expect a type L_1 sender to send the message l and play L . The best reply of a type L_2 receiver is, therefore, L ; this results in the risk dominant equilibrium (L, L) . What happens if a type L_2 receiver receives a counterfactual message h (given that the message l was expected)? Given assumption SH4, the type L_2 receiver believes that the message is sent by a truthful type L_0 player. The best response to such a message is to play H .

Type L_3 senders will send message h and play H because they believe that when type L_2 receivers observe this counterfactual message, they will respond with H . Type L_3 receivers know that type L_2 senders will send the message h and play the action H to which their best reply is H .

³¹ This assumption may seem strong, but it is consistent with the “non-equilibrium in beliefs” feature of level- k models. In any case, the reasonableness of this or similar assumption is eventually an empirical matter. For the moment, this is the most pedagogically convenient assumption.

Suppose that a type $L3$ receiver receives the unexpected message l . Given assumption SH4, the receiver then believes that it faces a truthful type $L0$ sender. Thus, the best response to this message is L . All higher types in their roles as senders and receivers will likewise play just as type $L3$ players do.

Hence, in any pairwise matching of types $L2$ or higher, the equilibrium play is the payoff dominant equilibrium (H, H) . ■

A SUMMARY

Coordination, when it occurs in a level- k model, is entirely accidental. When there are multiple equilibria, traditional concepts such as payoff dominance and risk dominance are not useful to choose among the equilibria in level- k models. The relative frequency of the various types determines the fraction of times that a particular equilibrium is played. Some other alternatives such as global games also do not rely on the traditional selection principles such as payoff dominance and risk dominance. In global games (see Morris and Shin, 1998), players observe privately some perturbations to their payoffs. The perturbed game is dominance solvable and leads to a unique outcome. In many models, such as models of bank runs, where global games choose the risk dominant outcome, so too do level- k models. However level- k models have better behavioral foundations and in more complex games, the two models have different predictions; see Crawford et al. (2013, pp. 40–41).³²

13.4.4 *The market entry game*

Consider the notion of *k-rationalizability* in Bernheim (1984) and Pearce (1984). The definition of *k-rationalizability* can be given iteratively. A strategy for a player is 1-rationalizable if it is a best response to some strategy profile of the opponents. A strategy is 2-rationalizable if it is a best response to a profile of strategies of the other players that are 1-rationalizable. For any k , a *k-rationalizable* strategy of a player is a best response to $k - 1$ -rationalizable strategies of the opponents. In two-player games, a *k-rationalizable* strategy survives k rounds of iterated deletion of strictly dominated strategies. A Nash equilibrium is *k-rationalizable* but the converse is not true. The cognitive requirements on the part of players to play *k-rationalizable* strategies are much more modest as compared to a Nash equilibrium, hence, such strategies are behaviorally more appealing.³³ Level- k models respect *k-rationalizability*.

Suppose that we restrict ourselves to dominance solvable two-player games in which iterated deletion of dominated strategies gives rise to a unique equilibrium strategy profile. We give a heuristic proof that level- k players will play such an equilibrium strategy profile. Suppose that type $L0$ players randomize over the set of pure strategies. Type $L1$ players believe that the opponent is of type $L0$ and each strategy of the opponent has a positive probability of being played. Since type $L1$ players always plays a best reply they will never play a dominated strategy (1-rationalizable strategy). Now consider a type $L2$ player who imagines the opponent to be of type $L1$ who has deleted his dominated strategies. Since type $L2$ also always plays a best reply, he too will never play any of his dominated strategies (2-rationalizable strategy). Proceeding in this manner, if there are k types, then the outcome is *k-rationalizable*. For high enough k , one obtains the unique equilibrium strategy profile.

³² A key implication of global games is that multiple equilibria arise on account of the common knowledge of payoff functions. However, Heinemann et al. (2004) find only very small differences in the behavior of their subjects in experiments for the private information and the common information conditions.

³³ For further discussion of these issues, see Crawford et al. (2013).

In level- k models, each type Lk , $k \geq 1$ acts in a manner similar to a Stackelberg leader to type $Lk - 1$. An important application of this idea is to the *market entry game* originally due to Selten and Güth (1982). Suppose that there is a market with a level of demand equal to $d > 0$ integer units. There are N potential entrants, each capable of supplying 1 unit. The entrants decide to enter simultaneously. If d or fewer entrants enter, so supply is no greater than demand, then each entrant earns a payoff of 1. If more than d entrants enter, then each entrant gets a payoff of zero. Firms that decide not to enter receive a certain payoff of 0.5. The payoffs for this game are typically set up as follows; see Sundali et al. (1995). Let π_i be the payoff to the i th entrant. Let $k \geq 0$ be the outside option and let $n \leq N$ be the number of entrants. Then

$$\pi_i = \begin{cases} k & \text{if firm stays out} \\ k + r(d - n) & \text{if firm enters and } n < d, \\ k & \text{if firm enters and } n \geq d \end{cases}$$

where $k \geq 0, r > 0$ are the two exogenous parameters.

The efficient outcome is for exactly d firms to enter. It is easily checked that this is a Nash equilibrium.³⁴ Can firms, who choose their entry decisions simultaneously, achieve an efficient outcome? Kahneman (1988) ran early experiments with the market entry game. Despite being unable to communicate or signal, close to the efficient number of firms make the entry decision. This finding amazed Kahneman and he commented that to a psychologist “it looks like magic.” This “magical” finding was replicated by other researchers, in particular, after the subjects were allowed a few rounds of learning. The result also survived when several aspects of the underlying game were varied.³⁵

The empirical results are consistent with a Nash equilibrium. However, a CH model applied to the market entry game also makes the same prediction. Suppose that with $\tau = 1.7$, the respective fractions of the players of levels, $L0, L1, L2$ is as given in (13.30), i.e., $f(0) = 0.18, f(1) = 0.31, f(2) = 0.26$, and so on. Players of type $L0$ randomize uniformly between entering and not entering. Players of type $L1$ correctly anticipate that half of the level $L0$ players will enter and they believe that all players are level $L0$. So if $0.5N < d$ they enter, otherwise they stay out. Level $L2$ players believe that the fractions of type $L0$ and $L1$ players is given by (13.31). Hence, they will enter if $N \left(\frac{g_2(0)}{2} + g_2(1) \right) < d$ otherwise they stay out. This analysis can be carried out until it is no longer profitable for a player of some level, Lk , to enter. For a large enough value of k , these responses smooth out, so the efficient outcome is achieved.

Crawford et al. (2013) suggest that the BOS game shown in Figure 13.12 can be considered to be a type of market entry game with suitable reinterpretation; see Figure 13.14. Figure 13.14 represents a two-player market entry game that has capacity $d = 1$. If both players enter they get a payoff of zero. If both players stay out, they get their reservation payoff of zero. If one player enters and the other does not, then the entrant gets a payoff of $a > 1$.³⁶ What entry decision should both firms make, if they choose their decisions simultaneously? The answer is given above in Section

³⁴ If less than d firms enter then it is a dominant strategy for an entrant to enter and if d or more firms enter then it is a dominant strategy to stay out.

³⁵ See, for instance, the findings of Sundali et al. (1995) who varied the size of the market, d . Further research varied the size of the outside option (Rapoport et al., 1998), allowed for asymmetric costs of entry (Rapoport et al., 2002), risky outside options (Rapoport et al., 2002), and asymmetric information about payoffs (Rapoport and Erev, 1998), among others. However, allowing for some learning, the magical result survives.

³⁶ There is a slight difficulty, though, of interpreting the payoffs from the strategy profile (Out, In); the player who stays out gets 1. Typically one expects that the outside option is unaffected by the decisions of the rival.

	In	Out
In	0, 0	a, 1
Out	1, a	0, 0

13.4.2 under various assumptions on the absence or presence of communication between the players.

Goldfarb and Yang (2009) and Goldfarb and Xiao (2011) conduct field studies of the market entry game. In Goldfarb and Yang (2009) managers must decide on technology adoption (which is the entry decision).³⁷ Level-0 managers assume that they are monopolists and maximize profits. Each of the higher types Lk , $k \geq 1$ assumes that all opponents are of lower types. The types are estimated assuming that they come from the Poisson CH model. The estimated value of τ is 2.67 (by contrast the estimated value of τ for the experimental games in Camerer et al. (2004a) typically lies between 1 and 2). There is heterogeneity in the estimated levels of managers. Greater rationality (higher k in the CH model) is associated with more education and larger cities; more rational managers also survive in the market longer. Following the US Telecommunications Act of 1996, Goldfarb and Xiao (2011) find that the CH model performs better than a noisy Nash model in 1998 as compared to 2002 when both models perform almost equally well. This is consistent with the agenda of level- k and CH models to fit better the evidence for new games and in the early rounds of play.

13.4.5 Empirical evidence on level- k models

Costa-Gomes et al. (2001) tested for the presence of level- k players with types $L0, L1, L2, \dots$ using MOUSELAB experiments that are described in the previous chapter. Costa-Gomes et al. (2001) consider four non-strategic types and five strategic types. *Altruists* maximize the sum of their and the opponent's payoffs. *Pessimists* make maximin decisions that maximize their payoffs over the minimum payoffs over all the choices of the opponents. *Optimists* make maximax decisions, i.e., maximize their payoffs over the maximum payoffs that arise by varying the opponents' actions. *Naive* players are $L1$ players who assume that the opponent chooses uniformly randomly over all possible actions. In addition to type $L2$, the four other strategic types are as follows.

1. The "Equilibrium type" is a player who satisfies the assumptions of traditional game theory in terms of cognition and rationality.
2. Type D1 (or Dominance 1) players engage in one round of iterated deletion of pure strategies and then play a best response assuming that the opponent will play each of the remaining strategies using a uniform probability distribution.
3. Type D2 (or Dominance 2) players engage in two rounds of iterated deletion of dominated strategies and then best respond by assuming a uniform probability distribution over the opponents' remaining strategies.

³⁷ There are four possible choices that relate to the adoption of two possible technologies, A and B. (1) Adopt no technology. (2) Adopt technology A only. (3) Adopt technology B only. (4) Adopt both A and B.

4. The “Sophisticated type” is a player who best responds to the (possibly) mixed strategies of other players, correctly forecasting the frequencies of the types of other players.

Costa-Gomes et al. (2001) build on the MOUSELAB experiments of Johnson et al. (2002) by exposing subjects in experiments to 18 normal form games that allow for various levels of iterated dominance. The strategy spaces in each game are fairly low (the games are either 2×2 , or 2×3 , or 2×4) and the experimental design minimizes learning effects and repeated game effects. Each game has a unique pure strategy equilibrium. The MOUSELAB interface for one of the games is shown in Figure 13.15. In order to minimize framing effects, (1) each player is treated as a row player and referred to as “You,” while the opponent is described as “S/He,” and (2) strategies of the row player are labeled as #,* while those of the column player are labeled as &, @. There are eight boxes corresponding to the payoffs (or points) for each player. The boxes in the first two columns show the payoffs of the row player, while the boxes in the last two columns show the payoffs of the column player. Moving the cursor to a box immediately reveals the contents. For instance, in Figure 13.15, the subject has moved the cursor to a box that reveals an own payoff of 42 when he plays # and the opponent plays @.

The design advantage of Costa-Gomes et al. (2001) over Johnson et al. (2002) is that individual searches can vary in three important dimensions.³⁸ Up–down searches in own payoffs and left–right searches in the opponent’s payoffs are suggestive of game theoretic reasoning. However, frequent transitions from own payoffs to the opponent’s payoffs are suggestive of social prefer-

³⁸ The work of Johnson et al. (2002) is described in the previous chapter.

ences. A baseline treatment was followed by a trained subjects treatment in which subjects were trained in identifying equilibrium outcomes. The findings are as follows:

1. There are systematic departures from equilibrium. Equilibrium strategies are more likely to be played when the game can be solved by one or two rounds of iterated dominance relative to cases where three or more rounds of iterated dominance are required.³⁹ Quantal response models would find it difficult to explain these findings.
2. Focusing on decisions alone (i.e., ignoring search and lookup data for the moment), there are high estimated frequencies of types *L2*, Naive (which is type *L1* here), Optimistic, and *D1*. The strategic types make up more than 70% of the types but the presence of Equilibrium and Sophisticated types is low. Type *D1* makes up about 20% of the sample.
3. The information searches of subjects are even more heterogeneous than their decisions (even when errors in decisions are taken into account). When search data is taken into account, along with data on actual decisions, the econometric results suggest that the most important types are Naive (i.e., *L1*) and *L2*; these make up about 67–89% of the population. Type *D1* players account for 0–20% of the subjects.

Brocas et al., (2014) consider two-player betting games that have three states and two-sided private information. Players observe one or two of the three states and must decide whether to bet or not. If at least one player chooses not to bet, then they each get a known payoff. If both bet, then they get a payoff that depends on the realized state. The payoffs are hidden in opaque boxes and players must click the boxes to reveal the payoffs. Following each round of the game, subjects are given feedback, so learning opportunities are present. Two different game situations, based on the degree of cognitive difficulty, are used—a simple situation and a more complex situation. The incidence of Nash equilibrium play in the simple and the complex games is, respectively, about 50% and 25%.

These results are in contrast to those from bargaining games in Section 12.5, where moving to the most cognitively challenging bargaining situation, bargaining under two-sided asymmetric information, improved the proportion of Nash choices. The pattern of lookups, using the MOUSELAB software, turns out empirically to be a good predictor about whether subjects will play Nash. There is substantial heterogeneity in choices that enables the separation of subject choices into four clusters. Three of these clusters enable the detection of play that is consistent with level-1, 2, and 3 players. A majority of subjects in these clusters do play in a manner that is consistent with the predictions of level-*k* models.

Costa-Gomes and Crawford (2006) consider 16 dominance solvable two-player normal form games of simultaneous moves called guessing games. The aim is to separate the various types of players more cleanly. Denote the two players by *i, j*, their respective guesses by x_i, x_j , their respective targets by $t_i > 0, t_j > 0$, and the respective domains of real numbers over which choices are made by $[a_i, b_i], [a_j, b_j]$. If a player makes a choice above the upper limit, then his choice is adjusted downwards to the upper limit. Conversely, if a player makes a choice below the lower limit, his choice is adjusted upwards to the lower limit. Denote the respective adjusted guesses of the players by $\hat{x}_i, \hat{x}_j$. The players make their guesses simultaneously following which the payoffs are realized.

Let $e_i = |\hat{x}_i - t_i \hat{x}_j|$ be the absolute value of how close player *i*'s guess is to the target times player *j*'s guess. The payoff of player *i* increases as $e_i \rightarrow 0$ and is highest at $e_i = 0$. Analogously,

³⁹ In games which can be solved by just two rounds of iterated deletion of strategies, the types *L2*, *D1*, and Equilibrium behave in an identical manner and so types can be confounded. This problem is addressed by considering a range of games with different structures.

the payoff of player j increases as $e_j = |\hat{x}_j - t_j \hat{x}_i|$ becomes closer to zero and is highest at $e_j = 0$. The games are dominance solvable in 3–52 rounds. The targets and limits of players vary independently from one game to the other.⁴⁰ In all games that are considered, $t_i t_j \neq 1$. The next proposition shows that in the unique equilibrium, if $t_i t_j < 1$, then the guesses of the players are determined by their lower limits a_i, a_j , while if $t_i t_j > 1$, then they are determined by their upper limit b_i, b_j .

Proposition 13.33

(i) Let $t_i t_j < 1$. Then in the unique equilibrium, the guesses of the two players are determined as follows.

$$\hat{x}_i = \begin{cases} a_i & \text{if } t_i a_j \leq a_i \\ \min \{t_i a_j, b_i\} & \text{if } t_i a_j > a_i \end{cases}; \hat{x}_j = \begin{cases} a_j & \text{if } t_j a_i \leq a_j \\ \min \{t_j a_i, b_j\} & \text{if } t_j a_i > a_j \end{cases}. \quad (13.36)$$

(ii) Let $t_i t_j > 1$. Then in the unique equilibrium, the guesses of the two players are determined as follows.

$$\hat{x}_i = \begin{cases} b_i & \text{if } t_i b_j \geq b_i \\ \max \{t_i b_j, a_i\} & \text{if } t_i b_j < b_i \end{cases}; \hat{x}_j = \begin{cases} b_j & \text{if } t_j b_i \geq b_j \\ \max \{t_j b_i, a_j\} & \text{if } t_j b_i < b_j \end{cases}.$$

Proof: (a) The proof involves checking that the various strategy profiles are a Nash equilibrium under the specified conditions. For part (i) we need to consider the following four cases. (1) $t_i a_j \leq a_i$ and $t_j a_i \leq a_j$. (2) $t_i a_j \leq a_i$ and $t_j a_i > a_j$. (3) $t_j a_i \leq a_j$ and $t_i a_j > a_i$. (4) $t_i a_j > a_i$ and $t_j a_i > a_j$. We only prove cases (1) and (2); the other two cases are similar, so they are omitted.

Consider case (1), $t_i a_j \leq a_i$ and $t_j a_i \leq a_j$. In this case, from (13.36), the claimed Nash equilibrium is $(\hat{x}_i, \hat{x}_j) = (a_i, a_j)$. To see that this is the case, conditional on $\hat{x}_j = a_j$, we have $e_i = |\hat{x}_i - t_i a_j|$. But $t_i a_j \leq a_i$, hence, the smallest possible value of e_i (and the highest payoff for player i) occurs when $\hat{x}_i = a_i$. Similarly, conditional on $\hat{x}_i = a_i$ we have that $e_j = |\hat{x}_j - t_j a_i|$ and $t_j a_i \leq a_j$. Thus, player j achieves his highest payoff by guessing $\hat{x}_j = a_j$.

Now consider case (2), $t_i a_j \leq a_i$ and $t_j a_i > a_j$. The claimed Nash equilibrium in this case is $(\hat{x}_i, \hat{x}_j) = (a_i, \min \{t_j a_i, b_j\})$. Conditional on the guess $\hat{x}_j = \min \{t_j a_i, b_j\}$ we have $e_i = |\hat{x}_i - t_i \min \{t_j a_i, b_j\}|$. First suppose that $\min \{t_j a_i, b_j\} = t_j a_i$, so $e_i = |\hat{x}_i - t_i t_j a_i|$. Since $t_i t_j < 1$ it follows that the minimum possible value of e_i (and highest payoff of player i) arises when $\hat{x}_i = a_i$, as claimed. If $\min \{t_j a_i, b_j\} = b_j$, then $b_j \leq t_j a_i$, hence, the lowest guess that player i can choose that is closest to $t_i \hat{x}_j$ is still $\hat{x}_i = a_i$. Now let us check that the guess of player j , $\hat{x}_j = \min \{t_j a_i, b_j\}$ is optimal given the guess of player i , $\hat{x}_i = a_i$. In this case, $e_j = |\hat{x}_j - t_j a_i|$ but $t_j a_i > a_j$. If $t_j a_i > b_j$, then the closest guess of player j to the guess of player i is $\hat{x}_j = b_j$. If on the other hand, $a_j < t_j a_i < b_j$, then the closest guess of player j is $\hat{x}_j = t_j a_i$. This completes the proof of part (i).

The proof of part (ii) is analogous to part (i), hence, it is omitted. ■

Subjects who make guesses consistent with Proposition 13.33 are known as Equilibrium types. Sophisticated types maximize their payoffs with the correct distribution of the other players in the sample.

Now consider the guesses of level- k players. Type $L0$ players make a uniform random guess over their intervals $[a, b]$. Type $L1$ players assume that all other players are of type $L0$.

⁴⁰ In the actual experiments, possible targets considered are 0.5, 0.7, 1.3, and 1.5 while the possible limits considered are [100, 500], [100, 900], [300, 500], and [300, 900].

Proposition 13.34 (Costa-Gomes and Crawford, 2006): Suppose the point payoff function of player i is $e_i = g(x_i - t_i x_j)$ where g is symmetric, continuous, almost everywhere differentiable function that is weakly decreasing in $|x_i - t_i x_j|$, where $\hat{x}_i$ is a random variable uniformly distributed on $[a, b]$. Then, for any player with a continuous, almost everywhere differentiable von Neumann–Morgenstern utility function u , his expected-utility maximizing choice is $x_i^* = t_i \left(\frac{a+b}{2} \right)$. If $t_i \left(\frac{a+b}{2} \right) > b$, then $\hat{x}_i = b$ and if $t_i \left(\frac{a+b}{2} \right) < a$, then $\hat{x}_i = a$.

Given the result in Proposition 13.34, the remaining guesses of higher-level players are straightforward. Player i of type $L2$ believes that others are of type $L1$, hence, $e_i = \left| \hat{x}_i - t_i \frac{a+b}{2} \right|$, which is minimized by a guess of $\hat{x}_i = t_i \frac{a+b}{2}$. If this guess falls outside some interval $[c, d]$ over which the player is allowed to guess then the guess is adjusted to the lower or the upper interval, whichever is nearest. Analogously, player i of type $L3$ makes the guess $\hat{x}_i = t_i^2 \frac{a+b}{2}$ and so on.

There were a total of 88 subjects in the main treatment. The guesses of 43 subjects conformed (within a very small margin of error) with the guesses of level- k types in 10 out of the 16 games. Of these the guesses of 12 subjects matched $L2$ very closely; 72% of the guesses were exact, which is difficult to ascribe to chance because there were 200–800 possible exact guesses in each game. The experimental design builds in risk neutrality and self-interested behavior, hence, the presence of level- k types is not the result of Equilibrium types making guesses that are confounded by issues of risk aversion or social preferences.

Based on the decisions made by subjects, the econometric analysis shows up the presence of only types $L1$, $L2$, $L3$, and Equilibrium. The breakdown was: 20 $L1$ types, 12 $L2$ types, 3 $L3$ types, and 8 Equilibrium types. The data reveals the complete absence of the Dominance types (e.g., types $D1$, $D2$ in the study of Costa-Gomes et al., 2001) as well as the Sophisticated types. The data is also hard to reconcile with QRE.

A MOUSELAB interface was used to elicit the search and lookup patterns of subjects. Subjects were presented with a six box display. Among the boxes, they could search for their own and their partner's limits and targets and then enter a guess. The maintained hypothesis is that each subject belongs to one of the types: Level- k , Dominance, or Equilibrium. The search pattern was then matched to types. Consider, for instance, a player i of type $L1$ whose ideal guess is $t_i (a + b) / 2$. Hence, the lookups must involve elements of the set $\{[a_j, b_j], t_i\}$ in any order. We leave it to the reader to construct the predicted lookup patterns of types $L2$, $L3$, $D1$, $D2$, Equilibrium, and Sophisticated.⁴¹

The searches of types $L1$, $L2$, and Equilibrium, were very similar in the baseline and the robot conditions. In the robot condition, subjects play against a robot in order to switch off their social preferences. The robots are preprogrammed to play a particular decision rule. Unlike the results in Johnson et al. (2002), explained in the previous chapter, the robot treatment does not nudge behavior towards equilibrium. In conjunction, the search and decision data confirm that a significant fraction of players are of types $L1$, $L2$, Equilibrium, or apparent combinations of Equilibrium and $L3$ types. Irrationality or social preferences can be ruled out as factors contributing to the departure from equilibrium behavior of subjects. In several cases, when the type of the subject is not evident from decisions (or guesses) alone, the search data on lookups is able to clarify the type of the subject.⁴²

⁴¹ The answers can be found in Table 4, page 1751 of Costa-Gomes and Crawford (2006).

⁴² For instance, the guesses of subject "309" seem to identify the subject as clearly type $L2$. However, when the search data was examined, it was entirely inconsistent with the pattern of lookups for a type $L2$.

Georganas et al. (2012) consider the stability of level- k types across two kinds of two-player games—undercutting games and guessing games. The guessing game is as in Costa-Gomes and Crawford (2006). The undercutting game is characterized by two integers p, q . Two players choose integers from the identical strategy sets $s_i = \{1, 2, \dots, p, \dots, q\}$, $i = 1, 2$. Any player $j = 1, 2$ pays player $i \neq j$ an amount \$10 if $s_i = p < s_j$ or if $1 + s_i = s_j \leq p$. If player i expects that the opponent will choose an integer greater than p , then the best response is $s_i = p$. If the expectation is that the opponent will choose an integer less than or equal to p , then the best response is $s_i = s_j - 1$, i.e., undercut by 1 the guess of the other player. If both players choose the number 1, then both earn a payoff of one. If both choose the highest number q , then they both lose 11 (this rules out mixed strategy Nash equilibria). If one player chooses 1 and the other chooses q , then the player choosing 1 loses 11. In all other cases, players earn a payoff of zero. In the unique Nash equilibrium, both players choose the number 1. The subjects in experiments are shown payoff tables corresponding to this game. The players play four undercutting games, UG1-UG4, and six guessing games, GG5-GG10.

For pooled data in the undercutting games, the percentage of types $L0$, $L1$, $L2$, $L3$, and Equilibrium (those who play the Nash equilibrium) are, respectively, 4.31, 28.45, 26.72, 5.17, 35.34. The corresponding percentages for the pooled data from the guessing games are 1.72, 50, 10.34, 10.34, and 27.59. These findings are somewhat similar to those in Costa-Gomes and Crawford (2006) except that the proportion of Equilibrium players in the undercutting games is significantly higher. In the four undercutting games, the distribution of types is similar. However, the distribution of types in the six guessing games is quite variable. For instance, the percentage of $L0$ players varies from 0.68% in GG6 to 43.10% in GG7; the percentage of $L1$ players goes up from 37.07% in GG7 to 70.69% in GG5. There is similar variability in the proportion that play Nash.

Another difference is that while Costa-Gomes and Crawford (2006) find that 48.9% of the choices are exact matches with the predictions of level- k models, this percentage is only 14.22 in the case of Georganas et al. (2012). Thus, one needs to fit the behavior of subjects by assuming that they play noisy best responses. The authors use five psychometric measures: An IQ quiz, an eye gaze test, memory quiz, the Cognitive Reflection test (CRT), and a one-player Takeover Game. But correlations in scores obtained by players in the psychometric measures are low and these measures are not able to predict the types of players in the level- k model.

The main argument in Georganas et al. (2012) is that the variability of types in the guessing game and stability in the undercutting games suggests that the level- k model may be a heuristic that is triggered in some games and not in others. They are unable to identify what activates the trigger to use a level- k model, identifying a possible limitation in the use of the level- k model. What accounts for the difference in their results from Costa-Gomes and Crawford (2006)? They argue that the source is the difference in instructions. The Costa-Gomes and Crawford (2006) instructions are extremely detailed and prior to the experiments, subjects were required to calculate their best responses to hypothetical questions and to hypothetical strategies of the opponent. This may have primed them to play an exact best response in the guessing games. By contrast, the instructions in Georganas et al. (2012) are minimal and subjects are not primed to play any best responses.

13.4.6 *Do non-strategic players exist?*

The estimates from Costa-Gomes et al. (2001) and other studies such as Stahl and Wilson (1994, 1995) and Costa-Gomes et al. (2006) show that type $L0$ players exist mainly as a model

that players of type $L1$ have about their opponents. However, several recent papers also make an intriguing case for the presence of non-strategic players. We now consider some of these papers.

Costa-Gomes and Weizsäcker (2008) consider 14 normal form two-player games. They record the actions of players in these games and also elicit their beliefs about other players. The beliefs are elicited using incentive compatible mechanisms. The behavior of subjects is largely inconsistent in the sense that the actions taken by the players are not consistent with their stated beliefs. One possible resolution to the problem is that players do not optimize. In order to account for this problem, a noisy best response model is used, however, the inconsistency remains. A second possibility is that players are not able to optimize due to cognitive limitations. To test this possibility, players were provided with calculators, yet the inconsistency remained. Eight behavioral models are used to fit the data. It appears that the play of subjects is consistent with level $L1$ players who expect their opponents to randomize over their actions. However, the elicited beliefs reveal that they expect their opponents to be of type $L1$ as well. This is problematic because then they should optimally be choosing strategies that are consistent with type $L2$ players. The authors rule out possible explanations of their results based on risk aversion and social preferences. In a similar vein, Danz et al. (2012) find that for repeated games, when no feedback is given, there is very little consistency between beliefs and actions. With feedback, the consistency improves but is not perfect.

Agranov et al. (2012) consider the presence of non-strategic players, defined as those who choose a dominated action in a p -beauty contest game in which $p = \frac{2}{3}$. They also check for the portability of strategic thinking by then asking subjects to play a Monty Hall problem. The authors implement a choice process from Caplin et al. (2011) in which subjects have a chance to reflect on their choices for a fixed length of time. The pattern of their choices is then used to classify them into alternative types.

Subjects in experiments were told that the p -beauty contest with $p = \frac{2}{3}$ was played with eight undergraduate students. If the subject can come up with a choice that is better (closer to $\frac{2}{3}$ of the average of the choice of the eight students), then they win a prize of \$10. Importantly, the choice of the subjects in experiments does not alter the original choices of the eight students. Two sub-treatments are run in which subjects are given, respectively, 180 and 30 seconds to make a choice.

In the *strategic choice process treatment* (SCP), the two sub-treatments of 180 and 30 seconds were run but with one important difference. Subjects could make as many choices as they wanted to during the respective time intervals. One of the seconds in each case is then chosen at random and the prevailing choice of the subject at that second is picked to reward the subject. In the $\frac{2}{3}$ -beauty contest, where subjects pick a number from $[0, 100]$, picking a number greater than 67 is a dominated strategy. *Naive players* are defined as those who choose a number greater than 67 at least once after 30 seconds or more in the experiments. Players who are not naive are classified as *strategic players*.

In the SCP experiments, 43.3% of the players were classified as naive players. If one used simply the final choice of the subjects, then 5% of the subjects are classified as naive. The authors argue that using final choices, thus, underestimates the proportion of naive players. The average choice of the naive players was 50 using either the final choices or the intermediate choice data. This is consistent with the assumed choice of level $L0$ players in level- k models. Over the relevant time period that subjects make choices in the SCP experiments, naive players change their choices more frequently, in a statistically significant sense, as compared to strategic players. Strategic players also converge much faster to their eventual choices. Another indicator of strategic reasoning is to see if players alter their guesses, over time, in steps of $\frac{2}{3}$ times their previous

choices (within some reasonable margin, chosen to be 5% by the authors). Strategic players make a larger number of such strategic choices as compared to naive players.

The portability of these results is tested using the Monty Hall game. In this game, subjects are shown three closed doors and told that there is a \$5 reward behind one of the three doors and nothing behind the other two doors. Each subject is then invited to choose one closed door. Having chosen the door, the experimenter reveals to the subject that he knows which of the doors hides the \$5 prize. The experimenter then opens one of the other doors that does not have the prize. Conditional on the move of the experimenter, should the subject keep to his original choice of the door or choose the other door? It can be shown that the subject can increase the probability of winning by altering his choice.⁴³ A probit regression is used in which the dependent variable equals 1 if the subject altered his choice and 0 otherwise. The main finding is that naive subjects are less likely to switch doors, while among strategic subjects, those who end with lower final choices (relative to intermediate choices) are more likely to switch doors. Thus, there seems to be an element of portability of strategic behavior across games in these experiments.

De Sousa et al. (2013) consider the possibility of non-strategic players among a pool of 270 chess players. In phase 1, the subjects played ten p-beauty contest games with $p = \frac{2}{3}$ and $p = \frac{4}{3}$; the guesses were chosen from the interval $[0, 100]$. Subjects played these games against other subjects classified into types A, B, C, or D based on their Elo chess rankings. A random type was also introduced; such a type chose numbers at random. Five games each were played with values of $p = \frac{2}{3}$ and $\frac{4}{3}$ against each of these five possible opponents.

In phase 2, subjects played a new game, the 11–20 game against another chess player of unspecified Elo ranking. In this game, due to Arad and Rubinstein (2012), two players must simultaneously request a number between 11 and 20 shekels. Both players receive their requests. In addition, if a player requests exactly one shekel less than the other player, he receives an extra 20 shekels. There is a unique, symmetric, mixed strategy Nash equilibrium in which players choose numbers 11–14 with probability zero, numbers 15 and 16 with probability $\frac{1}{4}$ and numbers 17, 18, 19, and 20 with respective probabilities $\frac{4}{20}$, $\frac{3}{20}$, $\frac{2}{20}$, $\frac{1}{20}$. In phase 3, subjects were given the chance to participate in a p-beauty contest game with $p = \frac{2}{3}$ against all other participants.

In the p-beauty contest with guesses allowed in the interval $[0, 100]$ the Nash prediction with $p = \frac{2}{3}$ is a guess of zero, while with $p = \frac{4}{3}$ it is 100. The authors define non-strategic players as those who choose a higher guess under $p = \frac{2}{3}$ as compared to under $p = \frac{4}{3}$. The number of times that players engage in such non-strategic choices when playing against the same opponent allows the authors to construct a pairwise rationalizable actions index (PRAI) that takes integer values between 0 and 5. A value of 0 for the index indicates that players consistently make non-strategic choices (i.e., relatively lower numbers chosen under $p = \frac{4}{3}$ as compared to under $p = \frac{2}{3}$), while a value of 5 indicates that they never make such choices. Intermediate values of the index, 2, 3, and 4 indicate decreasing non-strategic choices. Individuals with a PRAI index of 0–3 are classified as non-strategic and those with 4–5 are classified as strategic.

The non-strategic players do not react to changes in p from $\frac{2}{3}$ to $\frac{4}{3}$ and their mean play is close to a choice of 50.⁴⁴ On the other hand, strategic players show significant changes in guesses as p changes. Their average guess is 36.12 when $p = \frac{2}{3}$ and 70.09 when $p = \frac{4}{3}$. In each case, their

⁴³ Ex-ante, the probability that the chosen door hides the \$5 prize is $\frac{1}{3}$ and the probability that the other two doors contain the hidden prize is $\frac{2}{3}$. Conditional on the experimenter opening one of the doors and showing the absence of the prize, the remaining door now has a $\frac{2}{3}$ probability of containing the prize. This is greater than the $\frac{1}{3}$ probability associated with the player's chosen door.

⁴⁴ The average choice is 48.98 when $p = \frac{2}{3}$ and 51.25 when $p = \frac{4}{3}$.

behavior is roughly consistent with level $L1$ players who best respond to beliefs that other players are level $L0$ players who choose uniformly randomly. Strategic players earn more in the game relative to non-strategic players. Non-strategic players do not spend any less time contemplating about their guesses as compared to strategic players. Thus, the difference in guesses probably lies in the different manner in which they process the relevant information. Interestingly, when p changes, non-strategic players react in terms of the time spent on making their guesses, however, their mean guesses do not change. Changing the stakes has no effect on these results. Higher Elo rankings of chess players are not significantly correlated with their position on the PRAI index.

In phase 2, the authors added four comprehension questions to the 11–20 game. Non-strategic players made more mistakes in answering these questions relative to strategic players. Players typically fail to play the equilibrium strategies in the 11–20 game (as in Arad and Rubinstein, 2012). However, players who are ranked higher on the PRAI index in the p-beauty contest game make choices that are closer to equilibrium suggesting some portability of results.

Burchardi and Penczynski (2014) consider a p-beauty contest played between two teams of two players each. There are two stages. In the first stage, each player conveys a message to his team member along with a written justification that has no time limits or size limits. The number suggested in this stage is termed the *suggested decision*. This stage allows players to influence the team member's decision. In the second stage, players simultaneously make choices for the team—such choices are known as *final decisions*. The final decision of each player is chosen with probability one half and termed as the team *decision*; this is the basis on which the team's reward is decided. The suggested decision reflects an individual's reasoning and corresponds to choices in the existing p-beauty contest experiments. This is the basis for the statistical analysis. The final decision, by contrast, does not reflect individual decision making.

A total of 84 subjects played three rounds of a p-beauty contest with $p = \frac{2}{3}$. Unlike many other studies, students do not play any test rounds that involve strategic considerations. This ensures that students are not already primed to respond in a particular manner. The messages sent by the players in the first stage are then analyzed to classify them into various types of players. Since the messages are written in free-form text, two trained research assistants are employed to classify the messages into categories such as level- k players, Equilibrium players, and Sophisticated players.⁴⁵ Within level- k players, the research assistants are asked to state the lower and upper bounds on levels. This classification is rechecked by three more research assistants. Only when there is sufficient consensus among the research assistants on the response of a subject is the data on the subject included into the statistical tests.

The results are as follows. The mean of the suggested decisions in the first stage is 43.93 that is slightly higher than Nagel's (1995) figure of 36.73. For 50 out of the 84 subjects for which the lower and upper bounds coincide, there were 17 players of level $L0$, 26 players of level $L1$, 6 players of level $L2$, and 1 player of level $L3$. For 20 out of the remaining subjects for which the upper and lower bounds differ, the bounds are nevertheless between players of level $L0$ and $L2$. The behavior of one player each is consistent with the Equilibrium and the Sophisticated types. While 20% of the players are unambiguously of type $L0$, the possibility that a further 24 out of the 84 players are of type $L0$ cannot be excluded. In taking their final decisions, lower level- k players are influenced by the first stage messages sent by higher level- k players.⁴⁶

⁴⁵ Equilibrium players play in conformity with a Nash equilibrium and suggest a choice of zero, while Sophisticated players may figure out the equilibrium choice but prefer to play a non-equilibrium action, possibly because they believe that others are less than fully rational in the Nash sense.

⁴⁶ This particular result appears in a companion paper by Penczynski (2012).

The hypothesis that the level $L0$ players make uniform random choices is rejected using a Kolgomorov–Smirnov test. A structural level- k model fitted to the data reveals the following proportions of types. 37% are type $L0$, 47% are type $L1$, 15% are type $L2$, and 1% are type $L3$. The authors hypothesize that the relatively larger percentage of type $L0$ players in their sample, relative to many other studies (e.g., Camerer et al., 2004a) is due to the different methodologies employed by the studies and the nature of the pre-experimental instructions, particularly on account of the priming for strategic thinking that is implicit in the test questions.

13.5 Psychological game theory

In this section we consider psychological game theory. Consider an extensive form game in which the set of players is given by $N = \{1, 2, \dots, n\}$. Let Z be the set of terminal nodes of the game. In classical game theory, the utility function of player $i \in N$ is given by the mapping $u_i : Z \rightarrow \mathbb{R}$. In particular, the utility function does not depend on the beliefs of players about the choices and beliefs of other players. However, in a range of situations, it appears that the beliefs of players about the choices and the beliefs of others directly impact their utility.

Example 13.8 (*Guilt*): John frequently visits cities A and B , and he typically uses a taxi to get around. In city A , tipping a taxi driver is considered insulting, while in city B it is the norm to tip a percentage of the fare. Suppose that it is common knowledge that if taxi drivers do not receive a tip, they quietly drive away. In city A , John gives no tip, and feels no remorse from not giving it. However, in city B , the taxi driver expects John to give him a tip (taxi driver's first order belief) and John believes that the taxi driver expects a tip from him (John's second order belief). Based on his second order belief, John cannot bear the guilt of letting the taxi driver down and not paying the tip. Thus, he tips every time he takes a taxi in city B . Clearly, John does not have a utility function of the form $u_i : Z \rightarrow \mathbb{R}$. His utility seems to depend on his beliefs about the beliefs of others.

Guilt is just one of the emotions that creates a potential departure from the classical specification of utility, $u_i : Z \rightarrow \mathbb{R}$. However, players may derive additional psychological utility or disutility from a range of other emotions relating to kindness, anger, surprise, malice, joy, and hope, that can be captured by the beliefs in the game (Elster, 1998).

Can one not simply adjust the material payoffs in classical game theory to take account of such psychological utilities? As Geanakoplos et al. (1989) note in their pioneering paper, this solution will not work because *beliefs themselves are endogenous*. Hence, a new approach, *psychological game theory*, is needed to analyze such situations. Heuristically, if the set B captures the first and higher order beliefs of all players in the game, then in psychological game theory, the utility function takes the form $u_i : Z \times B \rightarrow \mathbb{R}$.⁴⁷ In equilibrium, one requires the actions of players to be consistent with beliefs of first, second, and higher orders and for the beliefs themselves to be consistent in a manner to be specified below. Most applications that we consider truncate beliefs at order 2. Clearly, explicitly incorporating higher order beliefs will be even more cognitively challenging for the players.

We now give further motivating examples in which we only consider first and second order beliefs, followed by a more formal development of the relevant theory.

⁴⁷ Gilboa and Schmeidler (1988) is an early attempt to model hierarchies of initial beliefs of players but they were mainly interested in issues of common knowledge in a manner that does not play a central role in modern psychological game theory.

Figure 13.16 The bravery game.

Example 13.9 (Geanakoplos et al., 1989: *The Bravery Game*) Consider the extensive form game is shown in Figure 13.16. There are two players, 1 and 2. Player 1’s strategy can take one of two possible values from the set {bold, timid}. Suppose that player 1 plays a mixed strategy in which he is bold with probability p and timid with probability $1 - p$. Player 2 is passive and does not choose any actions in the game. The monetary payoffs of the two players from the actions bold and timid, respectively, are $(2, 2)$ and $(3, 1)$.

A “psychological game” specifies, in addition to a classical extensive form game, the beliefs of players and the utility function is given by $u_i : Z \times B \rightarrow \mathbb{R}$. We only consider the first and second order beliefs. Since there is only one decision node in the game, the only relevant beliefs are the initial beliefs. In games with multiple sequential nodes, we need to take account of the revision in beliefs of the players. Let b_2^1 be the first order belief of player 2 about the probability, p , with which player 1 will play the strategy “bold.” Throughout, we will use the superscript on b for the order of beliefs and the subscript for the player. Let b_1^2 be the second order belief of player 1 about b_2^1 . Thus, beliefs are constructed in a hierarchical manner. Player 2 cares about his belief about how bold player 1 is (i.e., b_2^1). Player 1 cares about his belief about what player 2 thinks of his boldness (i.e., b_1^2). Interpret the payoffs at the terminal nodes that are inclusive of psychological beliefs as utilities.

Player 2 likes player 1 to be bold. At the upper branch where player 1 is revealed to be bold, player 2 receives a utility of $2(1 + b_2^1)$. The stronger player 2’s initial beliefs are that player 1 is bold (higher b_2^1), the greater is his utility from being vindicated. At the lower branch, where player 1 is revealed to be timid, the utility of player 2 drops to $1 - b_2^1$; a higher ex-ante confidence in the boldness of player 1, now hurts player 2 even more. Player 1 prefers to be timid rather than bold, so irrespective of his action, his utility is decreasing in his belief in the confidence that player 2 has in his boldness, b_1^2 .

Note that utilities at the terminal nodes are functions of beliefs, which are themselves endogenous. Hence, we cannot simply apply the backward induction argument of classical game theory. In this simple game, a “psychological equilibrium” arises when (i) conditional on the beliefs, players maximize their utilities, and (ii) strategies and beliefs coincide, i.e.,

$$p = b_2^1 = b_1^2.$$

The bravery game has the following three psychological equilibria.

- (a) $p = b_2^1 = b_1^2 = 1$. In this equilibrium, player 1 plays the strategy bold with probability 1 and the first and second order beliefs reflects this. Given $b_2^1 = b_1^2 = 1$, the strategy

- “bold” strictly dominates “timid,” so any deviation from $p = 1$ reduces the utility of player 1. The utilities of players 1 and 2 are, respectively, 1 and 4.
- (b) $p = b_2^1 = b_1^2 = 0$. In this equilibrium, player 1 plays the strategy timid with probability 1. When $b_2^1 = b_1^2 = 0$, the utility of both players corresponds to the material payoffs only. Hence, player 1 chooses his materially dominant strategy, timid. The respective utilities of the two players are 3 and 1.
- (c) $p = b_2^1 = b_1^2 = 0.5$. Player 1 randomizes equally between his two pure strategies and his utilities from both pure strategies are identical. The expected utility of player 1 is 1.5, while that of player 2 is 1.75.

The utility of player 1 is highest in case (b) where player 2 does not expect player 1 to be bold. As the expectation of player 2 about the boldness of player 1 successively increases, in cases (c) and (a), the utility of player 1 falls. Thus, player 1 benefits most if player 2 holds the most pessimistic expectations about his boldness.

Battigalli and Dufwenberg (2007) consider the role of guilt in the formation of beliefs. Consider the following simple example.

Example 13.10 (Dufwenberg, 2008: Guilt in psychological games.) Consider the two-player sequential move game in Figure 13.17. Player 1 derives utility only from material payoffs but player 2 derives utility from psychological payoffs as well. Suppose that player 2 plays r with probability p . Player 1 believes that player 2 will play r with probability b_1^1 (player 1’s first order beliefs) and the beliefs of player 2 about b_1^1 are given by b_2^2 (player 2’s second order beliefs).

Let us interpret the payoffs of the players at the terminal nodes as utilities. The utility of player 2 from the action profile (d, l) suggest that he is guilt-averse. The higher is b_2^2 , i.e., his belief that player 1 expects him to play r , the lower is the guilt-ridden utility of player 2 from playing l . In a psychological equilibrium of this game,⁴⁸ we require that (i) conditional on their beliefs, players maximize their utility comprising of material and psychological payoffs, and (ii) there is equality of the actual probability with which an action is played and the first and second order beliefs. So, we require that

Figure 13.17 A guilt game.

Source: Dufwenberg (2008). Setten Durlauf, *The New Palgrave Dictionary of Economics*, published 2008, Palgrave Macmillan UK, reproduced with permission of Palgrave Macmillan.

⁴⁸ A formal definition of a psychological equilibrium is given below.

$$b_1^1 = b_2^2 = p. \quad (13.37)$$

In the absence of “guilt aversion” (i.e., if we substitute 3 for $3(1 - b_2^2)$ in Figure 13.17) in the subgame beginning with player 2’s information set, l is the preferred strategy. However, the presence of guilt aversion could induce player 2 to play r instead.

One equilibrium is as follows. Let $b_1^1 = b_2^2 = 1$, player 2 plays r with probability $p = 1$ and player 1 plays d with probability 1. Given the psychological payoffs, this outcome is subgame perfect and satisfies (13.37). See Battigalli and Dufwenberg (2009) for discussion of how this equilibrium may furthermore be justified via a “psychological forward induction” argument.

Example 13.11 Charness and Dufwenberg (2006) conducted trust game experiments in which preplay communication was allowed. For instance, the second mover in a trust game, the trustee, could, in the preplay communication round, send a costless message to the first mover that she will reciprocate the first mover’s (trustor’s) trust. In traditional game theory, this is simply cheap talk and will not affect the outcome. However, Charness and Dufwenberg find that such preplay communication increases the likelihood of trust and trustworthiness. Guilt aversion provides one possible rationalization of these results. Once having made a promise, the trustee feels guilty if he lets down the expectations of the trustor. This model and the results are considered in greater detail in Section 13.5.5.

These results suggest that preplay communication can be a useful coordination device to narrow down the set of equilibria. Not only is the model useful to explain reciprocity in the gift exchange game, it can potentially explain behavior in diverse contexts such as collusion in oligopolistic markets (again through the effectiveness of preplay communication) and tipping behavior in restaurants. The model is thus useful in the domain of positive reciprocity, but does not attempt to explain why individuals hurt each other in negative reciprocity games.

13.5.1 Psychological Nash equilibria in single-stage games

Many factors that are salient in psychological games, for instance, guilt and reciprocity, require an extensive form game in which players move in sequence. However, the resulting general framework based on a refinement of sequential equilibrium for multi-stage games with conditional belief hierarchy may be fairly complicated for readers not already initiated in this area.⁴⁹ Hence, following Geanakoplos et al. (1989), there is pedagogical merit in considering first, a single-stage simultaneous move game.

Let $N = \{1, 2, \dots, n\}$ be the set of players. For any player $i \in N$, the pure strategy set is given by $S_i \subseteq \mathbb{R}$. The set of pure strategy profiles in the game is given by $S = \times_i S_i$. The pure strategy profiles of players other than player i are given by $S_{-i} = \times_{j \neq i} S_j$. The set of all possible mixed strategies of player $i \in N$ is given by $\Sigma_i = \Delta S_i$. The set of all mixed strategy profiles of all players is given by $\Sigma = \times_i \Sigma_i$. The mixed strategy profiles of players other than i belong to the set $\Sigma_{-i} = \times_{j \neq i} \Sigma_j$.

Let B_i^k be the set of k th order beliefs of player i . The beliefs are constructed recursively in a hierarchical manner, as follows. The set of first order beliefs of player i is given by

$$B_i^1 = \Delta S_{-i}, i \in N. \quad (13.38)$$

⁴⁹ See Battigalli and Dufwenberg (2009), that we consider below, for the most general framework.

First order beliefs are simply probability distributions over the pure strategy profiles of others. Define $B_{-i}^1 = \times_{j \neq i} B_j^1$ as the set of first order beliefs of all players other than player i . Then the set of second order beliefs of player i is given by

$$B_i^2 = \Delta(S_{-i} \times B_{-i}^1), i \in N. \quad (13.39)$$

From (13.39), second order beliefs are distributions over the opponents' strategy choices and the opponents' first order beliefs. Proceeding analogously, the set of third order beliefs of player i is given by

$$B_i^3 = \Delta(S_{-i} \times B_{-i}^1 \times B_{-i}^2), i \in N,$$

where $B_{-i}^2 = \times_{j \neq i} B_j^2$ is the set of second order beliefs of players other than player i . Thus, third order beliefs allow for a correlation between strategies, first order beliefs, and second order beliefs of others. In general, beliefs of order $k > 1$ are given by

$$B_i^k = \Delta(S_{-i} \times B_{-i}^1 \times B_{-i}^2 \times \dots \times B_{-i}^{k-1}). \quad (13.40)$$

The hierarchy of beliefs of any player $i \in N$ is denoted by $B_i = (B_i^1, B_i^2, B_i^3, \dots) \in \times_{j=1}^{\infty} B_i^j$. The profile of the hierarchy of beliefs of all players is then given by $B = (B_1, B_2, \dots, B_n) \in \times_{i=1}^n B_i$. In most applications that we consider, it suffices to take into account only beliefs of order $k = 2$. Given the cognitive limitations of humans, it would be surprising if beliefs of order 4 or above played a major role in human decisions, although this is entirely an empirical matter.

Using (13.39), we can recover from $\Delta(S_{-i} \times B_{-i}^1)$, the first order beliefs of the other players by taking the marginal distribution with respect to S_{-i} . If these beliefs coincide with the first order beliefs given in (13.38), then the first and second order beliefs are said to be *coherent*. In general, the beliefs of a player are coherent if the marginals computed from the k th order beliefs coincide with the $k - 1$ order beliefs for all $k > 1$.

In what follows, beliefs are assumed to be coherent for each player $i \in N$.⁵⁰ We also assume mutual knowledge of coherency, so no player believes that the beliefs of any other player are incoherent.

Example 13.12 Consider a two-player, simultaneous move game in normal form in which the strategy sets of the row player and the column player are, respectively, $S_1 = \{U, D\}$ and $S_2 = \{L, R\}$. We only consider beliefs up to order $k = 2$. Let the first order beliefs of the players be given by

$$b_1^1 = \{\sigma_2(L) = q, \sigma_2(R) = 1 - q\}, b_2^1 = \{\sigma_1(U) = p, \sigma_1(D) = 1 - p\}, \quad (13.41)$$

where $p, q \in [0, 1]$, $b_1^1 \in B_1^1 = \Delta S_2$ and $b_2^1 \in B_2^1 = \Delta S_1$ and $\sigma_i(x)$ is the probability with which player $i = 1, 2$ plays the pure strategy x . Suppose that the second order beliefs of player 1, $b_1^2 \in B_1^2$, defined in (13.39), are given as follows.

1. With probability $r_1 \in [0, 1]$, player 2 plays L and his first order beliefs are that player 1 plays U with probability $p_1 \in [0, 1]$ and D with probability $1 - p_1$.

⁵⁰ We avoid introducing extra notation for coherent beliefs, say, $\bar{B}_i$. But if this is confusing, the reader may, henceforth, wish to use the notation B_i for the belief hierarchy of player i and the notation $\bar{B}_i$ for the coherent belief hierarchy of player i .

2. With probability $r_2 \in [0, 1]$, player 2 plays L and his first order beliefs are that player 1 plays U with probability $p_2 \in [0, 1]$ and D with probability $1 - p_2$.
 3. With probability $1 - r_1 - r_2 \in [0, 1]$, player 2 plays R and his first order beliefs are that player 1 plays U with probability $p_3 \in [0, 1]$ and D with probability $1 - p_3$.
- The beliefs of player 1 must be coherent in the following sense. From (13.41), the first order beliefs of player 1 are that player 2 plays L with probability q . We can also recover the probability that player 1 assigns to L from the marginals of his second order beliefs. This probability is $r_1 + r_2$. Hence, coherency requires that $q = r_1 + r_2$.

The utility function of player $i \in N$ is given by

$$\bar{u}_i : B_i \times S \rightarrow \mathbb{R}. \quad (13.42)$$

Denote the vector of utility functions by $u = (u_1, u_2, \dots, u_n)$. Under any mixed strategy profile, $\sigma \in \Sigma$, player $i \in N$ maximizes his expected utility function, $u_i : B_i \times \Sigma \rightarrow \mathbb{R}$, such that

$$u_i(b_i, \sigma) = \sum_{s \in S} (\sigma_1(s_1) \times \sigma_2(s_2) \times \dots \times \sigma_n(s_n)) \bar{u}_i(b_i, s), \quad b_i \in B_i. \quad (13.43)$$

Definition 13.10 (Normal form psychological game): A normal form psychological game is given by $G_P = (N, S, u)$, where the utility function of any player $i \in N$ is given in (13.43).

A mixed strategy profile $\sigma^* = (\sigma_i^*, \sigma_{-i}^*) \in \Sigma$ is a psychologically consistent profile of strategies if it is consistent with the beliefs of players of all orders. For instance, let $N = 2$. Then (σ_1^*, σ_2^*) is a psychologically consistent profile of strategies if $b_1^1 = \sigma_2^*$, $b_2^1 = \sigma_1^*$, $b_1^2 = \sigma_1^*$, $b_2^2 = \sigma_2^* = \dots$. More generally, $(\sigma_i^*, \sigma_{-i}^*)$ is a psychologically consistent profile of strategies if for all i , $b_i^1 = \sigma_{-i}^*$, $b_{-i}^1 = \sigma_i^*$, $b_i^2 = \sigma_i^*$, $b_{-i}^2 = \sigma_{-i}^* = \dots$.

Definition 13.11 (Psychological Nash equilibrium): A psychological Nash equilibrium of a normal form psychological game, $G_P = (N, S, u)$, is a pair (b^*, σ^*) such that:

1. Given b^* , the strategy profile σ^* is a psychologically consistent profile of strategies.
2. $u_i(b_i^*, (\sigma_i^*, \sigma_{-i}^*)) \geq u_i(b_i^*, (\sigma_i, \sigma_{-i}^*))$ for all $i \in N$ and for all $\sigma_i \in \Sigma_i$.

Proposition 13.35 (Geanakoplos et al. 1989): Let G_P be a normal form psychological game. If for all $i \in N$, $u_i : B_i \times \Sigma \rightarrow \mathbb{R}$ is continuous and $B_i \times \Sigma$ is compact, then a psychological Nash equilibrium exists for the game G_P .

The proof of Proposition 13.35 is similar to the existence of a Nash equilibrium in normal form games, so it is omitted.⁵¹

Players may also derive utility from their beliefs about the beliefs of other players about others, not just beliefs about them.⁵² The next example illustrates such a case.

Example 13.13 [Geanakoplos et al. 1989] Suppose that player 1 takes a stranger on a date. Nature (player 0) chooses two possible types of strangers, player 2 and player 3, with equal probability. Player 2 accepts the proposal of player 1 with probability p and player 3 accepts the proposal with probability r . The payoffs at the terminal nodes are in the order of players 1, 2, and 3, respectively. Player 3 only cares for material payoffs and in the event that she is

⁵¹ The interested reader can see the proof in Geanakoplos et al. (1989, pp. 68–9).

⁵² Notice that for any player, $i \in N$ such beliefs also belong to the set B_i .

Figure 13.18 The confidence game in Geanakoplos et al. (1989).

Source: Reprinted from *Games and Economic Behavior*, 1(1): 60–79. Geanakoplos, J., Pearce, D., and Stacchetti, E., “Psychological games and sequential rationality.” Copyright © 1989, with permission from Elsevier.

proposed, she receives a payoff of 1 from rejecting and 0 from accepting, so she always rejects. Players 1 and 2 care for material and psychological payoffs.

Let the first order beliefs of player 1 about p and r be, respectively, b_{12}^1 and b_{13}^1 (in general, we will denote the k th order beliefs of player i about player $j \neq i$ by b_{ij}^k). Player 1 derives higher utility if he is confident of being accepted (perhaps it adds to his self-esteem); the total probability of this event is $b_{12}^1 + b_{13}^1$. However, he also suffers higher disutility if he is more confident and is rejected (perhaps on account of reference point effects). If Player 2 wishes to accept the proposal, she derives higher utility from a more confident player 1 (perhaps due to a social signaling role of partners). Hence, she needs to form beliefs about the unobservable beliefs of player 1, $b_{12}^1 + b_{13}^1$. Let b_{21}^2 be her beliefs about b_{12}^1 and let c_{21}^2 be her beliefs about b_{13}^1 . Then, the beliefs of player 2 about the confidence of player 1 are $b_{21}^2 + c_{21}^2$; these directly enter the utility function of player 2. The corresponding psychological game is shown in Figure 13.18. One of the exercises asks you to find all the psychological Nash equilibria for this game.

Geanakoplos et al. (1989) also extend this framework to extensive form games. However, even in extensive form games, the framework continues to employ the initial beliefs of players.⁵³ This is restrictive because as a sequential game unfolds, the beliefs of players change in response to the observed actions of others. Battigalli and Dufwenberg (2009) extend this framework in several directions that we now consider.

13.5.2 Psychological sequential Nash equilibria in multi-stage games

Following Battigalli and Dufwenberg (2009), consider a finite *multi-stage game*, $\Gamma = \langle N, H \rangle$, with observable actions, where the set of players is $N = \{1, 2, \dots, n\}$, $n \geq 2$, and H is the set of all possible histories of the game.⁵⁴ We assume that there are no moves by nature, no chance moves and there is complete information. The set of stages is given by $t = 0, 1, 2, \dots, \tau + 1$,

⁵³ Geanakoplos et al. (1989, p. 70) are fully aware of the limitations of their approach.

⁵⁴ The extensive form game Γ (see the Appendix on game theory) specifies a finite set of players with finite strategies, a specification of the set of nodes, the players who move at each node, the strategies available to players at each node, the information partition of the game, and the mapping of final nodes to payoffs.

where $\tau + 1$ is the terminal stage in which no player chooses any action (this corresponds to the terminal nodes in an extensive form game). In any stage t , all players simultaneously choose actions from the set of their available actions and the action profile in stage t is given by the vector $a^t = (a_1^t, a_2^t, \dots, a_n^t)$, where a_i^t is the action chosen by player $i \in N$. The profile a^t is immediately observed by all players. It is possible that a subset of the players choose no action in stage t , i.e., they are passive. For instance, the Stackelberg game is a two-stage game in which, in stage $t = 0$, the leader chooses a quantity that is immediately observed by both players but the follower is passive. In stage $t = 1$, the follower chooses a quantity but the leader is passive.

Histories are defined as follows. At the start of play, in stage $t = 0$, we have the null history, h^0 , and players choose the profile of actions a^0 . At the beginning of stage $t = 1$, the history is $h^1 = \{a^0\}$ and players choose the action profile a^1 . At the beginning of stage $t = 2$, the history is $h^2 = \{a^0, a^1\}$, and players choose the action profile a^2 , and so on. In particular, in stage t , the history is $h^t = \{a^0, a^1, \dots, a^{t-1}\}$, and players choose the action profile a^t , having observed the history h^t . Denote by H^t , the set of all possible stage t histories of the game.

The set of actions available to player $i \in N$ at history $h^t \in H^t$ is denoted by $A_i(h^t)$. We assume that $A_i(h^t)$ is non-empty, although it may be a singleton; the interpretation being that such a player is passive at that history. In the terminal history $h^{\tau+1}$ all players are passive, so $A_i(h^t) = \{\text{Do nothing}\}$ for all $i \in N$. The (updated) pure strategy for player $i \in N$ conditional on history h^t having been reached is denoted by $s_i^t : H^t \rightarrow A_i(H^t)$, so $s_i^t = s_i(h^t) \in A_i(h^t)$. A pure strategy for player $i \in N$ for the entire game, s_i , is a pure strategy choice conditional on each possible history having been reached, i.e., $s_i = (s_i^0, s_i^1, \dots, s_i^\tau)$.⁵⁵

Each player moves at most once at each history of the game. Hence, the set of all actions of player i for the game is $A_i = \cup_{h^t \in H^\tau} A_i(h^t)$. In short, a pure strategy for player i for the entire game is given by $s_i : H^\tau \rightarrow A_i$. Denote the set of pure strategies of player i for the entire game by S_i . We may define $S = \prod_{i \in N} S_i$ as the set of strategy profiles of all players for the entire game and $S_{-i} = \prod_{j \neq i} S_j$. Denote by $S_i(h^t)$ the set of strategies that allow history h^t to materialize. Hence, we can define $S(h^t) = \prod_{i \in N} S_i(h^t)$ and $S_{-i}(h^t) = \prod_{j \neq i} S_j(h^t)$, respectively, as the strategy profiles of all players, and the strategy profiles of players other than i , that allow history h^t .

In classical game theory, the utility of players is given by the function $u_i : H^{\tau+1} \rightarrow \mathbb{R}$. However, such a utility function does not explain the outcomes in Examples 13.8, 13.9, and 13.10 considered above.

We now define the behavior strategies of any player $i \in N$. At any information set given the history $h^t \in H^\tau$, the probability distribution over the stage t actions of player i is given by $\Delta A_i(h^t)$. A behavior strategy for player i , Φ_i , specifies the mixed strategy of the player at each history of the game, so it is an element of the set

$$\Phi_i = \Delta A_i(h^0) \times \Delta A_i(h^1) \times \dots \times \Delta A_i(h^\tau) = \prod_{h^t \in H^\tau} \Delta A_i(h^t). \quad (13.44)$$

Note that in contrast to behavior strategies, the set of mixed strategies of player i is given by $\Sigma_i = \Delta S_i$.⁵⁶ Define the behavior strategies of players other than player i by $\Phi_{-i} = \prod_{j \neq i} \Phi_j$.

⁵⁵ Just to be absolutely clear, the (updated) pure strategy, s_i^t , and the pure strategy for the entire game, s_i , are identical up to history h^t .

⁵⁶ Kuhn (1953) showed that in games of perfect recall, mixed and behavior strategies are equivalent; see Chapter 6 in Maschler et al. (2013).

Figure 13.19 A simple example of a sequential move psychological game.

Source: Reprinted from *Journal of Economic Theory* 144(1): 1–35. Battigali, P. and Dufwenberg, M. “Dynamic psychological games.” Copyright © 2009, with permission from Elsevier.

Suppose that some history $h^t \in H^t$ has materialized. Denote by $\Phi_i(h^t)$, the behavior strategy of player i that assigns probability 1 to all the actions of player i that allow history h^t to materialize. Let $\Phi_{-i}(h^t) = \prod_{j \neq i} \Phi_j(h^t)$.

We now define for any player $i \in N$, first order beliefs, second order beliefs, and so on. These are the analogues of (13.38) to (13.40), however, there is one main difference. In a multi-stage game, we allow for the beliefs of players to evolve as play progresses through the various stages. The hierarchies of beliefs can be revised, which is a major difference from the framework of Geanakoplos et al. (1989).⁵⁷

The most general case of multistage games may be pedagogically too complex for some readers, although this is the case considered in Battigalli and Dufwenberg (2009). For this reason, we first consider the issues in a simple example. This is followed by a heuristic discussion of how the insights from this example can be extended to general finite multistage games. Finally, following Dufwenberg and Kirchsteiger (2004), we consider an application of the general framework to issues of reciprocity.

Example 13.14 (Battigalli and Dufwenberg, 2009): Consider the two-player, two-stage game shown in Figure 13.19. Each player has two actions at each decision node, $t = 0, 1$. In each stage, only one player can move, while the other player is passive. Ann’s set of actions at the two histories are $A_A(h^0) = \{\text{Trust, Don't trust}\}$, $A_A(h^1) = \{\text{Do nothing}\}$. Bob’s action sets are $A_B(h^0) = \{\text{Do nothing}\}$ and $A_B(h^1) = \{\text{Share, Grab}\}$.

The set of behavior strategies of Ann, Φ_A , specifies all possible probabilities with which the action Trust is played at history h^0 . Likewise the set of behavior strategies of Bob specifies all possible probabilities with which the action Share is played at history h^1 . The strategy profiles of players leading to the three terminal nodes are {Don't trust, Do nothing}, {Trust, Grab}, and {Trust, Share}. The utility functions of the players map each of the terminal nodes to real numbers that we call utilities, as shown in Figure 13.19. The payoffs in the classical case from the strategy profile {Trust, Grab} are (0, 4) and the utilities from this strategy profile in the psychological game, as we see below, are (0, $4 - 5\beta$)

⁵⁷ To be sure, even in the classical framework, one allows for Bayesian updating of beliefs as play proceeds in a multistage game. Common knowledge of rationality, typically assumed in the classical framework, allows all higher order beliefs to be revised as well (the infinite regress case). However, in applications of psychological games, beliefs are typically truncated at some small integer value (typically between 2 and 3). In contrast when we consider the framework of psychological games for sequential games below, we shall allow not only for standard Bayesian belief revision, but also for revision of beliefs that directly enter into the utility functions of players.

Consider first the classical case that corresponds to $\beta = 0$ in Figure 13.19. The unique subgame perfect outcome is for Bob to play Grab at history h^1 and for Ann to play Don't trust at history h^0 . Hence, the utilities of the players are given by (1,1).

Let us now apply psychological game theory and restrict beliefs up to a maximum of order 2 for each player. We shall assume that players have utility functions as in (13.42), so they derive utility from their own beliefs only. At history h^0 , the set of first order beliefs of Ann, $B_A^1(h^0)$, must specify all possible beliefs about all possible strategies of Bob at nodes where Bob is not passive. A particular first order belief of Ann is that at history $h^1 = \text{Trust}$, Bob will play the action Share with probability α and the action Grab with probability $1 - \alpha$. We write this as

$$b_A^1(h^0) = \Pr(\text{Share} \mid \text{Trust}) = \alpha.$$

Letting $0 \leq \alpha \leq 1$ allows us to list all members of the set $B_A^1(h^0)$. One may specify Ann's second order beliefs but these are redundant in this game.

Now suppose that Bob is asked to make a choice between Share and Grab. Bob must assign probability 1 that he is at the history $h^1 = \text{Trust}$ (this is exactly as in Bayesian updating).⁵⁸ We now need to specify the belief hierarchy of Bob at history $h^1 = \text{Trust}$. Bob's first order beliefs about Ann $b_B^1(h^1 = \text{Trust})$ are irrelevant because Ann is passive at this history. The second order beliefs of Bob, $b_B^2(h^1 = \text{Trust})$, are probability distributions over sets of the form $\{\text{Trust}, \text{Don't}\} \times B_A^1(h^0)$. Let β be the probability assigned by Bob to the first order belief of Ann, $b_A^1(h^0) = \alpha$, when Bob observes that Ann has played the action Trust.

It remains to specify the utilities of the players. Recall that in (13.42), in a static game, we specified the utility of player i as $\bar{u}_i : B_i \times S \rightarrow \mathbb{R}$. However, in multistage games, we need to specify the beliefs of players that enter into the utility functions of players at each history of the game. A natural extension is given by

$$\bar{u}_i(h^k) : S(h^k) \times B_i(h^k) \rightarrow \mathbb{R}, h^k \in H, \quad (13.45)$$

where $B_i(h^k)$ is the belief hierarchy of player i at history h^k . In particular, we are interested in the role of "guilt aversion" in this example. This is modeled by allowing β to directly enter the payoff of Bob, following the strategy profile (Trust, Grab). Bob feels guilty from letting down the expectations of Ann, hence, he gets disutility from choosing the action Grab. In particular, we assume that Bob's utility from Grab is $4 - 5\beta$, thus, his disutility is increasing in his belief that Ann expects him to choose the action Share. This explains the utilities depicted in Figure 13.19 corresponding to each of the terminal nodes.

This completes the description of the psychological game in Figure 13.19. In addition to the usual extensive form game $\langle N, H \rangle$, we have now specified the belief hierarchy of each player at each node (although we have ignored beliefs that are not relevant) and the utilities of players at each terminal node, consistent with (13.45). As in static games (see Example 13.12), we require that beliefs be coherent in multistage games, although in the simple setup of this example this is fairly trivial.

How do we find the psychological equilibrium? We require that each player maximize his utility at each history of the game, after assigning probability 1 to the strategy profile that has led to that history, conditional on beliefs at that history and expectations of the strategy profiles in subsequent histories. Further, beliefs must be coherent in the sense of Example 13.12

⁵⁸ We may at this stage specify any first order beliefs of Bob at history h^0 . They do not affect the calculations.

(trivially satisfied in this example) and the strategies and beliefs of players must be consistent with each other. This is made precise in a manner that is analogous to a sequential equilibrium.

Let us now find the psychological equilibria of this game. Ann must choose her action at history h^0 to maximize her expected utility given her beliefs. If she chooses not to trust, she gets 1. If she chooses to trust, she gets 2α , so she should trust if $\alpha > \frac{1}{2}$. What action should Bob choose at history $h^1 = \text{Trust}$? Bob has no subsequent histories to worry about at history $h^1 = \text{Trust}$. So he chooses the action Share if $2 > 4 - 5\beta$, or if $\beta > \frac{2}{5}$. Here is one sequential psychological Nash equilibrium for this game: Ann plays Trust with probability 1, Bob plays Share with probability 1, and $\alpha = \beta = 1$. This satisfies the following requirements.

- (i) Ann's choice of action is optimal, given her belief, $\alpha = 1$, and the equilibrium choice of Bob in the next stage.
- (ii) Bob's choice is optimal, given the preceding choice of Ann, and his beliefs as captured by $\beta = 1$.
- (iii) The first order beliefs of Ann are derived from the equilibrium actions. The second order beliefs of Bob are consistent with the first order beliefs of Ann.

Example 13.15 (Example 13.14 continued) : Now suppose that instead of utilities of the form in (13.45), we have the following general utility function proposed by Battigalli and Dufwenberg (2009)

$$\bar{u}_i(h^k) : S(h^k) \times B_i(h^k) \times \prod_{j \neq i} (B_j(h^k) \times S_j(h^k)) \rightarrow \mathbb{R}. \quad (13.46)$$

In (13.46), the beliefs of other players directly enter the utility function of the player. In models of "social conformity," the utility functions of players also reflect the beliefs of others. As another example, consider a doctor who feels concerned about a patient's anxiety about her disease. The doctor has superior information about the disease and the patient's health. Yet, in the absence of mandatory disclosure, the doctor might be unwilling to reveal the true extent of the problem to the patient because his concern for the patient's anxiety following disclosure may reduce his own utility.

In the context of Example 13.14, one may redraw Figure 13.19 as shown in Figure 13.20.

In Figure 13.20, we have replaced β by α , where α and β are defined in Example 13.14. Since Bob maximizes his expected utility at history $h^1 = \text{Trust}$, the expected utility from the action Grab is $E[4 - 5\alpha \mid h^1] = 4 - 5\beta$. This leads to the same outcome as in Example 13.14.

Figure 13.20 Dependence of utilities on beliefs of others.

Source: Reprinted from *Journal of Economic Theory* 144(1): 1–35. Battigalli, P. and Dufwenberg, M. "Dynamic psychological games." Copyright © 2009, with permission from Elsevier.

However, one needs beliefs of one order lower, which may simplify the problem. In most cases that we consider below, we will be concerned with utility functions of the form (13.45) rather than (13.46). ■

Example 13.14 gives a blueprint of how one might proceed in any finite multistage game when players have the utility function in (13.45). We give a heuristic discussion of the general case, followed by a concrete application to reciprocity in Section 13.5.3.⁵⁹ Consider a multistage game $\Gamma = \langle N, H \rangle$. The belief hierarchies are constructed in a manner similar to that for static games in (13.38) to (13.40). The main difference is that we need to consider belief hierarchies at each history of the game and these beliefs are about the history-contingent strategies of others. At each possible history of the game, $h^k \in H$, let $B_i(h^k) = \{b_i^1(h^k), b_i^2(h^k), \dots, b_i^l(h^k)\}$ be the set of belief hierarchies of player i , up to level l . Example 13.14 shows how the first and second order beliefs are constructed in a simple game. Let $B_i = (B_i(h^k))_{h^k \in H}$ be the set of belief hierarchies of player i for all possible histories and let $B = (B_i)_{i \in N}$ be the set of belief hierarchies for all players for the entire game.

The first order beliefs at any history are probability distributions over the strategies of the other players. The second order beliefs are probability distributions over the strategies of others and the first order beliefs of other players and so on. This hierarchy in beliefs is *conditional* in the sense that it conditions on the history of play up to that point and on the strategies and beliefs of others (as in (13.40)). At any history, players must assign probability 1 to all strategy profiles that have led to that particular history. For instance, in Figure 13.19, if Bob is asked to move, then he must assign probability 1 to the action Trust having been played by Ann. We require beliefs to be coherent in the sense of Example 13.12. With these components in place, we can define a psychological game as $\Gamma = \langle N, H, (\bar{u}_i(h^k))_{i \in N, h^k \in H} \rangle$, where $\bar{u}_i(h^k)$ is defined in (13.45) (or more generally in (13.46)).

A behavior strategy for player i , Φ_i , is defined in (13.44). Denote by $\Phi = (\Phi_i)_{i \in N}$ the profile of behavior strategies of all players for the game. An *assessment*, defined as (Φ, B) , is said to be consistent if, for each history, the first order beliefs in B are derived from Φ and the higher order beliefs place probability 1 on lower order beliefs (see Example 13.14 for an illustration). Finally, a consistent assessment (Φ, B) is a sequential equilibrium of the psychological game $\Gamma = \langle N, H, (\bar{u}_i(h^k))_{i \in N, h^k \in H} \rangle$ if at each history $h^k \in H$, the pure strategies in the support of the behavior strategies of the players maximize their utility functions.

A NOTE ON THE COMPARISON WITH GAMES OF ASYMMETRIC INFORMATION

We describe the basics of games of asymmetric information in the Appendix. Let $N = \{1, 2, \dots, n\}$ be the set of players. In such games, the utility function of player $i \in N$ is given by $u_i : Z \times \Theta \rightarrow \mathbb{R}$ where Θ is a vector of exogenously given characteristics of the players such as tastes and ability. Each possible characteristic may be considered as the type of a player that is drawn by nature from a commonly known probability distribution. Players observe the type that nature draws for them but do not observe the types drawn for the other players (they do, however, typically have common priors about the distribution of types of other players). One may then have a hierarchy of beliefs about the exogenous types of players. These beliefs play an important role in the determination of an equilibrium outcome in the game. However, the payoffs at each terminal node are exogenous. By contrast, in psychological games, the hierarchy of beliefs determine not only the

⁵⁹ The formal framework requires the use of conditional belief hierarchies formulated in Battigalli and Siniscalchi (1999); see Battigalli and Dufwenberg (2009) for the details.

outcome of the game but also determines, endogenously, the material payoffs at each end node. Hence, these are quite different classes of games.

The assumption of common knowledge of the utility function in psychological game theory is a strong one. There is merit in developing a more general framework that incorporates asymmetric information about, say, the utility functions of other players, within psychological games. For an attempt in this direction, in the context of trust games, see Attanasi et al. (2015).

13.5.3 Fairness and reciprocity in extensive form games

In this section, we give a concrete application of the framework proposed in Section 13.5.2 to issues of reciprocity. The seminal application to reciprocity, using the machinery described in Section 13.5.1 for one-stage games is due to Rabin (1993). However, many important economic applications can be modeled in a satisfactory manner only in sequential games. In order to adequately explore the role of reciprocity in such cases, Rabin's model needs to be extended. When players move in sequence, they can observe the actions of others and infer the kindness (or unkindness) of their opponents prior to choosing their own actions. Furthermore, after observing the actions of others, players can update their belief hierarchy, which is not possible in normal form games. In this section, we consider the work of Dufwenberg and Kirchsteiger (2004) who extend Rabin's framework to sequential form games.

Consider the sequential prisoner's dilemma game in panel A of Figure 13.21. In the normal form corresponding to panel A (not shown), the strategy profile (C, c) is a psychological Nash equilibrium in the single-stage model in Rabin (1993). However, a consideration of the extensive form makes it difficult to sustain (C, c) as an equilibrium. Even if player 2 initially held a belief that player 1 is kind, once player 1 plays D , such a belief is difficult to entertain. By playing D , player 1 ensures that player 2 gets a lower payoff for each of her strategy choices, relative to the case where player 1 plays C .

In the extensive-form model proposed by Dufwenberg and Kirchsteiger (2004), the beliefs about players evolve over the course of an extensive form game, allowing player 2 to interpret the choice of D by player 1 as unkind. With some minor modifications, the Dufwenberg and

Figure 13.21 Sequential prisoner's dilemma game.

Source: Reprinted from *Games and Economic Behavior* 47: 268–98. Dufwenberg, M. and Kirchsteiger, G., "A theory of sequential reciprocity." Copyright © 2004, with permission from Elsevier.

Kirchsteiger (2004) model becomes a special case of Battigalli and Dufwenberg (2009). Falk and Fischbacher (2006) also consider issues of reciprocity but extend this framework further to allow concerns for inequity-aversion (see Section 13.5.4).

Consider a *multi-stage game*, Γ , where the set of players is $N = \{1, 2, \dots, n\}$, $n \geq 2$. There are no moves by nature and *each player only moves once* in any stage. Let Φ_i be the set of behavior strategies of player $i \in N$ for the game (see (13.44)). We denote a typical element of Φ_i by ϕ_i . A behavior strategy specifies the (possibly mixed) strategies that players play at each possible history of the multistage game when they are asked to make a choice. An example of a behavior strategy in the game in Panel A of Figure 13.21 is that player 1 plays C and player 2 plays c following C and d following D . Let $\Phi = \times_i \Phi_i$ be the set of behavior strategy profiles for the game, with typical element given by ϕ .

Dufwenberg and Kirchsteiger (2004) restrict attention to the case where players play pure strategies only. Hence, the interpretation of any particular behavior strategy of the opponents is that players believe that they are facing a population of pure strategy playing opponents, whose mixture is such that the population proportions are consistent with the behavior strategy.

We will only take account of beliefs of order 1 and 2 for each player. In order to capture the notion of history dependence of strategies and beliefs in the extensive form, we define, for any player $i \in N$ and at any history $h \in H$ in the game the following three entities. $\phi_i(h)$ is the behavior strategy of player i ; $B_i^1(h) = \left(B_{ij}^1(h)\right)_{j \neq i}$ and $B_i^2(h) = \left(B_{ijk}^2(h)\right)_{j \neq i, j \neq k}$ are, respectively, first and second order beliefs of the player. Notice that second order beliefs have elements of the form $B_{ijk}^2(h)$, i.e., the beliefs of player i about the first order beliefs of player $j \neq i$ about the strategy of player $k \neq j$.

Consider, for instance, the game in Panel A in Figure 13.21. Suppose that, at history h^0 , the first order belief of player 2 about the action of player 1, $b_{21}^1(h^0) \in B_{21}^1(h^0)$, is that player 1 will play C with probability p and D with probability $1 - p$. Consider the history of the game given by $h^1 = \{D\}$. In this case, consistent with Bayes' rule, the first order belief of player 2 about player 1, $b_{21}^1(h^1)$, specifies that player 1 plays C with probability 0 and D with probability 1. When player 2 observes the history $h^1 = \{D\}$, player 2 assumes that player 1 has deliberately played D , i.e., playing D is not a mistake on the part of player 1. This assumption allows player 2 to confidently retaliate against player 1.

We can now define the payoffs and utilities of players. The material payoffs of players, used in classical game theory, at any terminal history $z \in Z$ are defined by the mappings $\pi_i(z) : \Phi(z) \rightarrow \mathbb{R}$, $i \in N$. In contrast, in psychological games, players derive utility not at the final nodes that the game reaches but, at any history $h \in H$, (via $\Phi(h)$) from their own first and second order beliefs. Suppose that the utilities of players in psychological games at any history $h \in H$ are given analogously to (13.45), (13.46) by

$$u_i(h) : \Phi(h) \times \prod_{j \neq i} \left(B_{ij}^1(h) \times \prod_{k \neq j} B_{ijk}^2(h) \right) \rightarrow \mathbb{R}, i \in N. \quad (13.47)$$

Consider Panel B in Figure 13.21. In this case, if player 1 plays the strategy U , then both players get the inefficient payoff of -1000 each. Suppose that the first order beliefs of player 1 at history h^0 specify that player 2 will play c at the left node and d at the right node. By his actions, player 1 can now give player 2 one of the payoffs in the set $\{-1000, 0, 1\}$. Relative to the payoff of -1000 , a payoff of 0 seems high. Should player 2, on observing the history $h^1 = \{D\}$, infer that player 1 is being kind to him? Dufwenberg and Kirchsteiger (2004) view the inference of kindness by player 2, in this case, as perverse. They argue that player 2 should have the same beliefs about

the kindness of player 1 in both panels in Figure 13.21. This gives rise to the notion of efficient strategies in the next definition.

Definition 13.12 (*Efficient strategies*): A strategy profile is efficient if, given the history of play, and the subsequent choices of players, there does not exist another strategy profile that gives at least one player a higher payoff and no player a lower payoff. Denote the set of efficient strategies of player $i \in N$ at history h by $E_i(h)$.

Clearly, the choice of U by player 1 in Panel B of Figure 13.21 cannot be part of an efficient strategy profile.

Definition 13.13 Consider some history of the game, $h \in H$. Suppose that the first order belief of player i about player $j \neq i$ is $b_{ij}^1(h)$. Denote the vector of such beliefs by $B_i^1(h) = (b_{ij}^1(h))_{j \neq i}$ with typical element given by $b_i^1(h)$.

At any history h , if player i plays the behavior strategy $\phi_i(h)$ and believes that other players will play the vector of strategies $b_i^1(h)$, then player i believes that the material payoff of player $j \neq i$ is $\pi_j(\phi_i(h), b_i^1(h))$. We use these payoffs to define equitable payoffs, next.

Definition 13.14 (*Equitable payoff*): Consider some history of the game, $h \in H$. The equitable payoff of player j at node h , from the perspective of player i , is defined as

$$\bar{\pi}_j(b_i^1(h)) = \frac{1}{2} \left[\begin{array}{l} \{\max \pi_j(\phi_i(h), b_i^1(h)) : \phi_i(h) \in \Phi_i(h)\} \\ + \{\min \pi_j(\phi_i(h), b_i^1(h)) : \phi_i(h) \in E_i(h)\} \end{array} \right]. \quad (13.48)$$

In (13.48), note that we focus on different sets in calculating the maximum and minimum payoffs. In particular, for the reasons described above, when we calculate the minimum payoff of the player, we restrict attention to efficient strategies only.

We now define the kindness functions. In each case, departures of payoffs from equitable payoffs are used to measure kindness of players.

Definition 13.15 (*Kindness of player i to player j*): Suppose that at some history of the game, $h \in H$, player i chooses the behavior strategy $\phi_i(h)$ and believes that the strategy profile of other players is $b_i^1(h)$. Then player i perceives that his kindness towards player j is given by $k_{ij} : \Phi_i(h) \times B_i^1(h) \rightarrow \mathbb{R}$, where $\Phi_i(h)$ is the set of behavior strategies of player i at history h and $B_i^1(h)$ is the set of his first order beliefs about the behavior strategies of all other players. In particular,

$$k_{ij}(\phi_i(h), b_i^1(h)) = \pi_j(\phi_i(h), b_i^1(h)) - \bar{\pi}_j(b_i^1(h)); \phi_i(h) \in \Phi_i(h), b_i^1(h) \in B_i^1(h). \quad (13.49)$$

Thus, player i is kind to player j at history $h \in H$ if his actions ensure a payoff to j greater than his equitable payoff (in this case, $k_{ij} > 0$). Analogously, player i is neutral to player j at history $h \in H$ if $k_{ij} = 0$ and unkind if $k_{ij} < 0$.

We now define the kindness that player i perceives from the actions of player $j \neq i$, which we term as *reciprocity*, denoted by $\tilde{k}_{ij}$. At some history of the game, $h \in H$, when player i attempts to infer the reciprocity of player j he must infer what player j thinks about the actions of other players, $b_j^1(h)$, which is not observable. As a proxy, player i uses his second order beliefs, $b_{ij}^2(h)$, about player's j first order beliefs $b_j^1(h)$; $b_{ij}^2(h)$ is an element of the set $B_{ij}^2(h) = \Pi_{k \neq j} B_{ijk}^2(h)$, and

$$b_{ij}^2(h) = (b_{ij1}^2(h), \dots, b_{ijj-1}^2(h), b_{ijj+1}^2(h), \dots, b_{ijn}^2(h)). \quad (13.50)$$

Definition 13.16 (Reciprocity of player j to player i): Consider some history of the game, $h \in H$. Fix the first order beliefs of player i about player j , $b_{ij}^1(h)$. We now vary the second order beliefs of player i about player j 's beliefs about other players $k \neq j$, i.e., the vector b_{ij}^2 . The belief of player i about the kindness of player j towards him is given by a function, $\tilde{k}_{ij} : B_{ij}^1(h) \times B_{ij}^2(h) \rightarrow \mathbb{R}$ such that

$$\tilde{k}_{ij}(b_{ij}^1(h), b_{ij}^2(h)) = \pi_i(b_{ij}^1(h), b_{ij}^2(h)) - \bar{\pi}_i(b_{ij}^2(h)), \quad b_{ij}^1(h) \in B_{ij}^1(h), b_{ij}^2(h) \in B_{ij}^2(h), \quad (13.51)$$

where $\bar{\pi}_i$ is the equitable payoff of player i . $\pi_i(b_{ij}^1(h), b_{ij}^2(h))$ is the payoff of player i when he believes that player j plays $b_{ij}^1(h)$, and his (player i 's) beliefs about the belief of player j about the strategies of all non- j players is $b_{ij}^2(h)$, as defined in (13.50). (To be absolutely sure, $b_i^2(h) = (b_{i1}^2(h), \dots, b_{ii-1}^2(h), b_{ii+1}^2(h), \dots, b_{in}^2(h))$).

Recall that $B_{ij}^1(h)$ is the set of all first order beliefs of player i about player j at history h and $\Phi_j(h)$ is the set of all possible behavior strategies of player j at history h , hence, $B_{ij}^1(h) = \Phi_j(h)$. Similarly the set of all possible second order beliefs of player i about j is given by $B_{ij}^2(h)$; $b_{ij}^2(h)$, defined in (13.50) is a typical member of this set. $B_j^1(h)$ is the set of first order beliefs of player j about other players. In equilibrium these sets are equal, $B_{ij}^2(h) = B_j^1(h)$. Thus, comparing (13.49), (13.51) we get that mathematically, the function $\tilde{k}_{ij}$ is equivalent to k_{ji} ; for future reference we write this as

$$\tilde{k}_{ij} = k_{ji}. \quad (13.52)$$

(13.52) facilitates the computation of the function $\tilde{k}_{ij}$. Rather than computing the reciprocity of player j towards i , we can simply compute, using (13.49), the kindness function of player j towards i ; this is a simpler computation because it only requires first order beliefs.

Definition 13.17 (Utility function of players): Consider some history of the game, $h \in H$. The utility function of player $i \in N$ in (13.47) is operationalized in the following form

$$u_i(\phi(h), b_i^1(h), \{b_{ij}^2\}_{j \neq i}) = \pi_i(\phi(h)) + \sum_{j \neq i} \lambda_{ij} k_{ij}(\phi_i(h), b_i^1(h)) \tilde{k}_{ij}(b_{ij}^1(h), b_{ij}^2), \quad (13.53)$$

where $\lambda_{ij} \geq 0$, $\phi(h) \in \Phi(h)$, $b_i^1(h) \in B_i^1(h)$, $b_{ij}^1(h) \in B_{ij}^1(h)$, $b_{ij}^2 \in B_{ij}^2$.

The first term on the RHS of (13.53) gives the material payoff of player i , which depends on the behavior strategies chosen by all players. The second term gives the psychological payoffs that capture the interaction of kindness and reciprocity terms summed across all the other players. For each player $j \neq i$, the parameter λ_{ij} gives the *salience of the psychological payoff* with respect to that player. Each of these terms is made up of the product $k_{ij} \tilde{k}_{ij}$, i.e., the kindness of i towards j (k_{ij}) and the reciprocity of player j towards i ($\tilde{k}_{ij}$). Using (13.52) we can also write $k_{ij} \tilde{k}_{ij} = k_{ij} k_{ji}$. Thus, the psychological payoffs can be enhanced if player i responds to kindness with kindness and unkindness with unkindness; this is the essence of reciprocity payoffs.

Definition 13.18 (Psychological game with reciprocity incentives): The game $\Gamma^* = (\Gamma, (u_i)_{i \in N})$ where u_i is defined in (13.53) is known as a psychological game with reciprocity incentives.

Recall that a behavior strategy for a player, ϕ_i , is a description of the mixed strategy that player i chooses at each history $h \in H$. Let us pick a particular history $h \in H$. Denote by $\Phi_i^h \subseteq \Phi_i$,

the subset of behavior strategies such that Φ_i^h and Φ_i coincide for all histories preceding history h and succeeding history h (so they potentially differ only at history h). However, in Φ_i^h , we are free to choose the behavior strategy of player i at history h .

Definition 13.19 (Sequential reciprocity equilibrium, SRE): A strategy profile $\phi^* = (\phi_1^*, \phi_2^*, \dots, \phi_n^*)$ is a sequential reciprocity equilibrium if:

- (a) $\phi_i^* \in \arg \max_{\phi_i \in \Phi_i^h} u_i(\phi(h), b_i^1(h), \{b_{ij}^2\}_{j \neq i})$ for all $h \in H$ and for all $i \in N$, where u_i is defined in (13.53).
- (b) $b_i^1 = \phi_{-i}^*$ for all $i \in N$, where ϕ_{-i}^* is the vector of optimal behavior strategies of players other than i .
- (c) $b_{ij}^2 = (\phi_1^*, \dots, \phi_{j-1}^*, \phi_{j+1}^*, \dots, \phi_n^*)$ for all i and j such that $i \neq j$, where $b_{ij}^2(h)$ is defined in (13.51).

When $\lambda_{ij} = 0$ for all $i, j \in N$, then the psychological payoffs are irrelevant, so Definition 13.19 simply corresponds to the definition of a subgame perfect Nash equilibrium. However, when $\lambda_{ij} > 0$, the outcomes from the two concepts will typically differ. The reason is that psychological payoffs depend on the history of the game through the role of intentions that are revealed from the choices made by other players. However, in a subgame perfect equilibrium, as one solves the game backwards, one does not take account of such intentions (except updating of beliefs, consistent with Bayes' rule). Thus, backward induction is not suitable to solve the multi-stage game used in this section.

The proof of the existence of a SRE may appear to be difficult. However, from Definition 13.19(a), each individual optimizes at a particular $h \in H$, holding fixed the strategies at all other $h' \in H$ (hence, the restriction $\phi_i \in \Phi_i^h$). This observation simplifies the proof and an application of the Kakutani fixed point theorem to best reply correspondences ensures that a SRE exists; see Dufwenberg and Kirchsteiger (2004, p. 280).

The framework outlined above differs from Rabin (1993) in the definition of the efficient set $E_i(h)$, as well as in the definitions of the kindness functions. The kindness functions here are defined as differences from equitable payoffs, while in Rabin (1993) these are ratios that are normalized by a factor (difference between maximum and minimum payoffs) that restricts the ratios to lie between 0 and 1. Further, the sets from which the individual components on the RHS in (13.49), (13.51) are drawn are different in Rabin's framework.⁶⁰ We have also slightly modified the payoff functions in Dufwenberg and Kirchsteiger (2004) in this section in order to make them comparable to the framework developed in Section 13.5.2.

As an illustration of a SRE, consider the next example that we also use later to examine the evidence on reciprocity.

Example 13.16 (Dufwenberg et al., 2011) Consider a three-player public goods game, $N = \{1, 2, 3\}$, in which each of the three players is given an endowment of 20 tokens. The players simultaneously choose contributions $s_i \in S_i = [0, 20]$; we focus only on degenerate behavior strategies in this example. The total amount of the public good produced is $G = \frac{3}{2}(s_1 + s_2 + s_3)$. Each player gets a return of $\frac{1}{3}G = \frac{1}{2}(s_1 + s_2 + s_3)$ from the public good. The strategy profiles for the game are $s = (s_1, s_2, s_3) \in S = [0, 20]^3$. In the absence of any reciprocity considerations, the material payoffs of the players are given by $\pi_i : S \rightarrow \mathbb{R}$ such that

⁶⁰ For a discussion of the differences between the two frameworks and more on the rationale for the framework discussed in this section see Dufwenberg and Kirchsteiger (2004, Section 5).

$$\pi_i(s) = (20 - s_i) + \frac{1}{2} (s_1 + s_2 + s_3), \quad i \in N. \quad (13.54)$$

In a Nash equilibrium, it is optimal for each player to free-ride, so $s_i^N = 0$, $i = 1, 2, 3$. Now introduce the possibility of reciprocity. The utility function of each player has the form $u_i : S \times B \rightarrow \mathbb{R}$, where B is the set of all possible first and second order beliefs of each player about choices and beliefs. Denote by b_{ij}^1 , $i \neq j$, the first order beliefs of player i about the contributions, s_j , of another player j . Denote by b_{ijk}^2 the second order beliefs of player i about the first order beliefs of player j about the contributions of player k , b_{ijk}^1 , $j \neq k$. Using (13.53), and for all i , letting $\lambda_{ij} = \lambda_i$, $i \neq j$, the utility function of player $i \in N$ is

$$u_i = (20 - s_i) + \frac{1}{2} (s_1 + s_2 + s_3) + \lambda_i (k_{ij}\tilde{k}_{ij} + k_{ik}\tilde{k}_{ik}), \quad i \neq j \neq k. \quad (13.55)$$

The kindness of player i to players j and k is particularly easy to calculate in public goods games, due to the linearity and independence of contributions. Using (13.48), (13.54), we can compute the equitable payoff of player j , from the perspective of player i . Conditional on his beliefs about the contributions of others, player i can ensure the highest payoff for player j by contributing the entire endowment of 20, and the least payoff by contributing nothing. Thus,

$$\begin{aligned} \bar{\pi}_j(b_{ij}^1, b_{ik}^1) &= \frac{1}{2} \left[\left((20 - b_{ij}^1) + \frac{1}{2} (20 + b_{ij}^1 + b_{ik}^1) \right) + \left((20 - b_{ij}^1) + \frac{1}{2} (0 + b_{ij}^1 + b_{ik}^1) \right) \right], \\ &\Rightarrow \bar{\pi}_j(b_{ij}^1, b_{ik}^1) = (20 - b_{ij}^1) + \frac{1}{2} (b_{ij}^1 + b_{ik}^1) + \frac{1}{2} 10. \end{aligned}$$

The kindness of player i to player j , k_{ij} , can now be calculated by using (13.49)

$$k_{ij}(s_i, b_{ij}^1, b_{ik}^1) = \left[(20 - b_{ij}^1) + \frac{1}{2} (s_i + b_{ij}^1 + b_{ik}^1) \right] - \left[(20 - b_{ij}^1) + \frac{1}{2} (b_{ij}^1 + b_{ik}^1) + \frac{1}{2} 10 \right]. \quad (13.56)$$

The first term in (13.56) is the payoff of player j , $\pi_j(s_i, b_i^1(h))$, where $b_i^1(h) = (b_{ij}^1, b_{ik}^1)$. Varying his own contributions, s_i , player i can change player j 's payoff; this results in variations in k_{ij} . Simplifying (13.56), we get

$$\Rightarrow k_{ij}(s_i, b_{ij}^1, b_{ik}^1) = \frac{1}{2} (s_i - 10).$$

Let us now calculate the reciprocity that player i perceives that players j and k give to him, respectively, $\tilde{k}_{ij}$ and $\tilde{k}_{ik}$. Using (13.52), $\tilde{k}_{ij} = k_{ji}(s_j, b_{ji}^1, b_{jk}^1) = \frac{1}{2} (s_j - 10)$. But player i does not know s_j , which is chosen simultaneously. Hence, he substitutes his first order belief about s_j , b_{ij}^1 , so, $\tilde{k}_{ij} = \frac{1}{2} (b_{ij}^1 - 10)$. In an analogous manner, $\tilde{k}_{ik} = \frac{1}{2} (b_{ik}^1 - 10)$. Substituting these intermediate calculations in (13.55) we get

$$\begin{aligned} u_i &= (20 - s_i) + \frac{1}{2} (s_i + s_j + s_k) + \frac{\lambda_i}{4} \left[(s_i - 10) (b_{ij}^1 - 10) + (s_i - 10) (b_{ik}^1 - 10) \right]. \\ &\Rightarrow u_i = \left[(20 - s_i) + \frac{1}{2} (s_i + s_j + s_k) \right] + \frac{\lambda_i}{4} \left[(s_i - 10) (b_{ij}^1 + b_{ik}^1 - 20) \right]. \end{aligned} \quad (13.57)$$

From (13.57), $\frac{\partial u_i}{\partial s_i} = -\frac{1}{2} + \frac{\lambda_i}{4} (b_{ij}^1 + b_{ik}^1 - 20)$. Thus, if $b_{ij}^1 + b_{ik}^1 - 20 \leq 0$, then u_i is maximized by choosing $s_i = 0$. On the other hand, if $b_{ij}^1 + b_{ik}^1 - 20 > 0$ and λ_i is high enough,

then it may be optimal to choose $s_i = 20$, otherwise if λ_i is low, then $s_i = 0$ continues to be optimal.

Since λ_i is unobservable, Dufwenberg et al. (2011) test a weaker prediction of the theory, namely, that either $b_{ij}^1 + b_{ik}^1 = 20$ and $s_i = 0$ or there is positive correlation between s_i and $b_{ij}^1 + b_{ik}^1$. They consider a 2×2 factorial design that varies the “label frame” and the “valence frame.” The label frame simply changes the labels of the game, while the valence frame potentially alters the reference point of the participants. Variations in the label frame are achieved through the treatments: Neutral and Community. In the Neutral treatment, the instructions speak of “the experiment,” while in the Community treatment, the instructions speak of “the community experiment.” Both frames are then interacted with two further treatments: Give and Take. The Give treatment is as described in the public goods experiment above. In the Take treatment, subjects are endowed with the resources and then allowed to take from it (so s_i has the interpretation of the amount that player i withdraws from the common resource). The monetary payoffs and the equilibria in the two games are identical.

Subjects first make their contributions in a one-shot game. Then they are asked to guess the average contributions of others $(b_{ij}^1 + b_{ik}^1)/2$ and their guesses of the sum of guesses of others (second order beliefs). Subjects are paid for the accuracy of their guesses. Here we give the results on first order beliefs only. Section 13.5.5 below, on guilt aversion, considers the results for second order beliefs. Figure 13.22 shows a plot of average levels of s_i versus average levels of $b_{ij}^1 + b_{ik}^1$ from various treatments (the dotted line is the 45° trend line). Contributions and first order beliefs are positively correlated, which is consistent with the presence of reciprocity in explaining the actions of players. An OLS regression confirms the statistical significance of first order beliefs in explaining contributions by the players.

As a second application of a SRE, consider the sequential prisoner’s dilemma game in Panel A of Figure 13.21. Since there are only two players, relabel the parameter λ_{ij} in (13.53) by λ_i . The results for this game are summarized in the next proposition.

Proposition 13.36 Consider the sequential prisoner’s dilemma game in Panel A of Figure 13.21. In a sequential reciprocity equilibrium:

- (i) If player 1 chooses D, then player 2 chooses d.
- (ii) If player 1 chooses C, then the following hold. If $\lambda_2 > 1$, player 2 chooses c and if $\lambda_2 < 0.5$, player 2 chooses d. If $0.5 < \lambda_2 < 1$, then player 2 chooses c with probability $p = \frac{2\lambda_2 - 1}{\lambda_2}$.
- (iii) If $\lambda_2 < 0.5$, then player 2 chooses d irrespective of the action of player 1.
- (iv) If $\lambda_2 > 1$, then there are three possible outcomes. (a) Irrespective of the magnitude of λ_1 , player 1 chooses C. (b) $\lambda_1 > 1$ and player 1 chooses D. (c) $\lambda_1 > 1$ and player 1 chooses C with probability $q = \frac{\lambda_1 - 1}{2\lambda_1}$.

Proof: We only prove parts (i) and (ii). The proofs of parts (iii), (iv) are analogous, so they are omitted.⁶¹

(i) The choice of D by player 1 gives to player 2 a lower payoff for every strategy that 2 could choose. Hence, such a choice by player 1 is interpreted as unkind by player 2. Player 2 must then choose d on both counts—such a choice maximizes the material payoffs and improves the psychological payoffs by reciprocating the unkindness of player 1.

⁶¹ Readers interested in the proof may consult Dufwenberg and Kirchsteiger (2005, pp. 293–5).

Figure 13.22 Correlation between contributions and first order beliefs in a public goods game.

Source: Reprinted from *Games and Economic Behavior* 73: 459–78. Dufwenberg, M., Gächter, S., and Hennig-Schmidt, H., “The framing of games and the psychology of play.” Copyright 2011, with permission from Elsevier.

(ii) Suppose that player 2 wishes to calculate his kindness to player 1 when player 1 chooses C . The equitable payoff of player 1 in this case is $\frac{1}{2}(1 + (-1)) = 0$. Thus, if 2 plays c , then his kindness to 1 is $1 - 0 = 1 > 0$ and if he plays d , then his kindness is $-1 - 0 = -1 < 0$. Let us now calculate $\hat{k}_{21}$, given in (13.51), i.e., player 2's perception of 1's kindness towards him. b_{21}^2 gives the second order belief of player 2 about player 1's first order belief about the probability with which player 2 will play c . Hence, player 2 knows that the payoff that player 1 intended to give him by playing C is $b_{21}^2 + (1 - b_{21}^2)2$. Recall the definition of the equitable payoff in (13.48), and from part (i) the fact that if 1 plays D , player 2 responds with d . Hence, the equitable payoff for player 2 is $\frac{1}{2}(b_{21}^2 + (1 - b_{21}^2)2 + 0)$. Thus, the kindness of player 1 towards 2 as perceived by player 2 (the analog of (13.51)) is $b_{21}^2 + (1 - b_{21}^2)2 - \frac{1}{2}(b_{21}^2 + (1 - b_{21}^2)2 + 0) = 1 - \frac{b_{21}^2}{2}$.

Using the definition of the utility function in (13.53), if 1 plays C , player 2's utility from playing c is $1 + \lambda_2 \times 1 \times \left(1 - \frac{b_{21}^2}{2}\right)$. But when 2 plays d his kindness (see above) is -1 , hence, his payoff from d is $2 + \lambda_2 \times (-1) \times \left(1 - \frac{b_{21}^2}{2}\right)$. Thus player 2 prefers to play c rather than d if $\lambda_2(2 - b_{21}^2) > 1$. In equilibrium (Definition 13.19), the second order beliefs of players must equal the first order beliefs, which, in turn, are consistent with the actual choices of strategies. Thus, if c is to be an equilibrium following the choice of C by player 1, then $b_{21}^2 = 1$. In this case $\lambda_2(2 - b_{21}^2) > 1$

implies $\lambda_2 > 1$. However, if 2 plays d following the play of C , then it must be that $\lambda_2 (2 - b_{21}^2) < 1$, which implies that $\lambda_2 < 0.5$. For intermediate values, $0.5 < \lambda_2 < 1$, player 2 cannot play c or d as part of a SRE, which suggests that there is “randomized choice.”⁶² Indifference between the payoffs of player 2 from playing c and d give $\lambda_2 (2 - b_{21}^2) = 1$. The second order beliefs must hold in equilibrium, hence, b_{21}^2 must equal the probability, p , with which 2 plays c which gives $p = \frac{2\lambda_2 - 1}{\lambda_2}$. ■

13.5.4 Fairness, reciprocity, and inequity-aversion in extensive form games

We now extend the model in Section 13.5.3 to allow for a combination of *intention* and *outcome* based reciprocity. The resulting model can be fairly complex. We now give a simplified and intuitive treatment of the Falk and Fischbacher (2006) model. The empirical evidence in Falk et al. (2008) supports the predictions in Falk and Fischbacher (2006) over those in Dufwenberg and Kirchsteiger (2004).

Consider a finite, two-player, extensive form game of complete and perfect information.⁶³ Suppose that T is a finite set of nodes, and the set of terminal nodes is Z . Let the set of nodes where player $i = 1, 2$ have the move denoted by T_i with generic element denoted by t_i . Let $A(t_i)$ be the set of actions available to player i at node t_i . We list the strategy of player 1 first, followed by that of player 2.

The material payoffs of the players are given by $\pi_i : Z \rightarrow \mathbb{R}$. Let $\Delta A(t_i)$ be the set of probability distributions over the set of actions of player i at node t_i . The behavior strategies for player $i = 1, 2$ belong to the set $\Phi_i = \Pi_{t_i \in T_i} \Delta A(t_i)$, i.e., probability distributions over each of player i 's decision nodes. Let a generic element of Φ_i be denoted by ϕ_i . Suppose that the strategies chosen by the players are $\phi_i \in \Phi_i$, $i = 1, 2$. Then, the expected payoffs of the two players are given, respectively, by $\pi_1(\phi_1, \phi_2)$, $\pi_2(\phi_1, \phi_2)$. Denote the expected payoff of player i , conditional on being at node t_i by $\pi_i(\phi_1, \phi_2 | t_i)$. The first order beliefs of player i about the behavior strategy of player j , are denoted by b_i^1 . Second order beliefs of player i , are denoted by b_i^2 , and reflect beliefs about b_j^1 , $j \neq i$, where $b_i^2 \in \Phi_i$ and $b_i^1 \in \Phi_j$. These beliefs are node-dependent, i.e., we allow for the updating of beliefs as we progress through the game.

At any node, the kindness term, $\tilde{k}_j$, measures the perceived kindness of player i that is received from player $j \neq i$.⁶⁴ It depends on (1) *outcomes*, measured by an *outcome term* η_j , and (2) *intentions*, measured by an *intention factor* $\vartheta_j \in [0, 1]$, where $\vartheta_j = 1$ denotes full intent of player j in inducing a given outcome term for player i . Values of $\vartheta_j < 1$ denote less than full intent and lower values of ϑ_j denote lower intent.

Definition 13.20 *The kindness perceived by player i from player j at node t , is given by*

$$\tilde{k}_j(b_i^2, b_i^1 | t) = \vartheta_j(b_i^2, b_i^1 | t) \eta_j(b_i^2, b_i^1 | t), \quad (13.58)$$

where b_i^1 and b_i^2 are first and second order beliefs of player i at node t .

⁶² Recall our comment above that players in this model always choose pure strategies. Mixed strategies here have the interpretation of randomized choices in which the proportions of the population playing the different pure strategies are such that the opponent appears to be playing a mixed strategy that mirrors the population proportions playing the pure strategies.

⁶³ For the extension to finite n -player extensive form games, see the Appendix in Falk and Fischbacher (2006).

⁶⁴ We omit double subscripts on the kindness term because there are only two players and to differentiate the kindness function in this model, which is different to those in the previous sections.

Since ϑ_j is non-negative, the sign of the kindness term is determined entirely by the sign of the outcome term. The outcome term, η_j , at node $t \in T$ is given by

$$\eta_j(b_i^2, b_i^1 | t) = \pi_i(b_i^2, b_i^1 | t) - \pi_j(b_i^2, b_i^1 | t). \quad (13.59)$$

From Definition 13.20, when player i wishes to compute the kindness of player j toward him, the relevant beliefs are his first and second order beliefs, b_i^2, b_i^1 , as in the models of Rabin and Dufwenberg–Kirchsteiger. The payoff of player i , at node t , given the first and second order beliefs, is given by $\pi_i(b_i^2, b_i^1 | t)$ and the payoff of the opponent, $j \neq i$, is $\pi_j(b_i^2, b_i^1 | t)$. Player i takes as his reference payoff, the payoff of the opponent. In the Rabin and Dufwenberg–Kirchsteiger models, the relevant analogue was some notion of an equitable payoff. This is the sense in which the Falk–Fischbacher model incorporates inequity aversion. Outcomes are advantageous for player i when $\eta_j > 0$ and disadvantageous when $\eta_j < 0$. Thus, player i perceives player j to be kind if $\eta_j > 0$ and unkind if $\eta_j < 0$.

The outcome terms, η_1 and η_2 , do not provide information on the kindness or unkindness of intentions. For instance, they do not reveal if the other player had access to a fairer alternative. We now turn to beliefs about intentions.

Suppose that player i wishes to infer the intentions of player j . First, he would like to infer the set of payoffs, Π_i , that are available to both players. But these payoffs depend on the strategy chosen by player j , $\phi_j \in \Phi_j$, and the beliefs of player j about the strategy of player i , b_j^1 . Since b_j^1 is unobserved by player i he uses his beliefs about b_j^1 , i.e., $b_i^2 \in \Phi_i$, where Φ_i is the set of behavior strategies of player i . Denote by $\Pi_i(b_i^2, \phi_j | t)$, the relevant set of payoffs for both players (from the perspective of player i) at node $t \in T$.

$$\Pi_i(b_i^2, \phi_j | t) = \{\pi_i(b_i^2, \phi_j | t), \pi_j(b_i^2, \phi_j | t) | \phi_j \in \Phi_j\}. \quad (13.60)$$

Suppose that player j induces a payoff distribution $(\pi_i, \pi_j) \in \Pi_i(b_i^2, \phi_j | t)$ by a choice of his action $\phi_j \in \Phi_j$. How intentional is the payoff distribution (π_i, π_j) chosen by player j ? To answer this question, we define the *intention factor* $\vartheta_j(b_i^2, b_i^1 | t)$. Recall that if $\vartheta_j = 1$, then the choice is fully intentional. For less than fully intentional choices, ϑ_j is less than 1. Formally, letting $\epsilon_i \in [0, 1]$ be a *pure outcome concern parameter*,

$$\vartheta_j(b_i^2, b_i^1 | t) = \begin{cases} 1 & \text{if } \pi_i \geq \pi_j \text{ and } \exists \tilde{\pi}_i \in \Pi_i(b_i^2, \phi_j | t) : \tilde{\pi}_i < \pi_i, \\ \epsilon_i & \text{if } \pi_i \geq \pi_j \text{ and } \forall \tilde{\pi}_i \in \Pi_i(b_i^2, \phi_j | t) : \tilde{\pi}_i \geq \pi_i, \\ 1 & \text{if } \pi_i < \pi_j \text{ and } \exists \tilde{\pi}_i \in \Pi_i(b_i^2, \phi_j | t) : \tilde{\pi}_i > \pi_i, \\ \epsilon_i & \text{if } \pi_i < \pi_j \text{ and } \forall \tilde{\pi}_i \in \Pi_i(b_i^2, \phi_j | t) : \tilde{\pi}_i \leq \pi_i. \end{cases} \quad (13.61)$$

The interpretation of (13.61) is as follows. In the first two rows, player j treats player i kindly by the outcome criterion, i.e., $\pi_i \geq \pi_j$. However, the action of player j bears a different interpretation depending on the alternatives available. In the first row, an alternative exists that gives a worse payoff to player i ($\tilde{\pi}_i < \pi_i$). Thus, player j could have been unkind but chose to be intentionally kind, so $\vartheta_j = 1$. In the second row, player j induces a greater payoff for player i but player j had no alternative that would have given player i a lower payoff. Hence, the kindness of player j is untested in this case. So player i assigns a lower value to the intentional kindness factor, i.e., $\vartheta_j = \epsilon_i \leq 1$.

In the last two rows of (13.61), player i is at a disadvantage relative to player j (i.e., $\pi_i < \pi_j$). So is this unkindness by player j to player i , intentional? In the third row, player j could have improved

player i 's payoff in the alternative ($\tilde{\pi}_i > \pi_i$) but choose not to, hence, the unkindness of player j is fully intentional, so $\vartheta_j = 1$. By contrast, in row 4, player i is at a disadvantage but none of the alternatives can give player i a higher payoff, hence, player i cannot infer fully if player j wanted to treat him in an unkind manner, so $\vartheta_j = \epsilon_i \leq 1$.

Suppose $\epsilon_i = 1$. Then, from (13.61), ϑ_j always equals 1. Hence, from the kindness function (13.58) we get that $\tilde{k}_j(b_i^2, b_i^1 | t) = \eta_j(b_i^2, b_i^1 | t)$, thus, the players care only about the outcome, i.e., whether it is advantageous ($\eta_j > 0$) or disadvantageous ($\eta_j < 0$). On the other hand, if $\epsilon_i = 0$, then players assign weight only to fully intentional outcomes (rows 1 and 3 in (13.61)).

Example 13.17 Suppose that

$$\Pi_i = \{(10, 3), (8, 10), (6, 5)\},$$

where Π_i is defined in (13.60); the first number in any payoff pair represents the payoff of player i and the second number, the payoff of player j . If player j chooses the outcome (10, 3), then the first row of (13.61) applies, so $\vartheta_j = 1$. If player j chooses the outcome (8, 10), then the third row of (13.61) applies, so $\vartheta_j = 1$. Finally, if player j chooses the outcome (6, 5), then the second row of (13.61) applies, so $\vartheta_j = \epsilon_i$.

Definition 13.21 Pick an arbitrary node t . Let $z \in Z$ be a terminal node that follows node t . Denote by $\lambda(t, z)$ the unique node that is the immediate successor of node t on the path to node z .

Definition 13.22 (Reciprocation term r_i): The reciprocation term of player $i = 1, 2$ at node t is given by

$$r_i(t, z, b_i^2, b_i^1) = \pi_j(b_i^2, b_i^1 | \lambda(t, z)) - \pi_j(b_i^2, b_i^1 | t), j \neq i. \quad (13.62)$$

The reciprocation term of player i , given in (13.62), shows how player i alters the payoff of player j when he has the move at node $\lambda(t, z)$. For any given $\pi_j(b_i^2, b_i^1 | t)$, player i can choose to either reward (positive reciprocation, $r_i > 0$) or punish (negative reciprocation, $r_i < 0$) player j by choosing the size of $\pi_j(b_i^2, b_i^1 | \lambda(t, z))$ through his own actions.

The utility function in the psychological game for player $i = 1, 2$ is defined as

$$u_i(z, b_i^2, b_i^1) = \pi_i(z) + \mu_i \sum_{t'=t}^z \tilde{k}_j(b_i^2, b_i^1 | t') r_i(t', z, b_i^2, b_i^1). \quad (13.63)$$

Since $\pi_i : Z \rightarrow \mathbb{R}$, the material payoffs of any player are defined at each of the end nodes only. $\mu_i \geq 0$ is the *reciprocity parameter*; it is the relative weight placed by a player on the *psychological payoff* (second term), relative to the material payoffs (first term). While the material payoffs only depend on reaching a particular end node, the psychological payoffs depend on play along the entire path leading up to the end node. At each node where player i has a move, he computes the kindness of player j (the term $\tilde{k}_j$) as well as his own reciprocation to the kindness of j (the term r_i). So when player j is being kind ($\tilde{k}_j > 0$), positive reciprocation by player i ($r_i > 0$) improves the psychological payoff of player i .

Falk and Fischbacher (2006) call a subgame perfect psychological Nash equilibrium a *reciprocity equilibrium*. Heuristically, for any subgame that starts with some node $t \in T$, we can use (13.63) to compute the possible utilities of the players that players maximize. This allows us to determine the subgame perfect equilibria, which with the additional restriction of the consistency of actual actions with first and second order beliefs, constitutes a *reciprocity equilibrium*. For different parameter values, Falk and Fischbacher show that their model is consistent with

results from several kinds of experimental games such as the ultimatum game, the gift exchange game, the dictator game, the public goods game, and the prisoner's dilemma game.

As an application of this framework, consider an ultimatum game. Suppose that the proposer, P , who is given one dollar can offer an amount $0 \leq c \leq 1$ to a responder, R . Suppose that, conditional on a choice of c , R accepts the offer with some probability $p(c) \geq 0$. If R accepts, the payoffs of P and R are $1 - c$ and c respectively. Otherwise, each player gets zero each.

In any subgame where the history is c , let P 's first order beliefs about p be given by $b_P^1 = p'$ and R 's second order belief about p , or beliefs about b_P^1 , be given by $b_R^2 = p''$. Let the intention factor of P be $\vartheta_P(c)$. Using (13.63), we can write R 's utility from accepting P 's offer, U_R^a , as.

$$U_R^a = c + \mu_R \vartheta_P(c) p'' [c - (1 - c)] [(1 - c) - p'' (1 - c)]. \quad (13.64)$$

If R accepts, her material payoff is c (first term). The second term is the psychological payoff $\mu_R \tilde{k}_{PR}$. Using (13.62), the reciprocation term is $r_R = (1 - c) - p'' (1 - c)$; this is the difference between P 's payoff at the terminal and the penultimate node (hence, the usage of the probability p''). Using (13.59), $\eta_P = p'' [c - (1 - c)]$ (notice that before R makes his decision we compute the expected payoffs from R 's actions). In an analogous manner, we can derive the payoff of R when she rejects the offer, U_R^r .

$$U_R^r = 0 + \mu_R \vartheta_P(c) p'' [c - (1 - c)] [0 - p'' (1 - c)]. \quad (13.65)$$

Using (13.64), (13.65), the difference in the payoffs from acceptance and rejection is

$$U_R^a - U_R^r = c + \mu_R \vartheta_P(c) p'' (1 - c) (2c - 1). \quad (13.66)$$

A sufficient condition for acceptance to dominate rejection is that the second term on the RHS of (13.66) be positive $\Leftrightarrow c \geq 0.5$. Hence, in this case R always accepts, i.e., $p = 1$; we summarize this result in the next lemma.

Lemma 13.2 *All offers by P such that $c \geq 0.5$ are immediately accepted by R with $p = 1$.*

The next proposition gives the solution to the optimal probability, p , when $c < 0.5$. The proof is left as an exercise to the reader.

Proposition 13.37 *If $\mu_R > 0$, then in the unique reciprocity equilibrium, the acceptance probability of R is given by*

$$p^*(c) = \begin{cases} \min \left\{ \frac{c}{\mu_R(1-c)(1-2c)}, 1 \right\} & \text{if } c < 0.5 \\ 1 & \text{if } c \geq 0.5 \end{cases} \quad (13.67)$$

Proposition 13.37 is illustrated in a diagram in Figure 13.23. It is clear that the acceptance probability is increasing in the offer of P . For a given offer, the probability of acceptance is higher if the weight placed by R on the psychological payoff, μ_R is lower. In the limit as $\mu_R \rightarrow 0$ one gets the acceptance probability to be one, for all positive offers (as in classical game theory).

In the spirit of subgame perfection, given the acceptance probability schedule of R in (13.67), P now chooses the optimal value of c . From (13.67), we can find the smallest offer, c_0 , such that $p(c_0) = 1$; this is shown in Figure 13.23. A simple calculation shows that

Figure 13.23 The effect of c and μ_R on p .

$$c_0 = \frac{1 + 3\mu_R - \sqrt{1 + 6\mu_R + \mu_R^2}}{4\mu_R}. \quad (13.68)$$

Using (13.63), and the consistency condition $p = p' = p''$, we can write the utility of P . Suppose that the initial beliefs of R are that P is going to make some offer $\tilde{c}$. Let c be the actual offer made and observed by R at the node where she makes a decision to accept or reject. In equilibrium, $\tilde{c} = c$. Then P 's utility is given by:

$$U_P = p(c)(1 - c) + \mu_P \vartheta_R p(\tilde{c}) [1 - \tilde{c} - \tilde{c}] [p(c)c - p(\tilde{c})\tilde{c}]. \quad (13.69)$$

Notice that in writing (13.69) we have used (13.62), so that $r_P = [p(c)c - p(\tilde{c})\tilde{c}]$ and from (13.59) we get that $\eta_P = p(\tilde{c}) [1 - \tilde{c} - \tilde{c}]$. We leave the proof of the next proposition as an exercise for the reader.

Proposition 13.38 *The optimal offer by P is given by*

$$c^* = \max \left\{ c_0 = \frac{1 + 3\mu_R - \sqrt{1 + 6\mu_R + \mu_R^2}}{4\mu_R}, 0.5(1 - \mu_P^{-1}) \right\}. \quad (13.70)$$

In (13.70), the first term in the brackets on the RHS depends on μ_R , the weight placed on the psychological payoff by R . Falk and Fischbacher term this as the *reciprocal inclination* of R . The first term is the smallest offer that guarantees acceptance. The responder's reciprocal inclination is crucial for the size of this term. If R cares purely about her material payoffs, i.e., $\mu_R = 0$, then $c_0 = 0$. In the limit as $\mu_R \rightarrow \infty$, $c_0 = 0.5$. In the intermediate ranges of μ_R , c_0 is increasing in μ_R . If, on the other hand, R cares only about material payoffs (and so $c_0 = 0$), then the offer of P depends on the second term in the braces on the RHS of (13.70). This term depends on the concern of P for an equitable outcome, μ_P . If $\mu_P = 0$, then the offer is zero. In general, the second term is increasing in μ_P and as $\mu_P \rightarrow \infty$, then the second term tends to 0.5. Thus, the optimal offer is less than 0.5 in both cases.

13.5.5 Guilt in games

Battigalli and Dufwenberg (2007) consider a general framework for modeling *guilt*. Player i may experience guilt if he lets down player j , based on his second order beliefs (i.e., his beliefs about

the beliefs of player j). Consider Example 13.8 above. Let John and the taxi driver be respectively players 1 and 2. John's utility, u_1 , is given by

$$u_1(t) = y_1 - t - \gamma \max \{0, b_1^2 - t\}, \quad (13.71)$$

where y_1 is John's income, t is the tip that he pays to the taxi driver, and b_1^2 is player 1's beliefs about b_2^1 (i.e., John's belief about the taxi-driver's expectation of the tip). $\gamma \geq 0$ is a measure of the importance of the psychological cost of guilt.⁶⁵ The utility of player 1 from three different levels of tips is given below.

$$\begin{cases} u_1(t) = y_1 - b_1^2 & \text{if } t = b_1^2, \\ u_1(\hat{t}) = y_1 - \hat{t} & \text{if } t = \hat{t} > b_1^2, \\ u_1(\tilde{t}) = y_1 - b_1^2 + (1 - \gamma)(b_1^2 - \tilde{t}) & \text{if } t = \tilde{t} < b_1^2. \end{cases}$$

Since $\hat{t} > b_1^2$, we have $u_1(\hat{t}) < u_1(t = b_1^2)$, thus, John never pays a tip that exceeds his second order beliefs. However, depending on the value of γ we have the three cases $u_1(t = b_1^2) \begin{smallmatrix} \geq \\ \leq \\ = \end{smallmatrix} u_1(\tilde{t})$. If psychological payoffs are salient enough, in the sense $1 < \gamma$, then $u_1(t = b_1^2) > u_1(\tilde{t})$, so it is utility enhancing to pay exactly the tip that John thinks that the taxi driver expects. In other words if the emotion of guilt is strong enough, John always pays a tip that he believes is expected by the taxi driver.

Example 13.16 described contributions in a public goods game in the presence of *reciprocity*. Let us now invoke the role of *guilt* to explain contributions. Here we focus on *simple guilt*, which requires players to experience guilt if they believe that they have let down the expectations of others; see Battigalli and Dufwenberg (2007). For the case of the three-player public goods game in Example 13.16, the objective function of a player $i \in N$ who experiences such feelings of guilt is

$$U_i = \left[(20 - s_i) + \frac{1}{2} (s_1 + s_2 + s_3) \right] - \gamma_i \max \left(0, \frac{b_{ji}^2 + b_{ki}^2}{2} - s_i \right), \quad i \neq j \neq k. \quad (13.72)$$

Thus, players experience guilt if they think that their actual contribution to the public good, s_i , is lower than the average expectations of others about their contributions, $\frac{b_{ji}^1 + b_{ki}^1}{2}$; where b_{ji}^1 is the first order belief of player j about the contribution of player i . Since players do not know what others expect of them, they use their second order beliefs to form beliefs about the beliefs of others, i.e., player i uses $\frac{b_{ji}^2 + b_{ki}^2}{2}$ to guess the value of $\frac{b_{ji}^1 + b_{ki}^1}{2}$; where b_{ji}^2 is the belief of player i about the belief of player j about the contribution of player i . The parameter $\gamma_i > 0$ measures the degree of *guilt aversion* of the player. If $\gamma_i = 0$, then there is no guilt and the player optimally chooses to free ride, $s_i = 0$, as in classical game theory.

Suppose now that $\gamma_i > 0$ and we begin at $s_i = 0$. From the first term in (13.72), the marginal utility of an extra unit of s_i is $-\frac{1}{2}$, and, from the second, the marginal guilt aversion falls by γ_i . Hence, if $\gamma_i < \frac{1}{2}$, then it is still optimal to choose $s_i = 0$. Thus, low levels of guilt aversion do not alter the standard result. Now suppose that $\gamma_i > \frac{1}{2}$. If $\frac{b_{ji}^2 + b_{ki}^2}{2} > s_i$, then the marginal utility of

⁶⁵ For pedagogical simplicity, the utility from guilt is linear in (13.71). However, one needs further empirical evidence to distinguish between alternative functional forms; see Attanasi et al. (2015).

the player can be improved by increasing s_i and if $\frac{b_{iji}^2 + b_{iki}^2}{2} < s_i$, then the marginal utility can be increased by reducing s_i . Hence, if $\gamma_i > \frac{1}{2}$, then it is optimal to choose $s_i = \frac{b_{iji}^2 + b_{iki}^2}{2}$.

Dufwenberg et al. (2011) run experiments to test the predictions of this model. They do not observe γ_i but were able to isolate subjects for whom $s_i = 0$, $\frac{b_{iji}^2 + b_{iki}^2}{2} = 0$ and $\gamma_i < \frac{1}{2}$. For the remaining subjects, they choose to test the weaker hypothesis that the correlation between s_i and $\frac{b_{iji}^2 + b_{iki}^2}{2}$ is positive. The results are shown in Figure 13.24. The diagonal is drawn as a dotted line and the second line in the diagram is the best fitting line between pairs of contributions and second order beliefs. The results are generally consistent with the guilt-aversion model. There is a positive relation between contributions and second order beliefs in all treatments. The filled-in circles show zero contributions when $\frac{b_{iji}^2 + b_{iki}^2}{2} = 0$ and represent the case $s_i = 0$, $\frac{b_{iji}^2 + b_{iki}^2}{2} = 0$ and $\gamma_i < \frac{1}{2}$.

The frames, Give or Take, and Neutral or Community (see description in Example 13.16), have a significant affect on the second order beliefs. Mean contributions are highest in the Give-Neutral treatment, followed by the Give-Community treatment, Take-Neutral treatment and the Take-Community treatment. There are also important differences in the elicited first order beliefs (see Figure 13.22) and second order beliefs (see Figure 13.24) in different treatments. Hence, the framing of games has an important effect on beliefs.

Figure 13.24 The relation between contributions and second order beliefs in the public goods game.

Panel B: Partnership game in the presence of guilt

Figure 13.25 A partnership game in the absence and presence of guilt.

Source: Charness and Dufwenberg (2006) with permission of The Econometric Society.

So which of the two explanations, *reciprocity* (see Example 13.16) and *guilt*, explains the level of contributions in the public goods game. First and second order beliefs are highly correlated in each treatment. When a regression is run with contributions as the dependent variable and first and second order beliefs as the independent variables, except for the Take–Community treatment, second order beliefs lose significance. In the Give treatment, the first order beliefs are highly significant, as predicted by the reciprocity hypothesis. On balance, second order beliefs, and, so, guilt aversion is relatively more important in the Take–treatments. However, the high correlation between first and second order beliefs suggests that reciprocity and guilt cannot be neatly separated in the experimental results.

The first study of the relation between beliefs and observed behavior is due to Dufwenberg and Gneezy (2000). In their lost wallet game, player 1 has the opportunity to take money from a lost wallet or pass this decision to player 2 who then decides on an allocation of the money in the wallet between the two players. They find that player 2 passed a higher amount of money to player 1 if he believed that player 1 expects a higher level of transfer. Guerra and Zizzo (2004), Charness and Dufwenberg (2006), and Bacharach et al. (2007) elicit second order beliefs of players. They find that there is a close association between the elicited beliefs and the tendency of players to behave prosocially, a finding that is consistent with the guilt-aversion hypothesis.⁶⁶

Here we consider the work of Charness and Dufwenberg (2006) in more detail. It involves issues of guilt, communication, and promises that tie in nicely with the work on coordination and communication that we extensively analyze in Chapter 12 and other work on promises and ethics that we report in Part 2 of the book.

Consider the game in panel A in Figure 13.25 that is designed to mimic a situation of moral hazard in a principal–agent relation. There are two risk-neutral players who are making a decision to enter into a partnership. Player 1 (principal) and player 2 (agent) each have an outside option of 5. Player 1 can choose not to enter into the partnership by playing the strategy Out, leading to the outside option payoffs (5, 5). Or player 1 can choose to enter into a partnership (the strategy In). If a partnership is entered into, then players sign a contract that specifies a wage–effort tuple

⁶⁶ For a critical review of this evidence, see Attanasi and Nagel (2008).

$(w, e) = (14, 1)$. The wage, w , is contractible but the effort level of player 2 is not observable or verifiable to player 1.

Player 2 can choose an effort level e at a cost $4e$. When player 2 chooses to shirk, $e = 0$ (the strategy Don't Roll), the project fails in the sense that it yields a revenue of 14, so player 1 gets 0 and player 2 gets the promised wage of 14. When player 2 chooses the contractual effort level $e = 1$ (the strategy Roll), there is a cost of effort equal to 4, and the project succeeds with probability $p = \frac{5}{6}$. If the project fails, the total revenue is 14, of which player 2 gets $14 - 4 = 10$, leaving 0 for player 1. In the case of success, the project yields an extra revenue of 12 for a total revenue of 26 (player 2 gets $14 - 4$ and player 1 gets $26 - 14$). Importantly, in the event that the project fails, player 1 cannot tell if it was due to a low effort level on the part of player 2 or high effort but bad luck. Hence, the terminal nodes $(0, 14)$ and $(0, 10)$ are in the same information set for player 1. This is the sense in which there is a moral hazard problem.

Using classical game theory, the unique subgame perfect outcome in this game with risk-neutral players is (Out, Don't) but it is not efficient. Can communication in the form of free form messages from player 2 to player 1, prior to the start of the game, achieve an efficient outcome? Clearly if the players have completely self-regarding preferences (as reflected in the payoffs in panel A), then such communication will be ineffective.

Now introduce the possibility of guilt aversion; see Panel B in Figure 13.25. Suppose that player 2 plays Roll with some probability p . The first order beliefs of player 1 about p are denoted by b_1^1 . The beliefs of player 2 about b_1^1 are denoted by b_2^2 (these are second order beliefs about p). Thus, player 2 believes that player 1 hopes to get the expected payoff: $(1 - b_2^2)0 + b_2^2(\frac{5}{6}12 + \frac{1}{6}0) = 10b_2^2$. Letting the guilt-aversion parameter of player 2 be γ_2 , the guilt-incorporated payoffs of the players are shown in panel B. In particular, the utility of player 2 from Don't Roll is $14 - 10\gamma_2 b_2^2$.

The risk-neutral player 2 chooses Roll, i.e., prefers putting in the contractual effort level $e = 1$ to shirking, $e = 0$, if $14 - 10\gamma_2 b_2^2 < 10$. The higher the second order belief of player 2, b_2^2 , the more likely is this condition to be satisfied and the more likely is player 2 to fulfil the contractual obligations.

In the experiments, prior to the move by player 1, player 2 can send a non-binding promise to player 1 (written as a free-form message) about his intentions, e.g., that he will play the strategy Roll with high probability (or even certainty). Such promises may increase the first order belief of player 1, b_1^1 , as well as the second order belief of player 2, b_2^2 . Thus, promises may, in fact, optimally increase the probability that player 2 plays Roll. Hence, ex-ante communication may be effective in promoting partnerships and achieving the efficient outcome (In, Roll).

As a robustness check, players also play a second game, which is identical to panel-A of Figure 13.25 except that the outside option of both players is 7 each. This is the $(7, 7)$ treatment, while the original one is termed the $(5, 5)$ treatment because if player 1 chooses Out at the initial node, the payoffs are $(5, 5)$. Beliefs of the players, b_1^1 and b_2^2 , are directly elicited at the end of the experiment. Subjects in the role of player 1 were asked about the percentage of player 2s who are likely to choose Roll; the guesses were then rewarded for accuracy. Subjects in the role of player 2s were asked to guess the average guess of player 1s who choose In; these guesses were also rewarded for accuracy.

The results are shown in Figure 13.26. The results in the $(5, 5)$ and the $(7, 7)$ treatments are similar. Consider the $(5, 5)$ treatment. Communication enhances the likelihood of the following three events. (1) Player 1's choice of In (from 56% to 74.5%). (2) Player 2's choice of Roll (from 44% to 67%). (3) The overall play of the strategy (In, Roll) (from 20% to 50%). There is a strong positive correlation between the first order beliefs of player 1, b_1^1 , and the choice of In and the second order beliefs of player 2, b_2^2 , and Roll; this is consistent with the guilt-aversion hypothesis.

Figure 13.26 The effect of communication/promises on partnerships.

Source: Charness and Dufwenberg (2006) with permission of The Econometric Society.

Messages from player 2 to player 1 also significantly increase the first order beliefs of player 1s, b_1^1 (from 41.01% without communication to 59.02% with communication). Since the messages were free-form, messages that contained a statement of intent or promise were particularly effective in raising the level of beliefs, b_1^1 , b_2^2 , and the partnership enhancing actions of the two players, In and Roll. An exercise asks you to consider if these results can be explained by other models.

Ellingsen et al. (2010) implement a more direct method of eliciting beliefs; they find the absence of the guilt-aversion motive in their experiments. This is a potentially challenging finding for theories of guilt aversion that we now describe in more detail, followed by an explanation of these results based on Khlmetzski et al. (2015). The authors consider three games. A dictator game, a trust game, and the partnership game of Charness and Dufwenberg (2006) described in panel A of Figure 13.25. In each case, a player in the game (the dictator in the dictator game, the trustee in the trust game, and player 2 in the partnership game) is provided with *direct information* on the first order beliefs of the other player, before they make their decision.

Furthermore, players are not told that their first order beliefs will be communicated to others, hence, these beliefs are not misstated for strategic reasons. If players knew that their first order beliefs would be communicated to the other player then they could have tried to induce greater guilt on the part of the other player to get a selfishly better payoff. Thus, the second order beliefs of players (beliefs about the first order beliefs of others) are as accurate as possible. One might wonder if this violates the convention in economic experiments that the experimenter should not mislead the subjects. Ellingsen et al. (2010) give a robust defence of their procedure against such a charge.⁶⁷

In the dictator game, dictators were asked to split an amount of 20 Swedish Kroner (SEK) between themselves and a passive responder. Prior to the game, the responders' beliefs about the

⁶⁷ They did not lie to the subjects—rather they simply did not give any information to subjects about what would be done with their first order beliefs. In the exit interviews, none of the subjects complained about being cheated, once the information about the use of first order beliefs was conveyed to them. Obviously there might be externalities for other experimenters if the same subjects participate in other experiments. The authors assign very little probability to such an event.

Figure 13.27 Bubble plots of the relation between induced second order beliefs and contributions in the dictator game (left panel) and the amount sent back by trustees in the trust game (right panel).

Source: Reprinted from *Games and Economic Behavior* 68: 95–107. Ellingsen, T., Johannesson, M., Tjøtta, S., and Torsvik, G., “Testing guilt aversion.” Copyright © 2010, with permission from Elsevier.

likely donations of the dictators were elicited. These beliefs were then conveyed to the dictators before they made their decision. Let us term these as *induced second order beliefs*. If the guilt-aversion hypothesis holds, then one should expect a positive correlation between the amounts offered by the dictator to the receiver and the induced second order beliefs. The results are shown in the left panel of Figure 13.27 in a bubble plot. The size of the bubbles reflects the frequency of a particular combination of beliefs and contributions. The bubbles appear fairly random, and the absence of any statistically significant correlation is confirmed by a calculation of the parametric Pearson correlation coefficient (-0.075) and the non-parametric Spearman correlation coefficient (-0.044). A sensitivity analysis is conducted by removing dictators whose choices may appear unexpected, e.g., offering more than 50%, and those who may not suffer any guilt aversion, i.e., offer nothing. Yet, the correlation is insignificant.

In the trust game, the trustor can send 50 Norwegian Kroner (NOK) to the trustee. The experimenter multiplies the amount sent by 5. The trustee then sends back to the trustor an amount from the set $\{0, 50, 100, 150, 200, 250\}$. After the trustors have made their decisions, their first order beliefs about the modal amount that the trustees are likely to send back is elicited. Trustors are rewarded with NOK 50 if their guess is correct. Before the trustees make their decisions, the first order beliefs of the trustors are conveyed to them—these then become the induced second order beliefs of the trustees. Under the guilt-aversion hypothesis, we expect to see a positive correlation between the induced second order beliefs and the amount sent back by the trustee to the trustor. The results are shown in the right panel of Figure 13.27 in a bubble plot. The distribution of bubbles is almost random, and the non-parametric and parametric correlation coefficients are insignificant. These results are not consistent with the guilt-aversion hypothesis.

The third game, the partnership game (see Figure 13.25), allows a direct comparison with the results of Charness and Dufwenberg (2006). Suppose that player 2 chooses Roll with probability p . Player 1 is asked to guess p and this first order belief is conveyed to player 2 as an induced second order belief before player 2 makes his decision. Player 1 earns a reward of NOK 50 if his guess is within 5 percentage points of the actual p . Under the guilt-aversion hypothesis, we should expect a positive correlation between the induced second order beliefs and p . Yet the correlation is negative, statistically insignificant, and negligible. These results are in contrast to the Charness

and Dufwenberg (2006) results who find support for the guilt-aversion hypothesis with a different experimental design in which second order beliefs were elicited rather than induced in this manner.

The definition of guilt is one-sided in (13.71). In the context of Example 13.8, John experiences *guilt* if his tip is below his perceived expectation of the tip by the taxi driver. However, John experiences no *joy* or *elation* from the surprise of offering a tip that exceeds the expectation of the taxi driver. Khalmetski et al. (2015) extend the utility function in (13.71), in the context of dictator games, to incorporate both guilt and surprise. Their objective is to reconcile findings that support guilt aversion (e.g., Charness and Dufwenberg, 2006) with the results of Ellingsen et al. (2010) that find no support for guilt aversion.

Consider a dictator game in which the dictator has to divide one dollar between himself and the recipient. Denote by t , the amount transferred from the dictator to the receiver. Let us call the dictator and the receiver, respectively, players 1 and 2. Suppose that both players have the common utility function from material payoffs, m_i , $i = 1, 2$ that is strictly increasing and strictly concave ($m'_i > 0$ and $m''_i < 0$). Player 2 has the first order belief, b_2^1 , about the transfer to him, i.e., $b_2^1 = E_2[t]$. This assumption is in the spirit of the Köszegi–Rabin framework that allows for a distribution of reference points (see Part 1 of the book). The second order belief of player 1 about the belief, b_2^1 , is given by, b_1^2 , so $b_1^2 = E_1[b_2^1] = E_1E_2[t]$. Let the densities of b_2^1 and b_1^2 be given, respectively, by f_2^1 and f_1^2 (the corresponding cumulative distribution functions are F_2^1 and F_1^2). In contrast to (13.71), the dictator's utility function is given by

$$U_1(t | b_1^2) = m_1(1 - t) + S(t | b_1^2), \quad (13.73)$$

where

$$S(t | b_1^2) = \alpha \int_0^t (t - x) f_1^2(x) dx - \beta \int_t^1 (x - t) f_1^2(x) dx, \alpha \geq 0, \beta \geq 0. \quad (13.74)$$

Thus, conditional on his second order beliefs, player 1 derives elation from pleasantly surprising player 2 in states of the world where $t > x$, where x is a particular realization of his second order beliefs; this is the first term in (13.74). But he also feels guilty by letting down player 2 in states where $t < x$; this is the second term in (13.74). $\alpha \geq 0$ denotes the propensity of player 1 to make positive surprises (*surprise seeking*) and $\beta \geq 0$, the propensity to avoid negative surprises (*guilt aversion*). In order to make the problem interesting we assume that at least one of α and β is non-zero. The first term in (13.74) is the main difference between (13.71) and (13.73). A second difference is that (13.73) employs a framework that is similar to the Köszegi–Rabin utility function. Thus, players derive utility from the absolute levels of outcomes as well as gain–loss utility when outcomes are compared to all possible eventualities.

Player 1 does not directly observe b_2^1 but he observes an exogenously given informative signal, θ , which is the median of the distribution F_2^1 .⁶⁸ Thus, the conditional distribution of his second order belief is $F_1^2(b_2^1 | \theta)$ and the density is $f_1^2(b_2^1 | \theta)$. Since $t \in [0, 1]$, we assume that $F_1^2(b_2^1 | \theta)$ is continuously differentiable on $[0, 1] \times [0, 1]$. A higher value of the signal, θ , induces first order stochastic dominance in the conditional distribution of beliefs F_1^2 . Thus, we have

$$\theta' > \theta \Rightarrow F_1^2(b_2^1 | \theta') \leq F_1^2(b_2^1 | \theta) \text{ for all } b_2^1 \in [0, 1] \text{ and } \theta', \theta \in [0, 1].$$

⁶⁸ The model can also be solved if we assume that θ is the mean of the distribution F_2^1 .

Given the signal received by player 1 we can replace $S(t \mid b_1^2)$ by $S(t \mid \theta)$ and $U_1(t \mid b_1^2)$ by $U_1(t \mid \theta)$.

The dictator's transfer t to the recipient can now be found as the solution to the following problem.

$$t^*(\theta) \in \arg \max_{t \in [0,1]} U_1(t \mid \theta) = m_1(1-t) + S(t \mid \theta), \quad (13.75)$$

where

$$S(t \mid \theta) = \alpha \int_0^t (t-x) dF_1^2(x \mid \theta) - \beta \int_t^1 (x-t) dF_1^2(x \mid \theta), \alpha \geq 0, \beta \geq 0. \quad (13.76)$$

In what follows below we assume a strictly positive solution, i.e., $t \times (\theta) > 0$.⁶⁹ The intuition for the next proposition, Proposition 13.39, can be seen from (13.76). When the dictator is surprise seeking (relatively high α), then the first term in (13.76) is higher. Hence, there is a greater marginal incentive to create a pleasant surprise ($t^*(\theta) \geq \theta$). A high value of $t^*(\theta)$, in turn, magnifies the first term. The opposite case applies when β is relatively large.

Proposition 13.39 Suppose that there is a strictly positive solution, $t \times (\theta) > 0$, and $m'_i(x) \geq \frac{\alpha+\beta}{2}$.

- (i) If $\alpha > \beta$, then $t^*(\theta) \geq \theta$.
- (ii) If $\alpha < \beta$, then $t^*(\theta) \leq \theta$.

Proof: Applying Leibniz's rule to (13.75) we get

$$\frac{dU_1(t^*(\theta) \mid \theta)}{dt} = -m'_1(1-t^*) + (\alpha - \beta) [F_1^2(t^* \mid \theta)] + \beta \geq 0. \quad (13.77)$$

If $t^*(\theta) = 1$, then $\frac{dU_1(t^*(\theta) \mid \theta)}{dt} > 0$, otherwise if $0 < t^*(\theta) < 1$, then $\frac{dU_1(t^*(\theta) \mid \theta)}{dt} = 0$. Assuming that $m'_i(x) \geq \frac{\alpha+\beta}{2}$, we can rewrite the RHS of (13.77) as

$$(\alpha - \beta) [F_1^2(t^* \mid \theta)] + \beta - \frac{\alpha + \beta}{2} \geq 0,$$

or

$$(\alpha - \beta) \left[F_1^2(t^* \mid \theta) - \frac{1}{2} \right] \geq 0. \quad (13.78)$$

Since θ is assumed to be the median of the distribution $F_1^1, F_1^2(t^* = \theta \mid \theta) = E_1[F_2^1(\theta) \mid \theta] = \frac{1}{2}$. Thus, we have two main cases that satisfy (13.78).

- (a) If $\alpha > \beta$, then $F_1^2(t^* \mid \theta) \geq \frac{1}{2}$, or $F_1^2(t^* \mid \theta) \geq F_1^2(\theta \mid \theta)$. Thus, $t^*(\theta) \geq \theta$.
- (b) If $\alpha < \beta$, then $F_1^2(t^* \mid \theta) \leq \frac{1}{2}$, or $F_1^2(t^* \mid \theta) \leq F_1^2(\theta \mid \theta)$. Thus, $t^*(\theta) \leq \theta$.

A third case arises when $\alpha = \beta$ in which case we can have $t^*(\theta) \geq \theta$. ■

⁶⁹ Khametski et al., (2014) show that if we assume a lower bound on the marginal utility of consumption given by $m'_i(x) \geq \frac{\alpha+\beta}{2}$ for all $x \in [0, 1]$, then (in conjunction with the other assumptions made above) it is always the case that $0 < t^*(\theta)$.

Proposition 13.40 *The comparative static effects of the optimal transfer are as follows.*

- (i) $t^*(\theta)$ is increasing in θ if $\alpha < \beta$.
- (ii) $t^*(\theta)$ is decreasing in θ if $\alpha > \beta$.

Proof: We outline a heuristic proof for the case of a discrete distribution with two outcomes.⁷⁰ Suppose that there are only two values of second order beliefs of player 1 given by $x_L < x_H$ with respective probabilities p and $1 - p$. In order to ensure that both terms on the RHS of (13.76) are non-zero, suppose that the optimal solution $t^*(\theta)$ is such that $x_L < t^*(\theta) < x_H$. Then we can write (13.76) as

$$S(t | \theta) = \alpha p (t^*(\theta) - x_L) - \beta(1 - p) (x_H - t^*(\theta)), \alpha \geq 0, \beta \geq 0. \quad (13.79)$$

Now suppose that player 1 receives a higher signal $\tilde{\theta} > \theta$. Let $\tilde{p}$ be the probability of the outcome x_L under the signal $\tilde{\theta}$. We know that, by assumption, the distribution $F_1^2(b_2^1 | \tilde{\theta})$ first order stochastically dominates the distribution $F_1^2(b_2^1 | \theta)$, hence, $\tilde{p} < p$. From (13.79) we have

$$\frac{dS(t | \theta)}{dt} = \beta + p(\alpha - \beta).$$

Thus,

$$\frac{dS(t | \tilde{\theta})}{dt} - \frac{dS(t | \theta)}{dt} = (\alpha - \beta) (\tilde{p} - p). \quad (13.80)$$

Under both distributions, $F_1^2(b_2^1 | \tilde{\theta})$ and $F_1^2(b_2^1 | \theta)$, the marginal effect of a change in t on the first term in (13.75) is identical. Hence, the effect on the optimal solution t^* when θ changes, is determined entirely by the change in the marginal effect on the second term in (13.75). This is given by (13.80). Since $p > \tilde{p}$, the net marginal effect is determined entirely by the sign of $\alpha - \beta$. If $\beta > \alpha$, then $\frac{dS}{dt}$ goes up after the change in θ , hence, t^* also increases. Conversely, if $\beta < \alpha$, then t^* decreases. ■

Putting Propositions 13.39 and 13.40 together, the prediction of the model is as follows. If $\alpha > \beta$, then $t^*(\theta) \geq \theta$ (i.e., positive surprises) and there is a negative correlation between t^* and the signal θ . However, if $\alpha < \beta$, then $t^*(\theta) \leq \theta$ and there is a positive correlation between t^* and the signal θ . These predictions are confirmed by the empirical tests. If the dictator only had inequity-averse preferences then his transfer decision should not depend on his second order beliefs, nor should we observe the correlations between t^* and the signal θ that are suggested by Proposition 13.40.

The authors follow very closely the experimental design of Ellingsen et al. (2010) except that instead of the *direct-response method*, they use the *strategy method*. The dictator divides 14 euro between himself and the receiver. The receiver is asked to guess the average transfer that dictators will make in the population; this is a measure of θ in the experiments. Before these first order beliefs are revealed to the dictator (as in Ellingsen et al., 2010), the dictator is asked to reveal the transfers that he will make for each level of belief (rounded to the nearest 50 cents) of the receiver. It is assumed that the guess of the receiver is close to the median of her first order beliefs.

⁷⁰ Readers interested in the general proof can consult Khalmetski et al. (2015).

The strategy method allows for a within-subjects design, while earlier studies typically use the between-subjects design. For each dictator–receiver pair, the transfer (as revealed by the strategy method) that corresponded to the actual expectation level of the receiver, was implemented and paid out.

The results are as follows. First, the Ellingsen et al. (2010) results are replicated. Dictators transfer, on average, between 23–24% of their endowments. The average guesses of the recipients about the transfers are between 32–34% of the endowment. The correlation between guesses and transfers is statistically not different from zero. But there are within-subject differences in results that provide a more nuanced picture; 77% of the dictators alter their desired transfers at least once in response to a change in the guess of the recipient (as revealed by the strategy method). The within-subjects correlation between desired transfers and the guesses of the recipient is statistically significant for about 54% of the subjects. This is not consistent with purely outcome based models of inequity-averse social preferences.

When the within-subjects data from the strategy method is used to regress the desired transfers on the guesses of the recipients, the distribution of the coefficients on guesses that are significant at the 5% level is shown in Figure 13.28.

From Proposition 13.40, we expect the coefficient to be negative when $\alpha > \beta$ (surprise seeking dictators) and positive when $\alpha < \beta$ (guilt-averse dictators). Nearly 70% of the coefficients are distributed to the right of zero, so guilt aversion is relatively more important among dictators as compared to surprise-seeking. The distribution is asymmetric around zero (a two-sided sign test rejects the null that the median is zero). The average size of the positive coefficients is 0.58, while the average size of the negative coefficients is 0.53; these differences are statistically insignificant. In 27.2% of the cases, we have $t^* \geq \theta$, suggesting that surprise-seeking is more important than guilt aversion, i.e., $\alpha > \beta$; see Proposition 13.39. Furthermore, for 30% of the dictators who exhibit a significant correlation between transfers and guesses, the correlation is negative. This is consistent with $\alpha > \beta$; see Proposition 13.40. Thus, the authors draw very different conclusions from Ellingsen et al. (2010). Guilt aversion is very important but once one allows for surprise-seeking, which is found to be significant, then overall one does not find a correlation between actions and beliefs.

Figure 13.28 The distribution of the coefficients on guesses that are significant at the 5% level.

Source: Khalmetski et al. (2015).

In a second experiment, Khalmetski et al. (2015) also test for the importance of higher order beliefs, motivated by the idea of “guilt from blame” in Battigalli and Dufwenberg (2007). In the experiment reported above, receivers may not be sure of the intentionality of the transfers made by dictators. For instance, did the dictator really mean to surprise the receiver or did he make a mistake?

The authors consider two treatments. In the private treatment, the receiver is unaware that the dictator observes his first order belief. The dictator knows this, so he also knows that the receiver cannot impute any intentionality to his choice. In the public treatment, it is public knowledge that the dictator is told the first order beliefs of the receiver. Thus, the receiver can infer the intentionality of the dictator’s transfer (third order beliefs) and the dictator may in turn be influenced by his beliefs about the receiver’s third order beliefs. Thus, the fourth order beliefs of the dictator may be important in influencing the share given to the receiver. The experimental results show that average amounts sent in the public treatment are 70% higher than the private treatment, which is consistent with the importance of fourth order beliefs.

13.5.6 Dependence of utility on plans

In the framework of Geanakoplos et al. (1989), players derive utility only from the profile of equilibrium actions. However, the more general framework of Battigalli and Dufwenberg (2009) allows utility to depend on plans that are off the equilibrium path of play. Hence, players may evaluate their utility from the equilibrium strategy profile by taking account of their payoffs from non-equilibrium strategy profiles. This is reminiscent of the idea of stochastic reference points in Köszegi and Rabin (2006) and models of disappointment aversion that we discussed in Part 1 of the book.⁷¹ Here we illustrate the issues in a simple example from Battigalli and Dufwenberg (2009).

Suppose that we extend the trust game in Figure 13.19 by adding an extra stage, as shown in Figure 13.29; the first payoff in any pair of payoffs is Ann’s payoff. Ann can end the game by playing Out at the first node and both players get 0 each, or Ann could play Trust and give the move to Bob. Bob can then play Grab for payoffs (1, 3) (ignore the payoffs in the second row of this terminal node for now) or play Leave to pass the move to Ann. Ann then plays either Split or Reward for respective payoffs (2, 2) and (1, 3).

Now suppose that we consider this game as a psychological game. In particular, we are interested in the psychological utility of Ann. Let z be a terminal node (there are four such nodes in Figure 13.29), B be the set of beliefs for the game and s_A, s_B be respectively, the pure strategies of Ann and Bob (we rule out mixed strategies). Let $\zeta(s_A, s_B)$ be the terminal node that is reached when players play the strategy profile (s_A, s_B) . Suppose that Ann’s utility function at a terminal node z is given by

$$u_A(z, B, s_A) = \pi_A(z) - \theta \left[\sum_{s_B} b_A^1(s_B | h^0) \pi_A(\zeta(s_A, s_B)) - \pi_A(z) \right], \theta > 0. \quad (13.81)$$

The first term on the RHS in (13.81) is the material payoff of Ann at the terminal node z . The second term is gain–loss utility (in a manner similar to the Köszegi–Rabin framework) and θ is a parameter that captures the relative importance of psychological payoffs relative to material payoffs. Based on the initial beliefs of Ann at history h^0 about the strategy of Bob, $b_A^1(s_B | h^0)$, the second term compares each potential material payoff of Ann, $\pi_A(\zeta(s_A, s_B))$, as s_B is

⁷¹ See also Shalev (2000), who considers motivation similar to Köszegi and Rabin in settings with strategic interaction.

Figure 13.29 A psychological game in which utility depends on plans that are off the equilibrium path of play.

Source: Reprinted from *Journal of Economic Theory* 144(1): 1–35. Battigalli, P. and Dufwenberg, M. “Dynamic psychological games.” Copyright © 2009, with permission from Elsevier.

varied, with the actual material payoff at node z , $\pi_A(z)$. In this sense, Ann’s psychological utility depends on strategies that are off the path of play and on her beliefs about the plans of players.

To see the implications of this framework, consider Ann’s plans at history h^0 (where she has a choice between Trust and Out) about what she would do at history h^2 , where she has a choice between Split and Reward. Suppose also that Ann’s initial belief about the actions of Bob at history h^1 are given by $\alpha = b_A^1(\text{Leave} | h^0)$ and $1 - \alpha = b_A^1(\text{Grab} | h^0)$. Consider two possible plans for Ann.

I. Suppose that Ann’s initial strategy is to play (Trust, Split). Then, using (13.81), her initial expectation of the payoff from the strategy pair (Trust, Grab) is given by

$$1 - \theta [(1 - \alpha) 1 + \alpha 2 - 1] = 1 - \theta \alpha. \quad (13.82)$$

Thus, in Figure 13.29, in the second row of payoffs, following the strategy pair (Trust, Grab), we note the psychological payoff of Ann as $1 - \theta \alpha$. Therefore, Ann’s expected utility from the plan (Trust, Split) is

$$(1 - \alpha) (1 - \theta \alpha) + 2\alpha. \quad (13.83)$$

II. Suppose that Ann’s plan is (Trust, Reward). In this case, Ann’s material payoff at history h^2 is 1, which is independent of what Bob does at history h^1 (if Bob plays Grab, Ann still gets 1). Hence, Ann is never disappointed and her ex-ante payoff from the strategy pair (Trust, Reward) is given by 1.

Thus, using (13.82) and (13.83), Ann prefers the strategy (Trust, Split) to the strategy (Trust, Reward) if

$$(1 - \alpha) (1 - \theta \alpha) + 2\alpha > 1. \quad (13.84)$$

Thus, the lower is θ , the more likely is Ann to choose, ex-ante, the plan (Trust, Split). Conversely, if the inequality in (13.84) is reversed, then the ex-ante optimal plan is (Trust, Reward). But (Trust, Reward) is never optimal ex-post because at history h^2 , Ann always prefers to Split ($2 > 1$). Thus, plans can be *dynamically inconsistent*. If Bob can foresee this, he will know that Ann will always Split at history h^2 leading to disappointment for Ann from the strategy profile (Trust, Grab).

Solving the game backward, we now get that Ann will play Out at history h^0 if $0 > 1 - \alpha\theta$ or $\theta > \alpha^{-1}$.

13.6 Correlated equilibrium and social norms

In a series of papers that have culminated in Gintis (2009), Herbert Gintis provides a wide-ranging critique of the existing practice in classical game theory and other social sciences. He argues for a unification of the *behavioral sciences* (economics, anthropology, sociology, psychology, political science, and biology). The behavioral sciences ask the same underlying questions but propose incompatible models of human behavior and sociality. In this section, we give a brief account of some of the central arguments, particularly the shortcomings in classical game theory and the role of a correlated equilibrium.⁷²

Gintis favors retaining the assumption of rationality in economics, i.e., individuals have complete and transitive preferences. The evidence presented in this book in several places (e.g., from preference reversals and from time discounting) shows that individuals do not always make transitive choices. The solution advocated by Gintis is to fix the frame or context within which choices are transitive. Such conditional preferences ensure that intransitivity occurs only when the context or frame changes; for examples, see Sugden (2003) for a decision theoretic framework and al-Nowaihi and Dhami (2013) for work on time preferences.

The main shortcoming of classical game theory is that it provides no foundations for the assumption of *shared mental constructs*, e.g., common priors and common knowledge. The classical definition of a Nash equilibrium does not require a specification of the beliefs of the players. It merely requires that each player plays a best response to the strategy of the other player. Epistemic foundations for a Nash equilibrium give sufficient conditions for the existence of a Nash equilibrium (Aumann and Brandenburger, 1995). These conditions turn out to be extremely stringent. For instance, they require, in games with more than two players, that there be common priors about the state of the world and common knowledge of conjectures of each player in each state. However, there exist no epistemic foundations for common priors or common knowledge of conjectures.

It might be that *social norms* provide one possible source for mutual consistency of beliefs. As Gintis (p. 145) puts it: “It is not *reason* but *humanity* that leads us to believe that the Pareto-superior equilibrium is obvious.” Social norms may allow players to coordinate their conjectures about each other on Pareto optimal outcome. Such social norms may provide the underpinnings to common priors and to mutual and common knowledge among players.

It is sometimes argued that social norms are simply Nash equilibria that are based on *methodological individualism* (social phenomena are to be explained as arising from individual actions alone) and, typically, self-regarding preferences. There are two objections to this view. First, the epistemic foundations of a Nash equilibrium show that the requirements are too stringent relative to the cognitive limitations of humans. Second, most social norms are not Nash equilibria. Such norms do not in fact implement Nash equilibria, but they implement a correlated equilibria (Gintis, 2009, p. 132). Furthermore, Gintis (2009, chapters 10 and 11) argues forcefully that social norms are best explained by sociobiological models of *gene-culture coevolution*.⁷³

⁷² We suppress references to the research papers that the interested reader can find in Gintis (2009).

⁷³ See Section 12.1 in Gintis (2009) for the details. For gene-culture coevolution, see also Chapter 14.

Consider the following problem of coordination from Gintis (2009, Section 2.11), shown in the normal form game in Figure 13.30.

There are two players, the row player (Robin) and the column player (Colin). Each player has two strategies and there are two pure strategy Nash equilibria (*U*, *L*) and (*D*, *R*). However, *Bayesian rationality*⁷⁴ does not provide any guidance on which of the two Nash equilibria will arise. There is also a mixed strategy Nash equilibrium, in which each player plays the two pure strategies with equal probability; the payoffs from this mixed strategy profile are (2.5, 2.5). The Pareto optimal outcome is (*D*, *L*) but it is not a Nash equilibrium. How can cooperation be sustained between the two players?

Classical game theory is based on *methodological individualism*. By contrast, the epistemic conditions for a Nash equilibrium require common priors and common knowledge, which appear to transcend personal characteristics of individuals. Indeed, these constructs appear to depend on social institutions that help align the beliefs and expectations of individuals.

Classical game theory explains human cooperation through *instrumental rationality arguments* within the setup of infinitely repeated games (or finitely repeated games with some irrationality). In this framework, players have self-regarding preferences but may cooperate because the discounted future monetary payoffs arising from cooperation are greater as compared to non-cooperation. For instance, if perfect public signals of the actions taken by the players are available, then any player who plays non-cooperatively is punished by the other players. If players are *patient enough*, then they are sufficiently deterred by the threat of future punishment, so they cooperate. These results can be extended to imperfect public signals.⁷⁵

Gintis raises three main objections to explaining cooperation in classical game theory. First, many of the results require players to be *too patient*. By contrast, players may have a high degree of present bias in their preferences (see Part 3 of this book). Second, the more realistic case is one of private signals. However, the set of conditions under which cooperation can be attained in repeated games under private signals is quite stringent. In particular, these results typically hold only for near-public signals in which the private signals are ϵ close to public signals.⁷⁶ Gintis (2009, p. 182) expresses reservations about the inability to specify the size of ϵ : “It is difficult to access how critical the information requirements of these folk theorems are because generally the theorem is proved for ‘sufficiently small ϵ ’ with no discussion of the actual order of magnitude involved.” A related objection is the evidence of human cooperation in static and even finitely repeated contexts under full information. Third, players often play mixed strategies in repeated

⁷⁴ *Bayesian rational* individuals satisfy the axioms for Savage’s subjective expected utility model (see Part 1 of the book for details).

⁷⁵ For the case of perfect public signals see Fudenberg and Maskin (1986) and for the case of imperfect public signals see Fudenberg et al. (1994).

⁷⁶ See, for instance, the set of papers in the *Journal of Economic Theory*, 2002, Volume 102.

games, yet the standard theoretical justification for such strategies based on purification theorems does not hold for such games (Gintis, 2009, Chapter 6).

An epistemic game is a normal form game, augmented to include the structure of knowledge in the game. In this framework, there is a state space, Λ , where each element of Λ refers to the pure strategy choices of the players. A knowledge partition specifies, for each player, the information players have about which states have arisen. The epistemic game also specifies in each state, the conjectures of each player and their subjective priors. Readers interested in a formal treatment can consult Chapters 4 and 5 in Gintis (2009).

Gintis argues that the *correlated equilibrium* is a more natural equilibrium criterion as compared to a Nash equilibrium. The most famous result in this regard is due to Aumann (1987) who showed that in an epistemic game, Bayesian rational agents with common subjective priors will play a correlated equilibrium. A correlated equilibrium is a Nash equilibrium of an epistemic game that is augmented with a social planner, or *choreographer*, who moves first, observes a random variable and then gives recommendations to each player to play a particular strategy. The resulting recommendations are a Nash equilibrium in the sense that it is optimal for any player to follow the recommendations, conditional on the other players following their recommendations.

One of the central insights in Gintis is to assign to social norms and conventions, the role of a choreographer in a correlated equilibrium. A *social norm* specifies the responsibilities, expectations, and entitlements that are associated with a particular social role. Let us consider the play of a correlated equilibrium in the example given in Figure 13.30. We will show that the Pareto optimal outcome (D, L) , which is not a Nash equilibrium in the normal form game, can be a part of the correlated equilibrium.

Suppose that there are three states $\Lambda = \{\omega_1, \omega_2, \omega_3\}$. The choreographer (who reflects social norms and conventions) observes the state in Λ but the players do not. The choreographer announces that the three states $\omega_1, \omega_2, \omega_3$ will occur with respective probabilities $\alpha_1, \alpha_2, \alpha_3 = 1 - \alpha_1 - \alpha_2$. Suppose that the actual realization of the state is some $\omega \in \Lambda$. The choreographer then gives recommendations to the players to play their pure strategies in the following manner. If state ω_1 occurs, then Robin is recommended to play U and Colin is recommended to play L . Under state ω_2 the respective recommendations are (D, L) , and under state ω_3 the recommendations are (D, R) . Both players know these rules, i.e., the state-based recommendations and the underlying distribution of the states, $\alpha_1, \alpha_2, \alpha_3$. However, the players (i) hear only their own recommendation, and (ii) do not observe the state.

The recommendations generate a *knowledge partition* of the set Λ . The respective knowledge partitions for Robin and Colin, P_R, P_C , are given by

$$P_R = \{\{\omega_1\}, \{\omega_2, \omega_3\}\}; P_C = \{\{\omega_3\}, \{\omega_1, \omega_2\}\}. \quad (13.85)$$

From (13.85), Robin knows when state ω_1 occurs because only in that state is he given the recommendation to play U . However, if he is given the recommendation to play D , he does not know which of the two states ω_2, ω_3 occurred. P_C can be explained analogously. Consistent with Bayes' rule, the probabilities assigned by Robin to the two states ω_2, ω_3 , when given the recommendation to play D are

$$p_R(\omega_2) = \frac{\alpha_2}{\alpha_2 + \alpha_3}; p_R(\omega_3) = \frac{\alpha_3}{\alpha_2 + \alpha_3}. \quad (13.86)$$

Similarly, when given a recommendation to play L , Colin assigns the following probabilities to the two states ω_1, ω_2

$$p_C(\omega_1) = \frac{\alpha_1}{\alpha_1 + \alpha_2}; p_C(\omega_2) = \frac{\alpha_2}{\alpha_1 + \alpha_2}. \quad (13.87)$$

The recommendations to the players are in pure strategies. However, given the knowledge partitions in (13.85), it is as if each player faces an opponent who plays mixed strategies. For instance, when Robin is given the recommendation to play D , he imagines facing an opponent who plays L with probability $p_R(\omega_2)$ and R with probability $p_R(\omega_3)$. Analogously, when given a recommendation to play L , Colin imagines that he is playing an opponent who plays U with probability $p_C(\omega_1)$ and D with probability $p_C(\omega_2)$.

Let us now check the conditions, which ensure that it is optimal for each player to follow the recommendations of the choreographer. First consider Robin. When given a recommendation to play U he is certain that the state is ω_1 , so he knows for sure that Colin's recommendation is to play L . The best response to L is indeed, U . On the other hand, when given a recommendation to play D , Robin imagines that his opponent is playing a mixed strategy, so D is optimal if

$$4p_R(\omega_2) + p_R(\omega_3) \geq 5p_R(\omega_2) \Leftrightarrow \alpha_1 + 2\alpha_2 \leq 1 \text{ (since } \alpha_3 = 1 - \alpha_1 - \alpha_2 \text{)}. \quad (13.88)$$

Now consider Colin. When given the recommendation to play R , Colin is certain the state is ω_3 and that Robin has been given the recommendation D . Clearly, R is the best response to D . However, when given a recommendation to play L , Colin imagines that Robin plays a mixed strategy. It is optimal for Colin to follow the recommendation L if

$$p_C(\omega_1) + 4p_C(\omega_2) \geq 5p_C(\omega_2) \Leftrightarrow \alpha_2 \leq \alpha_1. \quad (13.89)$$

From (13.88), (13.89) a correlated equilibrium must satisfy the two conditions

$$\alpha_1 + 2\alpha_2 \leq 1 \text{ and } \alpha_2 \leq \alpha_1. \quad (13.90)$$

These conditions ensure that the players will follow their respective recommendations, conditional on other players complying with their recommendations.

Suppose that the choreographer, in the spirit of a social planner, wishes to choose (α_1, α_2) in order to maximize the joint payoffs of the two players ($\alpha_3 = 1 - \alpha_1 - \alpha_2$ is determined residually). Recall that the payoff pairs $(5, 1)$, $(4, 4)$, and $(1, 5)$ occur with respective probabilities α_1, α_2 , and $1 - \alpha_1 - \alpha_2$. The problem of the choreographer (similar to that of a Stackelberg leader) is to maximize

$$\alpha_1 (5, 1) + \alpha_2 (4, 4) + (1 - \alpha_1 - \alpha_2) (1, 5)$$

subject to the constraints in (13.90). The solution to this linear programming problem is $(\alpha_1^*, \alpha_2^*) = (\frac{1}{3}, \frac{1}{3})$ and the symmetric payoffs of the two players, $(\frac{10}{3}, \frac{10}{3})$, exceed the joint payoffs from both pure strategy Nash equilibria as well as from the mixed strategy Nash equilibria. *Thus, social norms, in their manifestations as correlation devices, maximize aggregate payoff of both players.*

This result requires a *normative predisposition* on the part of the players to follow the choreographer, unless the players can do better by defecting to alternative strategies. The following quote is instructive (Gintis, 2009, pp. 143–4): “Humans have evolved psychological predispositions that render social norms effective. Social evolution . . . has favored the emergence both of social norms and human predispositions to follow social norms, to embrace common priors, and to recognize

common knowledge of many events. Nor is this process limited to humans.” Further, individuals are often willing to enforce social norms at a cost to themselves (see Part 2 of the book).

Two important remarks follow from this discussion that generalize to games with a finite number of players and strategies. First, a correlated equilibrium is a Nash equilibrium of the overall game in which the choreographer moves first and announces (α_1, α_2) as well as the recommendations to the two players, followed by the choice of players to follow or reject the recommendations. Second, any Nash equilibrium of the original game (in this case (U, L) and (D, R)) is a correlated equilibrium. The reason is that if the choreographer simply asked each player to play their part of a Nash equilibrium, it would be optimal for each player to do so. However, the set of correlated equilibria is much larger than the set of Nash equilibria, e.g., the Pareto optimal strategy profile (D, L) , which is not a Nash equilibrium was played as part of the correlated equilibrium in the example, above. Thus, social norms may lie outside the set of Nash equilibria.

13.7 Other behavioral models of how people play games

We now describe a range of other models in behavioral game theory that have been successful in explaining a subclass of the available games and the experimental results.

13.7.1 Analogy-based equilibrium

Jehiel (2005) considers how players might simplify complex games in order to make them cognitively more tractable. His proposal is that players may partition a set of games into exogenously given *analogy classes*. Thus, analogy classes are simply a primitive of the game, much as one takes information sets as part of the description of extensive form games. Each player attempts to learn the average behavior of the opponents in each analogy class. Each player then plays a best response to beliefs about the average behavior of others in an analogy class and these beliefs turn out to be correct in equilibrium. Players need not know the analogy classes of their opponents or the payoffs of the opponents. The resulting equilibrium is known as an *analogy-based expectations equilibrium* (ABEE).

The consistency of beliefs is a strong requirement, hence, it is unlikely to apply to games that are played only a few times. Rather, consistency may be viewed as the outcome of a learning process. In the finest possible partition, an ABEE coincides with a Nash equilibrium, but for coarser partitions, the two typically differ. Indeed, from an empirical perspective, interest centers on games where these two concepts differ.

Let us motivate an ABEE for extensive form games, using the extensive form game in Figure 13.31. There are two players A and B who move sequentially. At each node, $i = 1, 2, 3$, each player can either take action T_i to end the game or pass the move to the other player (action P_i), except at node $i = 3$ where the action P_3 ends the game. This is a finite game of perfect information, and the solution is easily found by backward induction. In the subgame perfect solution, player A plays T_3 at the last node, player B plays T_2 at the penultimate node, and player A plays P_1 at the first node.

Suppose that we now wish to find the ABEE. Assume that, player B exogenously groups together nodes 1 and 3, at which player A moves, into a single analogy class.

Proposition 13.41 (i) *The following is an ABEE for the game in Figure 13.31 when player B groups together nodes 1 and 3 into a single analogy class. Player A plays P_1 at node 1 and*

Figure 13.31 A sequential move game.

Source: Reprinted from *Journal of Economic Theory* 123: 81–104. Jehiel, P., “Analogy-based expectation equilibrium.” Copyright © 2005, with permission from Elsevier.

T₃ at node 3. Player B plays P₂ at node 2. (ii) Given the analogy partition in (i), the subgame perfect solution is not an ABEE.

Proof: (i) Player B groups together nodes 1 and 3 into a single analogy class, so he considers the average behavior of player A at these nodes. Thus, player B believes that he faces a player A who will pass half the time and take half the time. This is equivalent to believing that player A plays a mixed strategy that randomizes uniformly over the two choices. Hence at node 2, when it is player B's turn to move, he gets 2 from taking (action T₂) and $\frac{1}{2}(1 + 4) = 2.5 > 2$ from passing (action P₂). Thus, he prefers to play P₂ at node 2, as claimed. Player A finds it optimal to play T₃ at the third node ($2 > 0$). Conditional on the subsequent optimal actions, player A's choice of P₁ at node 1 is optimal (because $-1 < 2$).

(ii) Conditional on the analogy classes, it is never optimal for player B to play T₂ at the second node. Hence, the subgame perfect outcome cannot be sustained as an ABEE. ■

The benefits from cognitive simplifications arising from analogy classes are obvious from Proposition 13.41. Players do not need to know (1) the payoffs of others, or (2) how their opponents group nodes into analogy classes. At the moment, we do not have a satisfactory theory of how players form analogy classes. The concept of an ABEE will be strengthened if the foundations for analogy classes can be developed.

Let us now consider the concept of an ABEE for two-player normal form games. Suppose that we have a set of normal form games $G = \{G_1, G_2, \dots, G_T\}$; to save on notation we shall label a particular element by G . The probability that game G is played is $p(G) \geq 0$ and $p(G) = 1$. Suppose that we index the two players by r and c (respectively, for the row and the column player). The respective pure strategy sets of the two players, S_r and S_c , are identical across all games. For any game, $G \in G$, the action profile is given by $(s_r, s_c) \in S_r \times S_c$ and the payoffs of the players are given by $u_j(s_r, s_c | G)$, $j = r, c$. The mixed strategy sets of players r and c are given, respectively, by Σ_r and Σ_c ; these are probability distributions over the sets S_r and S_c .

A strategy for any player specifies the mixed strategy that he intends to play for each game in the set G . Thus, a mixed strategy for player $j = r, c$ is denoted by $\sigma : G \rightarrow \Sigma_j$ so $\sigma_j(s_j | G)$ denotes the probability with which player j plays strategy s_j in game G .

Consider for player $j = r, c$, a partition A_j of the set G and call this an analogy partition. Let the cells of the partition A_j be denoted by $a_1, a_1, \dots, a_{n_j}$. If a game $G \in G$ appears in the cell $a_j \in A_j$, then $a_j(G)$ is called the analogy class of player j at G . Suppose that $\sigma_j(s_j | G)$ is the actual strategy of player $j = r, c$, and game G belongs to the analogy partition $a_i(G)$ of the other player, player $i = r, c$, $i \neq j$. Player i is then assumed to *know* the average strategy of player j , $\bar{\sigma}_j$, for each of the analogy classes but not the disaggregated behavior of player j across

the individual games in a_i .⁷⁷ Note that it is not assumed that player i can “compute” the average strategy from disaggregated information, but only that player i somehow “knows” the average strategy, perhaps as a steady state of some process of learning that occurs outside the model; not all readers will find this aspect of the model persuasive. Player i believes that the probability with which player j plays the strategy s_j for any game in the analogy partition $a_i(G)$, is computed as follows.

$$\bar{\sigma}_j(s_j | G) = \frac{\sum_{G' \in a_i(G)} p(G') \sigma_j(s_j | G)}{\sum_{G' \in a_i(G)} p(G')}. \quad (13.91)$$

In computing the average strategy of player j in (13.91), the actual strategy $\sigma_j(s_j | G)$ of player j for each game $G' \in a_i(G)$ is required but player j does not observe the disaggregated strategies. Given the beliefs in (13.91) about their opponents and the analogy partitions of both players, each player plays a best response. The mutual best responses computed in this manner, constitute an ABEE, as stated formally in the next proposition.

Definition 13.23 (*Analogy-based expectations equilibrium, ABEE*) : A strategy profile (σ_1, σ_2) is an analogy-based expectations equilibrium (ABEE), given the analogy partitions A_1, A_2 , if for all $G \in \mathbf{G}$ and all s_j^* in the support of $\sigma_j(G)$, $j = r, c$ we have

$$s_j^* \in \arg \max_{s_j \in S_j} \sum_{s_i \in S_i} \bar{\sigma}_i(s_i | G) u_j(s_j, s_i | G), \quad i \neq j \text{ and } i = r, c,$$

and $\bar{\sigma}_i$ is given in (13.91).

From Definition 13.23, when players use the finest possible analogy partitions, then $\bar{\sigma}_j(s_j | G)$ coincides with $\sigma_j(s_j | G)$, hence, an ABEE coincides with a Nash equilibrium. Further, none of the players is required to know the payoff of the other player—just the aggregate distribution of play of the opponent in each analogy class.

Huck et al. (2011) test for an ABEE in simple two-player games. Consider games G1 and G2 in Figure 13.32. Each of the two games has a unique pure strategy Nash equilibrium that can be found by iterated deletion of strictly dominated strategies- (A, c) in G1 and (B, d) in G2.

In order to consider an ABEE in these games one needs to specify the analogy classes and the probability that each of the two games occurs. Here we have the following: $S_r = \{A, B, C\}$,

⁷⁷ This behavior is similar to that of a fully cursed player in a cursed equilibrium; see Section 13.7.3.

$S_c = \{a, b, c, d, e\}$, $G = \{G1, G2\}$ and $p(G1) = p(G2) = 0.5$. The analogy partition used by the column player is always fine, i.e., $A_c = \{\{G1\}, \{G2\}\}$. However, we consider two possible cases of the analogy partitions of the row player. A fine partition in which $A_r = \{\{G1\}, \{G2\}\}$ and a coarse partition in which $A_r = \{\{G1, G2\}\}$.

When the row player uses a fine partition, as already noted, an ABEE coincides with a Nash equilibrium. Hence, there is a unique ABEE for games G1 and G2 in this case. The results when the row player uses a coarse partition are given in the next proposition that the reader is asked to prove as an exercise.

Proposition 13.42 *Suppose that the row player uses the coarse analogy partition $A_r = \{\{G1, G2\}\}$ and the column player uses the fine analogy partition $A_c = \{\{G1\}, \{G2\}\}$. Then in the unique ABEE, the row player plays B in game G1 and A in game G2. The column player plays a in game G1 and b in game G2.*

From Proposition 13.42, the ABEE is different from the Nash equilibrium of the game. It is, however, the case that strategy a in Game 1 and b in Game 2 give the column player the highest payoffs in each row, which could be one reason that subjects in experiments play these strategies; an even more stringent test would be to differentiate the predictions of Nash and ABEE when this is not the case.

Four different treatments are considered by Huck et al. (2011). These treatments are differentiated by the type of feedback that is given to a player about the play of the opponent in the last five rounds of play. Column players are given accurate feedback but the row player is given different feedback in the alternative treatments. For instance, in the COARSE treatment, the row player is simply informed about the actions of the column player in the last five rounds without identifying which of the two games, G1 or G2, those actions come from. In the FINE treatment, the difference from the COARSE treatment is that the games which gave rise to these actions are identified. In two other treatments, FEASIBLE and HARD, players are given the joint distribution of actions and games in which these actions were chosen in the last five rounds. With unlimited cognitive powers, subjects can, in principle, convert this data to the same form as in the treatment FINE, but with limited cognitive powers that would be difficult.

In each treatment, the behavior of subjects in experiments stabilizes by about round 15, but it converges to different equilibria. In treatments FINE and FEASIBLE, behavior converges to the Nash equilibrium but in treatments COARSE and HARD it converges to the unique ABEE of the game. The behavior of row players in the treatment COARSE fits well players who play a best response to the aggregate play of the column players over both games G1 and G2, which is consistent with an ABEE.

Experiments in which data is processed from multiple games at the same time are not very common. These results call for more empirical testing of games in this category. The ABEE can be extended to other classes of games. For an extension to static two-player games of incomplete information, see Jehiel and Koessler (2008).

13.7.2 *Subjective heterogeneous quantal response equilibrium*

The QRE and the level- k /CH models are two distinct approaches to relaxing the assumptions of a Nash equilibrium. The former relaxes the assumption of strict best replies and the latter relaxes the assumption of equilibrium in beliefs. Rogers et al. (2009) propose the *subjective heterogeneous quantal response equilibrium* (SQRE) that combines and clarifies the link between QRE and CH.

Consider the logit QRE framework for normal form games with n players that is described in Section 13.2.1 above; we carry the same notation forward in this section. The logit density is a one-parameter family with a single parameter λ . Assume that we have a distribution of types indexed by i such that $\lambda_i \in [0, \infty)$ is the type of player i . Let us introduce heterogeneity among the players about their perceived distribution of types of other players. The subjective belief of a player of type λ_k about the type of player $i \neq k$ is denoted by $F_i^k(\lambda_i | \lambda_k)$; we denote the corresponding density by $f_i^k(\lambda_i | \lambda_k)$.

The logit choice probabilities of players may now be computed in a manner similar to that in (13.7). The probability that a player of type λ_i chooses the action s_{ij} is given by

$$\phi_{ij}(\lambda_i, \bar{u}_i(\sigma)) = \frac{\exp(\lambda_i \bar{u}_{ij}(\sigma))}{\sum_{k=1}^{n_i} \exp(\lambda_i \bar{u}_{ik}(\sigma))}. \quad (13.92)$$

A strategy of player i , $\phi_i : [0, \infty) \rightarrow \Sigma_i$ gives the optimal choice probabilities with which each of the possible types plays each of the pure strategies in the set S_i .

Thus, the beliefs of a type λ_k of player k that player i will play the action s_{ij} is given by

$$\sigma_{ij}^k(\phi_i | \lambda_k) = \int_0^\infty \phi_{ij}(\lambda_i, \bar{u}_i(\sigma)) f_i^k(\lambda_i | \lambda_k) d\lambda_i. \quad (13.93)$$

One may analogously compute the beliefs of a player i of type λ_i about the probability with which all other types of all other players play their respective pure actions; denote this by $\sigma_{-i}^i(\phi_{-i} | \lambda_i)$. Thus, we can find the expected payoff of a type λ_i of player i by $\bar{u}_{ij}^{\lambda_i}(\sigma_{-i}^i) = \{\bar{u}_{i1}^{\lambda_i}, \bar{u}_{i2}^{\lambda_i}, \dots, \bar{u}_{in_i}^{\lambda_i}\}$ where $\bar{u}_{ij}^{\lambda_i}(\sigma_{-i}^i)$ is the payoff to player i from the strategy s_{ij} when others play σ_{-i}^i .

$$\bar{u}_{ij}^{\lambda_i}(\sigma_{-i}^i) = \sum_{s_{-i} \in S_{-i}} \sigma(s_{-i}) u_i(s_{ij}, s_{-i}). \quad (13.94)$$

In a SQRE, the three equations, (13.92), (13.93), (13.94) hold simultaneously. A SQRE reflects the fact that beliefs of players are subjective, so there is no assumption of common priors. The SQRE concept is too general and requires empirically plausible restrictions to make it operational.

A special case of SQRE arises when there is heterogeneity with respect to the types of the players but this heterogeneity is common knowledge. In this case, $F_i^k(\lambda_i | \lambda_k) = F_i(\lambda_i | \lambda_k)$ for all $i, k = 1, 2, \dots, n$. This formulation gives rise to *heterogenous quantal response equilibrium*, HQRE. Thus, $F_i(\lambda_i | \lambda_k)$ is common knowledge but the type of any player, λ_i , is private knowledge to player i . When the heterogeneity in types becomes degenerate, then HQRE reduces to the logit QRE that is described in Section 13.2.

It is possible that players might not be able to imagine types of other players above a certain bound but accurately perceive types lower than this bound—the authors' term for this is an *imagination bound*. Possible reasons include not being able to perceive higher types than one's own (overconfidence) or being cognitively limited in making the computations required to perceive higher types.

Suppose that type λ_i of player i believes that any type λ_{-i} of another player cannot be higher than the imagination bound, $b_i(\lambda_i)$. Higher types of players (higher values of λ_i) are interpreted as more skilled players in terms of payoff responsiveness. The function b_i is commonly known, increasing, and continuous. The positive slope of b_i implies that higher types imagine other players to be also higher or more skilled (although possibly lower than their own type). In this case,

the beliefs of a player k of type λ_k about any players i of type λ_i are given by

$$F_i^k(\lambda_i | \lambda_k) = \begin{cases} F_i(\lambda_i)/F_i(b_k(\lambda_k)) & \text{if } \lambda_i \leq b_k(\lambda_k) \\ 1 & \text{if } \lambda_i > b_k(\lambda_k) \end{cases}. \quad (13.95)$$

Player k of type λ_k cannot imagine other types to be higher than the upper bound $b_k(\lambda_k)$. The division by $F_i(b_k(\lambda_k))$ normalizes the cumulative density of all types λ_i of player i lower than type $b_k(\lambda_k)$. Such a model is known as a *truncated quantal response equilibrium model* (TQRE). In the special case where $b_i \rightarrow \infty$ for all $i = 1, 2, \dots, n$, the TQRE collapses to the standard HQRE model. At the other extreme when the imagination bound $b_i \approx 0$, then player i believes that all other types of all other players choose randomly (similar to the beliefs of level $L1$ players in level- k models). If $b_i(\lambda_i) \leq \lambda_i$, then player i of type λ_i is said to be *self-limited* because he cannot imagine that any of the other types is more skilled in the sense of payoff responsiveness.

The existence of a HQRE and TQRE in finite games is guaranteed; see Rogers et al. (2009).

In a TQRE, heterogeneity is indexed by payoff responsiveness, λ_i , while in level- k models and CH, it is indexed by k . In level- k models, for $k \geq 1$, although the source of the heterogeneity is different, we have $b_k(\lambda_k) \leq \lambda_k$. Rogers et al. (2009) give two restrictions on TQRE models such that the behavioral predictions of TQRE and the CH model can be made arbitrarily close and the approximating equilibrium in TQRE is unique. Suppose that the allowed values of λ are discrete: $0, \gamma, 2\gamma, \dots, k\gamma, \dots$. The parameter γ is known as the grid size. A player of type k or a level- k player is associated with $\lambda = k\gamma$. The first restriction is that for any value of λ we must have $b_i(\lambda) = \frac{k}{1+k}\lambda$, where k is the type associated with the chosen value of λ . Thus for the lowest possible value of $\lambda = 0$, we have $b_i(0) = 0$; these players choose randomly like type $L0$ players. Level-1 players correspond to $\lambda = \gamma$ and, in this TQRE model, they quantal best-respond, assuming that others are type $L0$ and so on.

In level- k and CH models, recall that players best-respond to their inaccurate beliefs about others. If we let $\gamma \rightarrow \infty$, then we have $\lambda \rightarrow \infty$. This corresponds to players playing best replies to their beliefs about others (as in a Nash equilibrium). In the main result of the paper, Rogers et al. (2009) show that as $\lambda \rightarrow \infty$, in almost all finite games, the behavioral predictions of TQRE and CH are essentially equivalent in the approximate sense.

Rogers et al. (2009) test the four different models, QRE, HQRE with uniform distribution of types, Poisson TQRE, and Poisson CH on 17 different full information games. Maximum likelihood methods are used for model estimation and model fits. Across the games, the parameter values for each of the models is similar but there are also a few games that are outliers. Results are quite different for pooled and game-specific data. For instance, CH gives the best fit in game-specific results but the worse fit for the pooled data. Heterogeneity in types appears not to be too important. However, once downward looking heterogeneity of the truncated types is assumed, as in the TQRE, then TQRE gives a better fit than CH in 10 out of 17 games and a better fit than the QRE in 15 out of 17 games. The authors conclude (p. 1456): “Overall, our results indicate that a combination of ‘strategic’ heterogeneity and stochastic choice are significant factors in explaining behavior in these games, and a downward looking belief structure helps explain behavior in some of the games.”

Further support for the HQRE has come from the bubbles game in Moinas and Pouget (2013). Consider sequential trading games in which trading occurs at discrete intervals and at any point in time, the owner of a single asset can sell or not sell a single unit of an object. Assume also that it is commonly known that the fundamental value of the object is zero. Under common knowledge of rationality, a price cap should not result in any bubbles. The argument proceeds by backward

induction (as in centipede games). Suppose that an investor finds himself saddled with an asset whose price equals the price cap. Then he cannot sell it and make a profit. Going back a period, the investor would not buy such an asset. Proceeding backwards in this manner, one can rule out a bubble ever forming on the asset. However, the higher the price cap, the greater is the number of steps of iterated reasoning that are required to make the argument (as in centipede games with a higher number of moves by players). In contrast to the theoretical predictions, Moinas and Pouget (2013) find that bubbles form in the presence as well as absence of price caps.⁷⁸ The model that best fits their data is HQRE and the analogy-based equilibrium model (ABEE).

13.7.3 Cursed equilibrium

Eyster and Rabin (2005) introduce the notion of a *cursed equilibrium*, a solution concept that can be applied to Bayesian games. Relative to fully rational players, cursed players do not fully take account of the correlation between the actions of other players and their types. Rather, each player believes that with some probability $\chi \in [0, 1]$, all types of the opponent play their average optimal action (and not the type-contingent optimal action). With the complementary probability, $1 - \chi$, the opponent is believed to play the optimal type-contingent actions. Such players are said to be χ -cursed.

Consider a simple, static, game of incomplete information, the Akerlof (1970) model of the market for lemons. Suppose that there are two types of used cars, lemons and peaches, that are distinguished by their quality. The proportion of each type among the used cars is commonly known to be $\frac{1}{2}$. A lemon is worth nothing to either the buyer or the seller. A peach is worth \$3000 to the buyer and \$2000 to the seller. Suppose that the market price is \$1000. Since this price is lower than the value of the car to the sellers of a peach, there is no supply of peaches in the market. Hence, at a price of \$1000, the only cars on the market are lemons. The optimal type-contingent actions of the sellers are: the peach seller sells with probability 0, and the lemon seller sells with probability 1. Thus, the average action over the two types is to sell with probability $\frac{1}{2}$.

Knowing this, a fully rational buyer will not buy cars in this market (market failure). However, a χ -cursed buyer thinks that with probability χ , each seller plays the average action, i.e., sell with probability $\frac{1}{2}$. Hence, the probability, in the mind of a χ -cursed buyer, that the car on the market is a “peach” is given by:

$$(1 - \chi) \times 0 + \chi \times \frac{1}{2} = \frac{\chi}{2}. \quad (13.96)$$

In (13.96), a fully rational buyer corresponds to $\chi = 0$, and correctly believes that a peach has a zero probability of being on the market at the given price. However, a fully cursed buyer sets $\chi = 1$ and mistakenly believes that the car is a peach with probability $\frac{1}{2}$. Hence, a χ -cursed buyer thinks that the expected value of the car is $\frac{\chi}{2} \times \$3000$. Since the market price is \$1000, it is therefore optimal to buy if $\chi > \frac{2}{3}$.

We now give a more formal account of a χ -cursed equilibrium. Recall the notation and definitions for finite Bayesian games in the Appendix on game theory, which we summarize first. In a finite Bayesian game, $G(N, S, u, T, \mu)$, $N = \{1, 2, \dots, n\}$ is the set of n players, nature is denoted

⁷⁸ The classic experimental paper by Smith et al. (1988) showed that even in the absence of asymmetric information, one gets price bubbles on assets followed by crashes. The difficulty of accounting for bubbles within a neoclassical framework is discussed in Shiller (2000).

by player $i = 0$; $S_i \subset \mathbb{R}$ is the finite pure strategy set of player i and $S = \times_i S_i$ is the set of all pure strategy profiles (nature's strategy set S_0 is empty); $S_{-i} = \times_{j \neq i} S_j$ is the set of pure strategy profiles of all players other than player i . T_i is the finite set of possible types of player i ; $T = \prod_i T_i$ is the set of all possible types. $\mu : T \rightarrow \mathbb{R}$, which is common to all players, gives the set of conditional probability distributions over T ; $u_i : S \times T \rightarrow \mathbb{R}$ is the payoff of player i and it depends on the chosen strategies and player types; the vector of payoffs of all players is denoted by $u = (u_1, u_2, \dots, u_n)$. ΔS_i is the set of all probability distributions over S_i ; the type-contingent mixed strategy of player i is denoted by $\sigma_i : T_i \rightarrow \Delta S_i$, where $\sigma_i(s_i | t_i)$ is the probability with which type t_i of player i plays strategy s_i under the mixed strategy $\sigma_i(t_i)$; $\sigma_{-i}(s_{-i} | t_{-i})$ is the probability with which other players of type $t_{-i} \in T_{-i}$ play some pure strategy profile $s_{-i} \in S_{-i}$ under the mixed strategy $\sigma_{-i}(t_{-i})$.

Definition 13.24 (*Bayesian Nash equilibrium*): Consider the static Bayesian game $G = \{N, S, u, T, \mu\}$. The strategy vector (σ_i, σ_{-i}) is a Bayesian Nash equilibrium if for all $i \in N$, all types $t_i \in T_i$ and all actions s_i^* such that $\sigma_i(s_i^* | t_i) > 0$ we have

$$s_i^* \in \arg \max_{s_i \in S_i} \sum_{t_{-i} \in T_{-i}} \mu(t_{-i}, t_i) \sum_{s_{-i} \in S_{-i}} \sigma_{-i}(s_{-i} | t_{-i}) u_i(s_i, s_{-i}; t_i, t_{-i}). \quad (13.97)$$

In a cursed equilibrium, players imagine that with some probability, all the types of other players play the average strategy. Consider the mixed strategy of all players other than player i , $\sigma_{-i}(t_{-i})$. The average strategy of all other players is then given by

$$\bar{\sigma}_{-i}(s_{-i} | t_i) = \sum_{t_{-i} \in T_{-i}} \mu(t_{-i}, t_i) \sigma_{-i}(s_{-i} | t_{-i}). \quad (13.98)$$

When other players actually play $\sigma_{-i}(s_{-i} | t_{-i})$, player i believes that with some probability $\chi \in [0, 1]$ they play the average strategy $\bar{\sigma}_{-i}(s_{-i} | t_i)$. The size of χ gives the degree of cursedness of player i . The types of players can be correlated, so, the computation of $\bar{\sigma}_{-i}(s_{-i} | t_i)$ may depend on the type t_i . Thus, different types of the same player may have different beliefs about the average actions of other players. However, if the types of the players are independent, i.e., $\mu(t_{-i} | t_i) = \mu(t_{-i} | t'_i)$ for all $t_i, t'_i \in T_i$, then all players have the same beliefs about the average actions of others.

The χ -cursed equilibrium is defined as follows.

Definition 13.25 (χ -cursed equilibrium): Consider the static Bayesian game $G = \{N, S, u, T, \mu\}$. The strategy vector (σ_i, σ_{-i}) is a χ -cursed equilibrium, if for all $i \in N$, all types $t_i \in T_i$ and all actions s_i^* such that $\sigma_i(s_i^* | t_i) > 0$ we have

$$s_i^* \in \arg \max_{s_i \in S_i} \sum_{t_{-i} \in T_{-i}} \mu(t_{-i}, t_i) \sum_{s_{-i} \in S_{-i}} [\chi \bar{\sigma}_{-i}(s_{-i} | t_i) + (1 - \chi) \sigma_{-i}(s_{-i} | t_{-i})] u_i(s_i, s_{-i}; t_i, t_{-i}). \quad (13.99)$$

When $\chi = 0$, from Definitions 13.24 and 13.25 we have that the cursed equilibrium and the Bayesian Nash equilibrium coincide. When $\chi = 1$, players are said to be *fully cursed*. In this case, they completely ignore the correlation between the types and actions of the other players and believe that each type of the other player plays the average action only. This case appears quite similar to the case of the analogy-based equilibrium of Jehiel (2005); see Jehiel and Koessler (2008). It is as if, for each opponent, all types have been put into one analogy class and the average action is assigned to all types. The theory allows different players to be cursed to different degrees.

Proposition 13.43 (Eyster and Rabin, 2005): For any finite Bayesian game $G = \{N, S, u, T, \mu\}$, and each $\chi \in [0, 1]$, a χ -cursed equilibrium exists.

One drawback of a cursed equilibrium is that the psychological underpinnings are not as persuasive as some of the other behavioral game theory models. Indeed, as the authors themselves point out (p. 1633): “All said, however, our primary motivation for defining cursed equilibrium is not based on learning or any other foundational justification, but rather on its pragmatic advantages as a powerful empirical tool to parsimoniously explain data in a variety of contexts.” However, the similarity with the analogy-based equilibrium and other justifications that the authors suggest (e.g., overconfidence) may lead to better foundations for such an equilibrium concept in the future. A second drawback is that the concept applies to Bayesian games only. For games of full information, the concept of a cursed equilibrium reduces to the standard Nash equilibrium and its refinements. This, we know, does not explain the experimental results from a variety of full information games. The case for a cursed equilibrium would be even stronger, if it could be shown that it is a heuristic that is somehow turned-on only when individuals encounter games of incomplete information.

One of the main applications of the χ -cursed equilibrium is to the explanation of bidding behavior in auctions that we consider in Section 13.8.

13.7.4 Evidential equilibrium

In static games, players are often uncertain of the actions of their opponents. This could be because, say, the game represents a relatively new strategic situation, or the players have not played much against each other before. In these situations, evidence, mainly from psychology, suggests that players assign *diagnostic significance* to their own actions in forming inferences about how others may behave. Such reasoning by players is known as *evidential reasoning* (ER), also sometimes known as *social projection*.

ER is most likely to apply when one views the opponents in a game as *like-minded*. Following the literature in psychology, we may refer to the reasoning used in classical game theory as *causal reasoning*. Causal reasoners assign no diagnostic value to their own actions. We argue that the evidence is best described by a mixture of evidential and causal reasoners in the population; indeed the theoretical framework, below, allows for such a mixture.

Robbins and Krueger (2005) describe ER as follows: “Using their own disposition or preferences as data, people can make quick predictions of what others are like or what they are likely to do.” In a survey article, Krueger (2007) writes “The concept of social projection is once again generating vigorous theory development and empirical research . . . social projection is among the simplest, oldest, and arguably most central concepts of the field.”

The rest of this section draws on al-Nowaihi and Dhami (2015) in giving a formal account of evidential reasoning for static games of full information.⁷⁹ The claim is not that ER helps us to explain the data for all static games but that it adds an important element to the toolkit of behavioral economists, enabling them to explain puzzles that are difficult to explain otherwise.

Consider some suggestive examples of evidential reasoning.

Example 13.18 (*False consensus effect*): Ross et al. (1977) asked subjects if they would walk around a university campus wearing a sandwich board with the word “REPENT” written on it. Those who agreed to do so, estimated that 63.5% of their peers would also agree to do so,

⁷⁹ For static games of incomplete information, see Dhami and al-Nowaihi (2013).

while those who refused, expected 76.7% of their peers to also refuse. Clearly these fractions add up to more than one and so cannot constitute consistent beliefs. This evidence is consistent with many subjects using evidential reasoning to impute diagnostic value to their own actions in forming beliefs about the likely actions of other like-minded people (the student population in the university in this case). This is an example of the “false consensus effect.”

Example 13.19 (Contributions among like-minded people in public goods games): In public goods games under causal reasoning (see Part 2), it is a Nash equilibrium for each player to free-ride (zero contributions). The experimental evidence shows that in the absence of punishment of non-cooperators, contributions decay over successive rounds. Gächter and Thöni (2005) investigate whether cooperation in public goods games is higher among like-minded people. They initially run a single-round of the public goods experiment. The subjects are then grouped by the amount of contributions they made in this round. For instance, the top three contributors are grouped into a separate group (the TOP group) as having the greatest inclination to contribute. The public goods game is then played separately for each group. Over the next ten rounds, contributions are much higher and free riding much lower in the TOP group, which achieves nearly the first best level of contributions in several rounds.⁸⁰ Evidential reasoning would predict that when high contributors have greater confidence that they are grouped with like-minded people, they take their own predisposition to contribute more as evidence that like-minded others are also likely to contribute more. In conjunction with reciprocity, this may achieve high levels of contributions.

Example 13.20 (Evidential reasoning about states of other humans): In an experiment conducted by Van Boven and Loewenstein (2005), participants were asked to imagine a hiker who is lost in the woods and asked whether the hiker was more likely to be thirsty or hungry. When the experimental participants were made to experience these states (thirst or hunger) they attributed similar states to the hypothetical hiker despite their own states having no correlation or cue value with the state of the lost hiker. In each case, they seem to assign diagnostic significance to their own state in inferring the state of the lost hiker.

Example 13.21 Table 13.4 reports survey evidence from successive US Presidential elections on the beliefs of voters, who voted for each political party, about the winning chances of their preferred political party. Voters who intend to vote Democrat typically assign higher probabilities to the Democrat candidate winning relative to those who intend to vote Republican. By contrast, voters who intend to vote Republican assign higher probabilities to a Republican win relative to voters who vote for Democrats. The assigned probabilities do not add up to one despite the fact that most people get their information from common sources such as TV, newspapers, and opinion polls. This is consistent with voters taking their own actions as diagnostic of what other like-minded voters might do. These findings show that, in some circumstances at least, people behave as if their actions were causal even when they are merely diagnostic or evidential. Quattrone and Tversky (1984) use these insights to explain why voters vote in elections. Voters who have a predisposition to vote (say, due to a sense of civic responsibility) believe that other like-minded responsible voters will also vote. On the other hand, if

⁸⁰ Even the endgame effect, i.e., the sharp drop in contributions in the last round of the experiment is most pronounced among the BOTTOM group.

Table 13.4 Percentage of voters from each political party expecting their own candidate to win in US presidential elections.

Year	Presidential candidates	% of Democrat voters expecting Democrat win	% of Republican voters expecting Republican win
1988	Dukakis vs. Bush	51.7	94.2
1984	Mondale vs. Reagan	28.8	99.9
1980	Carter vs. Reagan	87.0	80.4
1976	Carter vs. Ford	84.2	80.4
1972	McGovern vs. Nixon	24.7	99.6
1968	Humphrey vs. Nixon	62.5	95.4
1964	Johnson vs. Goldwater	98.6	30.5
1960	Kennedy vs. Nixon	78.4	84.2
1956	Stevenson vs. Eisenhower	54.6	97.6
1952	Stevenson vs. Eisenhower	81.4	85.9

Source: Forsythe et al. 1992.

they procrastinate and choose not to vote for their party, other like-minded people might also reason in a similar manner, and the other party could win the elections. So they vote.

Under each of the examples above, players who use evidential reasoning do not believe that by altering their own action they are able to alter the actions of the other players. They simply take their own predisposition to follow an action as diagnostic evidence for what other, like-minded, players might do.

IS EVIDENTIAL REASONING RATIONAL OR IS IT A USEFUL HEURISTIC?

One may be interested in the epistemic foundations of equilibrium concepts in economics (Aumann and Brandenburger, 1995; Polak 1999). Empirical violations of the Nash equilibrium (see Chapter 12) also violate the epistemic conditions for a Nash equilibrium. A related question is about the *rationality* of classical reasoning in games (causal reasoning) and non-classical reasoning such as ER (Rapoport, 1966, pp. 139–41; Bicchieri and Green, 1997; Bonanno, 2013). Economists accustomed to traditional notions of rationality may find evidential reasoning to be less than fully rational.

Our interest is neither in the epistemic foundations nor in the rationality or otherwise of ER, although the independent study of these issues is very worthwhile.⁸¹ The relevant issue is whether the evidence on human behavior supports ER. The results of experimental games appear to be best explained by a mixture of people; some appear to use evidential reasoning while others appear to use causal reasoning. At the same time, it appears that there is no single theory that is capable of explaining the evidence from all static games.

The motivation for evidential reasoning may be given with an analogy. Ever since the work of Allais (1953), the evidence from a large number of experiments turned out to be inconsistent with the predictions of models of formal decision theory that were based on the axioms of rationality (Kahneman and Tversky, 2000). In the early 1970s Daniel Kahneman and Amos Tversky proposed an alternative approach, the *heuristics and biases* approach (Kahneman et al., 1982; Kahneman,

⁸¹ The older literature on conjectural variations (or reaction function approach, see Friedman, 1977) and the newer literature on psychological game theory, that requires a weaker consistency of beliefs with actions relative to a Nash equilibrium, are not relevant to our arguments, since both use causal reasoning.

	C	D
C	2, 2	0, 3
D	3, 0	1, 1

Figure 13.33 The prisoner's dilemma game.

2003). In this approach, instead of optimizing in the classical sense, decision makers follow simple heuristics that are *fast* and *frugal* in the use of information. The heuristics often work well but sometimes lead to errors relative to a strictly optimizing behavior. This approach is considered in Part 7.

Indeed, many other alternatives to a Nash equilibrium, such as level- k models, may also be viewed in a similar manner. For instance, ex-post, players who use level- k models are often surprised by the outcome; their beliefs and the equilibrium actions need not be mutually consistent, unlike in a Nash equilibrium. However, under level- k models, one should not observe the play of dominated strategies by any level- k player, $k > 1$. This makes it difficult to explain why there is so much cooperation in prisoner's dilemma games or why people vote.

We propose here, a heuristics and biases approach to game theory, using ER as the appropriate vehicle for static games. A range of other evidence supports the interpretation of ER as a heuristic. People who use evidential reasoning are not aware of using it despite their behavior being obviously consistent with evidential reasoning. Evidential reasoning appears to arise as an *automatic* response, rather than as a *deliberate* response, i.e., it does not require awareness, effort, or intention. Evidence supporting this view comes from experiments which show that evidential reasoning was not hampered by cognitive load or time required to complete an action; see Krueger (2007). Furthermore, other evidence, also reported in Krueger (2007), suggests that considerable cognitive effort is required to suspend evidential reasoning. The evidence from Acevedo and Krueger (2005) indicates that evidential reasoning applies to human–human interaction but not to human–nonhuman interaction.

WHY IS THERE SO MUCH COOPERATION IN THE PRISONER'S DILEMMA GAME?

Consider the static prisoner's dilemma shown in Figure 13.33. Defection is a strictly dominant strategy. Hence, a player using causal reasoning should defect. However, experimental evidence indicates relatively high cooperation rates. Rapoport (1988) finds cooperation rates of 50% in the prisoner's dilemma game. In a study of the prisoner's dilemma based on high stakes outcomes from a British TV show called *Goldenballs*, Darai and Grätz (2010) find unilateral cooperation rates of 55% for stakes above £500 and cooperation rates of 74% for stakes below this level. Zhong et al. (2007) show that the cooperation rates in prisoner's dilemma studies go up to 60% when positive labels are used (such as a “cooperative game” rather than a “prisoner's dilemma game”). When purely generic labels are used (such as C and D), then the cooperation rates are about 50%. In a novel study, Khadjavi and Lange (2013) find that actual prison inmates cooperate far more than the student population. In particular, while the cooperation rates among students playing the static prisoner's dilemma game is 37%, the cooperation rate among prison inmates is 56%.

al-Nowaihi and Dhami (2015) show that one cannot explain cooperation in the prisoner's dilemma game simply by invoking social preferences. Since the action C is a dominated strategy it is not *rationalizable* and cannot be supported in a *correlated equilibrium* either. Cooperation

in a prisoner's dilemma game cannot be explained by using evolutionary games either. The reason is that the set of evolutionary stable equilibria is a subset of the Nash equilibria of the game, which, in this case, is the unique outcome (D,D); see Part 5 for evolutionary game theory. All models that require players to play their best responses, e.g., level- k models and CH models cannot also explain the cooperative outcomes in the prisoner's dilemma game because cooperation is a strictly dominated strategy. In QRE models, players play the strategies that give a higher expected payoff with a greater probability. Hence, they will always play the strategy defect with a greater probability. Thus, over time, we expect most of the outcomes to converge towards (D,D).

In the light of the evidence, the explanation of cooperative behavior in prisoner's dilemma games is an open problem in economics and social science. This cannot be dismissed as just a minor annoyance; the prisoner's dilemma game is the most widely used game in the social sciences (outside economics) as a metaphor for why cooperation may break down.

Lewis (1979) used ER to explain the unexpected levels of cooperation in the one-shot prisoner's dilemma game. Mutual cooperation is better than mutual defection. Furthermore, some players may be hard-wired to cooperate and/or they may be inequity averse. If players use ER, they may take their own preference for mutual cooperation as diagnostic evidence that their rival also has a preference for mutual cooperation, in which case both players are more likely to cooperate. These views are borne out by the evidence. Cooperators (those who play C) believe the probability that other players cooperate is between 0.6 and 0.7. Similarly, players who defect believe that other players will defect with probabilities between 0.6 to 0.7; see Krueger (2007). Darai and Grätz (2010) find that preplay promises of players to cooperate with each other and shake hands on it, increase the cooperation rates. In classical game theory this should have no effect, but evidential reasoning may provide one possible explanation. Such actions may increase the likelihood, in the minds of players, that they are facing like-minded players, hence, they cooperate more.

Like-mindedness is compatible with both outcomes, C and D, and we do observe both outcomes in the PD game. Those who play C (respectively, D) also believe that a disproportionately large share of the other players will play C (respectively, D). However, why then do we observe so much cooperation in the static prisoner's dilemma game? The reason is that most humans intrinsically like to cooperate, especially when the cooperative outcome is also Pareto optimal. Consider, for instance, the following quote from Gintis (2009, p. 145):

It is not reason but humanity that leads us to believe that the Pareto-superior equilibrium is obvious. We humans by virtue of our gene-culture coevolutionary history and our civilized culture, harbour a default frame that says "in coordination games, unless you have some special information that suggests otherwise, conjecture that the other player also considers the frame to be a default frame and reasons as you do, and choose the action that assumes your partner is trying to do well by you."

This also explains the label salience of outcomes in the prisoner's dilemma game: When framed as a cooperative game, the cooperation rate is higher (see above).

The explanation of cooperation based on evidential reasoning appears compelling. The fact that a sizeable fraction of the subjects in experiments also defect suggests that the results are best accounted for by a mixture in the population of people who use evidential reasoning and causal reasoning. A more formal account of the prisoner's dilemma game under evidential reasoning is given in Section 13.7.4, below.

EVIDENTIAL GAMES AND EVIDENTIAL EQUILIBRIUM

We now give an exposition of evidential games and provide a general framework of analysis for static games that is suitable for extensions to other heuristics. Consider a static game of complete information, $\{N, S, u\}$. The set of players is $N = \{1, 2, \dots, n\}$. $S_i \subseteq \mathbb{R}$ is the set of actions open to player i . $S = \times_{i=1}^n S_i$ gives all possible action profiles of the players. $S_{-i} \subseteq \mathbb{R}^{n-1}$ is the set of actions open to the other players. Σ_i is the set of probability distributions over S_i . Any $\sigma_i \in \Sigma_i$ is a mixed strategy of player i ; $\sigma_i(s_i)$ is the probability with which player i plays action $s_i \in S_i$. Since a pure strategy corresponds to $\sigma_i(s_i) = 1$, we will simply refer to σ_i as a strategy for player i .

A strategy profile of all players is denoted by $\sigma = (\sigma_1, \sigma_2, \dots, \sigma_n) \in \Sigma$, where $\Sigma = \times_{i=1}^n \Sigma_i$ is the set of all possible profiles of strategies. Players choose their strategies simultaneously. A particular profile of the strategies of the other players is denoted by $\sigma_{-i} = (\sigma_1, \dots, \sigma_{i-1}, \sigma_{i+1}, \dots, \sigma_n) \in \Sigma_{-i} = \times_{j \neq i} \Sigma_j$. The von-Neumann utility function of player i is $u_i : \Sigma \rightarrow \mathbb{R}$ and u is the vector of payoffs of the players. Given a strategy profile $\sigma = (\sigma_i, \sigma_{-i}) \in \Sigma$, the payoff of player i is $u_i(\sigma_i, \sigma_{-i}) \in \mathbb{R}$. The structure of the game, $\{N, S, u\}$, is common knowledge among the players.

A social projection function captures the beliefs of a player about the strategies of the other players, conditional on his own strategy.⁸² These beliefs are based on introspection that is founded on evidential reasoning. Evidential reasoning rules out the possibility that these beliefs cause the other players to play the expected strategies.

Definition 13.26 (Social projection functions, SPF): A social projection function for player i (SPF for short), is a mapping $P_i : \Sigma_i \rightarrow \Sigma_{-i}$, that assigns to each strategy, $\sigma_i \in \Sigma_i$, for player i , an $(n-1)$ vector of strategies for the other players. We write $P_{ij}(s_j|\sigma_i)$ for the “subjective belief” that player i assigns to player j playing $s_j \in S_j$, conditional on player i playing $\sigma_i \in \Sigma_i$. Hence, $P_{ij}(s_j|\sigma_i) \geq 0$ and $\sum_{s_j \in S_j} P_{ij}(s_j|\sigma_i) = 1$. We may write $P_i(\sigma_i) = \sigma_{-i}^e(\sigma_i) = (P_{i1}, \dots, P_{ii-1}, P_{ii+1}, \dots, P_{in})$ to indicate that $P_i(\sigma_i)$ is the $(n-1)$ vector of strategies that player i “expects” that the other players will follow if player i adopts the strategy σ_i .

We now define causal reasoning, the dominant type of reasoning used in classical game theory, and evidential reasoning.

Definition 13.27 (Causal reasoning): We say that player i uses causal reasoning if $P_{ij}(s_j|\sigma_i)$ is independent of σ_i for each $s_j \in S_j$ and each $j \neq i$, i.e., if $P_i(\sigma_i) = P_i(\sigma'_i)$ for all $\sigma_i, \sigma'_i \in \Sigma_i$.

Definition 13.28 (Evidential reasoning) We say that player i uses evidential reasoning if it is not necessarily the case that $P_i(\sigma_i) = P_i(\sigma'_i)$ for all $\sigma_i, \sigma'_i \in \Sigma_i$.

We now discuss Definitions 13.26–13.28. In a static game of full information, players may be uncertain of the actions taken by others. Under evidential reasoning, player i resolves this uncertainty by assigning diagnostic significance to his own choice of strategy, σ_i , in inferring the strategies of the other players, σ_{-i} , using his social projection function, P_i . For this reason, Definition 13.28 allows for $P_i(\cdot|\sigma_i)$ to change as σ_i changes.

It is quite important to realize that there is no causal connection between σ_i and σ_{-i} . The choice of σ_i by player i merely influences his “belief” about the strategies, σ_{-i} , of the other players. In particular, players who use evidential reasoning know that their own actions have no causal effects in altering the actions of others when they change their own actions. Further, a SPF (Definition 13.26)

⁸² We use the term social projection function because, on the one hand, it is obviously connected with social projection and evidential reasoning and, on the other hand, to distinguish it from the term projection function as commonly used in mathematics.

specifies the beliefs of a player for all possible actions of others, including out-of-equilibrium actions. The beliefs of a player need not be fulfilled in equilibrium, as in other disequilibrium-in-beliefs models such as the level- k model.

If player i uses causal reasoning as in classical game theory (see Definition 13.27) then he assigns no diagnostic significance to his own strategy, σ_i , in inferring the strategies, σ_{-i} , followed by the other players.⁸³ Thus, under causal reasoning, $P_i(\sigma_i)$ remains fixed as σ_i changes. From Definitions 13.27, 13.28, causal reasoning is a special case of evidential reasoning.

Example 13.22 *This framework is quite general, hence, there is merit in considering it in some detail. The social projection function simply captures beliefs that a player has about other players. We have introduced evidential reasoning in this section. However, there are other plausible methods of belief formation that could be modeled using the machinery introduced here. For instance, in level- k models applied to static games, denote the strategy of a type L_k player by σ_k and the pure strategy set by S_k that has n_k elements. Suppose also that type L_0 players choose uniformly randomly. Then the social projection function of a level L_1 player is given by $P_{10}(s_0|\sigma_1) = \frac{1}{n_0}$ for all $\sigma_1 \in \Sigma_1$ and for all $s_0 \in S_0$. Suppose that, conditional on these beliefs, the best response of type L_1 is, say, σ_1^* . Then the social projection function for any level L_2 player is $P_{21}(s_1|\sigma_2) = \sigma_1^*(s_1)$ for all $\sigma_2 \in \Sigma_2$ and for all $s_1 \in S_1$. The social projection functions of higher types can be constructed analogously.*

Players need not impute diagnostic significance to their actions when others are perceived not to be like-minded. Here we assume the special case that all players are like-minded. al-Nowaihi and Dhami (2015) consider the case where other players may be a mixture of like-minded and non like-minded players (ingroup and outgroup members).

Many different types of social projection functions (SPFs) are possible. There are possibly various degrees of like-mindedness. However, the examples above suggest a particularly salient SPF that imparts the main predictive content to theory. This SPF seems important when choices are low dimensional, such as the binary choices “cooperate” or “defect” in a prisoners’ dilemma game, or vote Democrat or Republican in US Presidential elections, or coordinate or fail to coordinate in simple coordination games. In each of these cases, players may think that other like-minded players will choose *identical actions* to their own. The corresponding SPF in these cases is the *identity social projection function*. In this case, conditional on playing any strategy σ_i , player i believes that like-minded players will play an identical strategy; for more general social projection functions, see al-Nowaihi and Dhami (2015).

Definition 13.29 (*Identity social projection function*): Suppose that all players in N have the same action set, i.e., $S_i = S_j = S$ for all $i, j \in N$. Let P_i be the social projection function for player $i \in N$. Recall that $P_{ij}(s|\sigma_i)$ is the probability that player i assigns to player j playing action s when the strategy of player i is given by σ_i . If $P_{ij}(s|\sigma_i) = \sigma_i(s)$ for all $s \in S$ and all $j \in N$, then we say that P_i is an identity social projection function.

Definition 13.30 (*Evidential game*): Consider the static game of complete information, $\{N, S, u\}$. Let $P = (P_1, P_2, \dots, P_n)$ be a profile of social projection functions, where P_i is the social projection function of player $i \in N$ (Definition 13.26). Then, the game augmented

⁸³ By contrast, in a dynamic game (under causal reasoning), if (say) player 1 moves first, choosing the strategy σ_1 , followed by player 2 who chooses strategy σ_2 , having observed a realization of σ_1 , then σ_2 may very well depend on σ_1 . When choosing σ_1 , player 1 will take into account the influence of his choice on the future behavior of player 2. This should not be confused with evidential reasoning.

with the vector of social projection functions, P , denoted by $\Gamma = \{N, S, u, P\}$, is called an evidential game. We say that players in such a game use evidential reasoning. In particular, if each $P_i(\sigma_i)$ is independent of σ_i , then we say that Γ is a causal game.

From Definition 13.30, a causal game is a special case of an evidential game. Suppose $P_i(\sigma_i)$ is independent of σ_i , for each player, i , so that $\Gamma = \{N, S, u, P\}$ is a causal game. Γ is still richer than the static game of complete information, $\{N, S, u\}$, because Γ incorporates players' beliefs about other players' actions, as given by P .

Definition 13.31 (Optimal strategies): An optimal strategy for player i , $\sigma_i^* \in \Sigma_i$, in the evidential game $\Gamma = \{N, S, u, P\}$ (Definition 13.30), maximizes the payoff function of player i , $u_i(\sigma_i, P_i(\sigma_i)) \equiv u_i(\sigma_i, \sigma_{-i}^e(\sigma_i))$.

Definition 13.32 (Evidential equilibria): The strategy profile $\sigma^* = (\sigma_1^*, \sigma_2^*, \dots, \sigma_n^*) \in \Sigma$ is an evidential equilibrium of the evidential game $\Gamma = \{N, S, u, P\}$ if σ_i^* is an optimal strategy for each $i \in N$ (Definition 13.31).

The optimal actions of each player in an evidential equilibrium are found by solving a decision theoretic problem in what is classically a strategic game. There are no higher order beliefs. Each player does not think about strategically exploiting the SPF of the other player. Indeed the game $\Gamma = \{N, S, u, P\}$ does not involve any assumptions about the mutual or common knowledge of P . Requiring u_i and P_i to be continuous functions on compact mixed strategy spaces guarantees that an equilibrium exists in the decision theoretic problem..

Note that Definition 13.32 only requires that a strategy for a player be optimal given *his* beliefs. But, of course, beliefs may not turn out to be correct, ex-post. Ultimately, the choice among models in all science is guided by the evidence. The evidence from many static games reviewed in this book, shows that beliefs about others can often turn out to be incorrect, at least when the game is new and played only a few times. Nevertheless, it is of interest to consider the special case where beliefs turn out to be correct, at least in equilibrium. This is the subject of the next two definitions.

Definition 13.33 (Mutually consistent strategies): A strategy profile $\sigma^* = (\sigma_1^*, \sigma_2^*, \dots, \sigma_n^*) \in \Sigma$ of the evidential game $\Gamma = \{N, S, u, P\}$ (Definition 13.30) is a mutually consistent vector of strategies if $P_i(\sigma_i^*) = \sigma_{-i}^*$ for all $i \in N$, i.e., if $P_{ij}(s_j | \sigma_i^*) = \sigma_j^*(s_j)$, for all $i, j \in N$, $i \neq j$, and all $s_j \in S_j$.

In other words, a strategy profile $\sigma^* = (\sigma_1^*, \sigma_2^*, \dots, \sigma_n^*)$ is a mutually consistent vector of strategies, if for all players $i, j \in N$, $i \neq j$ and all actions, s_j , open to player j , the probability $P_{ij}(s_j | \sigma_i^*)$ that player i “believes” that player j will play action s_j (given σ_i^*) is equal to the “actual” probability $\sigma_j^*(s_j)$ with which player j plays s_j . Indeed, imposing such a social projection is quite strong, as are the epistemic conditions for a Nash equilibrium.

Definition 13.34 (Consistent evidential equilibria): A consistent evidential equilibrium of the evidential game $\Gamma = \{N, S, u, P\}$ is an evidential equilibrium, $\sigma^* \in \Sigma$, which is also a mutually consistent vector of strategies (Definitions 13.32 and 13.33).

As one might expect, there is a natural correspondence between Nash equilibria and consistent evidential equilibria. This is formally stated and established by the following proposition, which is a special case of the famous result of Aumann and Brandenburger (1995) on the epistemic foundations of a Nash equilibrium. The proof, which is straightforward, is left as an exercise for the reader.

Proposition 13.44 (*al-Nowaihi and Dhami, 2015*):

- (a) Let $\sigma^* \in \Sigma$ be a Nash equilibrium in the static game of complete information, $\{N, S, u\}$. Consider the (constant) social projection functions: $P_i(\sigma_i) = \sigma_{-i}^*$, for all $\sigma_i \in \Sigma_i$ and for all $i \in N$. Then σ^* , is a consistent evidential equilibrium in the evidential game $\Gamma = \{N, S, u, P\}$. Furthermore, Γ is a causal game.
- (b) Let $\sigma^* \in \Sigma$ be an evidential equilibrium in the evidential game $\Gamma = \{N, S, u, P\}$, where P is the profile of constant social projection functions $P_i(\sigma_i) = \sigma_{-i}^*$, for all $\sigma_i \in \Sigma_i$ and for all $i \in N$ (hence, σ^* is a consistent evidential equilibrium and Γ is a causal game). Then σ^* is a Nash equilibrium in the static game of complete information $\{N, S, u\}$.

AN APPLICATION: THE PRISONER'S DILEMMA GAME

We now use the prisoner's dilemma game in Figure 13.33 to illustrate some of the implications of evidential reasoning. Call the row player "player 1" and the column player "player 2." Consider the following cases.

- Case 1. Both players use evidential reasoning.
- Case 2. One player uses evidential reasoning but the other uses causal reasoning.
- Case 3. Both players use causal reasoning but beliefs turn out to be wrong ex-post.
- Case 4. Both players use causal reasoning and beliefs turn out to be correct ex-post.

The last case illustrates Proposition 13.44a, namely, that there will always be a profile of social projection functions for which a given Nash equilibrium corresponds to a consistent evidential equilibrium. A comparison of Cases 3 and 4 shows that causal reasoning does not guarantee mutual consistency of beliefs.

For the prisoner's dilemma, $N = \{1, 2\}$, $S_1 = S_2 = \{C, D\}$, $S = \{C, D\} \times \{C, D\}$, and u is shown in the payoff matrix in Figure 13.33. Each player has a dominant action, D , thus, the unique Nash equilibrium of this game is (D, D) . By contrast, the empirical evidence reviewed above, shows that 50% or more of the outcomes involve the play (C, C) . We can set up this game as either an evidential game or a causal game. Since the Nash equilibrium for a prisoner's dilemma game is in pure strategies, we focus on pure strategies.

From Definition 13.28, in general, $P_{ij}(\cdot|\sigma_i)$ will vary with σ_i , but under causal reasoning $P_{ij}(\cdot|\sigma_i)$ will be independent of σ_i (Definition 13.27). For all cases below, we consider the identity social projection function (Definition 13.29).

Case 1: The social projection function for each player is given by

$$\begin{cases} P_{12}(C|C) = 1, P_{12}(D|C) = 0; P_{12}(D|D) = 1, P_{12}(C|D) = 0, \\ P_{21}(C|C) = 1, P_{21}(D|C) = 0; P_{21}(D|D) = 1, P_{21}(C|D) = 0. \end{cases} \quad (13.100)$$

From (13.100), both players use evidential reasoning, so this is an evidential game. Given the social projection functions, the unique optimal choice is C for each player. Hence, (C, C) is the unique evidential equilibrium. Notice that (C, C) is a mutually consistent vector of strategies (Definition 13.33). Hence, (C, C) , the Pareto optimal outcome, is a consistent evidential equilibrium (Definition 13.34).

Readers trained in classical game theory could wish to make the following argument. Since $P_{12}(C|C) = 1$ and players cannot change the actions of opponents by changing their action, why does not player 1 defect and increase his outcome to 3, hence, breaking the cooperative equilibrium? Rapoport (1966, pp. 139–41) argues along the following lines. It is also the case that

$P_{12}(D|D) = 1$. Player 1 knows that player 2, who is like-minded, will also benefit by thinking in an analogous manner and, hence, both will defect, in which case both get a payoff of 1. However, given (13.100), this does not maximize the individual payoffs, which is required for an evidential equilibrium (see Definitions 13.31, 13.32). Hence, player 1 finds it worthwhile to cooperate. For analogous reasons, player 2 also cooperates. Thus, mutual cooperation is sustained. Whether such a simple heuristic, independent of epistemic foundations, is reasonable or not, is entirely an empirical matter.

Remark 13.4 *We now make a set of observations that apply to each of the four cases that we consider in this section. The SPF for each player in (13.100) also specifies out-of-equilibrium beliefs. For instance, $P_{12}(D|C) = 0$ specifies the belief of player 1 that if he were to find it optimal to play C, then the probability that player 2 will play D is zero. It does not mean that by playing C, player 1 can induce player 2 to play D; indeed there is no such causal link. The optimal actions of each player, (C, C) in this case, are found from solving a decision-theoretic problem, using the heuristic of evidential reasoning, and none of the players attempt to strategically exploit the SPF of the other player. Indeed there is no requirement in an evidential game that there even be mutual knowledge of the SPF.*

Case 2. The social projection function for each player is given by

$$\begin{cases} P_{12}(C|C) = 1, P_{12}(D|C) = 0; P_{12}(D|D) = 1, P_{12}(C|D) = 0, \\ P_{21}(C|C) = 1, P_{21}(D|C) = 0; P_{21}(C|D) = 1, P_{21}(D|D) = 0. \end{cases}$$

Player 1 uses evidential reasoning and, in particular, his identity social projection function. Player 2 uses causal reasoning and, in particular, mistakenly assumes that player 1 will always cooperate. This is an evidential game. The unique evidential equilibrium (Definition 13.32) is (C, D). It is an evidential equilibrium because each player's chosen action is optimal, given his beliefs, which are captured by his social projection function. It is not a consistent evidential equilibrium because the belief of player 1 turns out to be mistaken in equilibrium ($P_{12}(C|C) = 1$ but player 2 plays D instead). By contrast, the belief of player 2 that player 1 always plays C turns out to be correct in equilibrium.

Case 3. The social projection function for each player is given by

$$\begin{cases} P_{12}(C|C) = 0, P_{12}(D|C) = 1; P_{12}(D|D) = 0, P_{12}(C|D) = 1, \\ P_{21}(C|C) = 0, P_{21}(D|C) = 1; P_{21}(C|D) = 1, P_{21}(D|D) = 0. \end{cases}$$

Both players use causal reasoning (Definition 13.27). Given these social projection functions, the unique payoff maximizing strategy for each player is to play D (Definition 13.31). Hence, (D, D), is the unique evidential equilibrium (Definition 13.32). However, (D, D), is not a mutually consistent vector of strategies (Definition 13.33) because each player expects his opponent to play C in response to D but the opponent's response is D. Hence (D, D) is not a consistent evidential equilibrium (Definition 13.34). The importance of this case arises because it is sometimes believed that a Nash equilibrium under causal reasoning requires mutual consistency of beliefs.

Case 4. The social projection function for each player is given by

$$\begin{cases} P_{12}(C|C) = 0, P_{12}(D|C) = 1; P_{12}(D|D) = 1, P_{12}(C|D) = 0, \\ P_{21}(C|C) = 0, P_{21}(D|C) = 1; P_{21}(C|D) = 0, P_{21}(D|D) = 1. \end{cases}$$

	S	R
S	10, 19	4, -7
R	(-14, -7, -1), 4	19, 10

Figure 13.34 A coordination game.

As in Case 3, both players use causal reasoning. Given the social projection function, playing D is the unique optimal strategy for player 1 and player 2 (Definition 13.31). Hence (D, D) is the unique evidential equilibrium (Definition 13.32). Furthermore, (D, D) is a mutually consistent vector of strategies (Definition 13.33) because each player expects his rival to play D and, in fact, his rival does play D . Hence, (D, D) is a consistent evidential equilibrium (Definition 13.34). The unique Nash equilibrium of this game is, of course, (D, D) . Hence this case illustrates Proposition 13.44a, namely, a Nash equilibrium of the game $\{N, S, u\}$ is also a consistent evidential equilibrium of the game $\{N, S, u, P\}$ with a suitable choice of social projection functions, P .

The machinery developed above applies to static games of full and incomplete information and as argued above (see Example 13.22) to potentially many other belief formation processes. For further applications of evidential reasoning to oligopolistic competition and Nash bargaining, see al-Nowaihi and Dhami (2015). However, the empirical evidence on evidential reasoning comes largely from static games. It would be of interest to see if the evidence also develops in the direction of dynamic games because the theoretical framework is amenable to such an analysis.

13.7.5 Noisy introspection

Goeree and Holt (2004) propose a model of noisy introspection (NI). The essential idea is to relax the assumption of rationality of beliefs in the QRE. Consider the coordination game in Figure 13.34 from Guyer and Rapoport (1972).

The row and column players have two pure strategies, S and R . Three different versions of this game can be generated by choosing, successively, the three alternative payoffs to the row player from the strategy profile (R, S) : -14 , -7 , and -1 . The two pure strategy Nash equilibria are (S, S) and (R, R) in the three different versions. The equilibrium (S, S) is also the maximin equilibrium. When the payoff from (R, S) is $(-14, 4)$, there is also a mixed strategy Nash equilibrium in which the column player plays S with probability 0.39 and the row player plays S with probability 0.19.⁸⁴ The strategies S and R are short for, respectively, “safe” and “risky.”

The strategy profile (R, R) is risky because if any of the players unilaterally deviates, then the opponent’s payoffs become negative. Thus, a player is likely to play R only if there is a high probability that the opponent will also play R . In the Harsanyi–Selten (1988) sense, the outcome (S, S) is risk dominant. These equilibria are identical in the three different versions of the game. Hence, the equilibrium that the players choose to coordinate on should not change. Experimental evidence, however, shows that as the payoff of the row player from the strategy profile (R, S) increases, successively, from -14 to -7 to -1 , the incidence of S falls from 89% to 88% to 75%. The likely reason is that the strategy R tends to be perceived as less risky.

⁸⁴ One can also compute the mixed strategy when the payoffs from (R, S) are, respectively, $(-7, 4)$ and $(-1, 4)$.

Denote the expected payoffs of player i (where i can be the row or the column player) from playing, respectively, the strategy S and R by u_{iS} and u_{iR} . Then the logit probabilities in a QRE, as in (13.7), with $\mu^{-1} = \lambda$, require that the probability of playing S by player i is

$$\pi_{iS} = \frac{\exp(\mu^{-1}u_{iS})}{\exp(\mu^{-1}u_{iS}) + \exp(\mu^{-1}u_{iR})}, \quad (13.101)$$

where μ is a noise parameter. As $\mu \rightarrow 0$, the strategy with the greatest payoff is chosen with probability 1 (check that when $\mu \rightarrow 0$ and $u_{iS} > u_{iR}$, the RHS of (13.101) equals 1).

In Figure 13.35, the darker step-functions show the logit best responses for a small level of noise, $\mu = 0.1$. This accounts for the slightly rounded edges of the step-functions (for $\mu = 0$ we get sharp edges as in a Nash equilibrium). The interior intersection of the Nash best response functions (for $\mu = 0$) give the mixed strategy equilibrium of the game, (0.39, 0.19). The Nash best responses also intersect at the southwest and the northeast edges, picking out the two pure strategy Nash equilibria (S, S) and (R, R).

For a higher value of $\mu = 6.6$, estimated from the Guyer and Rapoport (1972) data, the logit best responses are shown as the lighter curves. These intersect close to the northeast edge of Figure 13.35 and their point of intersection gives the QRE at (0.97, 0.98). In a QRE, the row and column players play S with respective probabilities 0.97 and 0.98.

By contrast, the experimental evidence indicates that beliefs are given by the spot marked with a cross (southwest of the QRE). Clearly, any explanation for such behavior must depart from equilibrium theories such as QRE and Nash. Goeree and Holt (2004) argue that mutual consistency of beliefs may be a reasonable assumption if players play repeatedly against each other and learn. However, many strategic interactions last for very few periods, or involve entirely new circumstances such as legal disputes, election campaigns, international conflicts, and 3G spectrum auctions. In such situations, mutual consistency of beliefs appears less reasonable.

Figure 13.35 Logit best responses for the game in Figure 13.34 when the payoff from (R, S) is $(-14, 4)$.

Source: Reprinted from *Games and Economic Behavior* 46: 365–82. Goeree, J. K. and Holt, C. A., “A model of noisy introspection.” Copyright © 2004, with permission from Elsevier.

Suppose that players do not have experience of playing against each other and each player believes that the other will play S (the safe strategy) with probability 0.7. The points marked with a star on the logit response functions in Figure 13.35, for each player, indicate the best response of each player on such a supposition. Allowing for one round of best responses to the response of the opponent leads us to the point marked with a cross in Figure 13.35 that is consistent with the experimental evidence. Of course, the beliefs in this case are not self-reproducing in equilibrium. However, moving away from the rational expectations assumption gives us a better fit with the evidence. Since the point marked with a cross is to the southwest of the QRE, and northeast of the Nash equilibrium point, this point is referred to as a *pull to the centre*. If, however, the logit response functions were downward sloping, then we would get a *push to the edge* phenomenon.

In order to deal with such behavior, Goeree and Holt (2004) relax the “mutual consistency of beliefs” assumption. They do so by using “iterated conjectures” in a noisy version (that introduces noise as in (13.101)) of the rationalizability notion introduced by Bernheim (1984) and Pearce (1984). Let

$$\pi_{iS}(q | \mu_0) = \frac{\exp(\mu_0^{-1} u_{iS})}{\exp(\mu_0^{-1} u_{iS}) + \exp(\mu_0^{-1} u_{iR})}$$

denote the logit probability that player i plays S, conditional on a belief that the opponent plays S with probability q and an error rate $\mu = \mu_0$. q represents a player’s *first order beliefs* about the other player. So we can recursively define higher order beliefs as follows.

1. ρ^0 represents a player’s choice probability ($\rho^0 \equiv \pi_{iS}(q | \mu_0)$).
2. ρ^1 represents a player’s first order beliefs about the strategy choice of the opponent ($\rho^1 \equiv q$).
3. ρ^2 represents a player’s second order beliefs. These are the beliefs of a player about the first order beliefs of the other player. And so on ...

The first order beliefs of player i respect the fact that player j is playing a logit best response, conditional on what player j thinks about the choice probability of player i . This implies that $q = \pi_{jS}(\rho^2 | \mu_1)$. This, the second level of introspection by player i involves his guess of what player j thinks about i ’s choice probability, so might involve a greater degree of error relative to first order beliefs, hence, we would reasonably expect that $\mu_1 > \mu_0$. In general, as we consider increasingly higher order beliefs, we get increasing error rates, $\mu_0 < \mu_1 < \mu_2 < \mu_3 < \dots$. One suggestion made by the authors is the geometrically increasing case, $\mu_k = t^k \mu_0$, $t > 1$.

Several other models can be recovered from the NI model. For instance, setting $\mu_0 = \mu_1 = \mu_2 = \mu_3 = \dots = \infty$, all pure strategies are played with an identical probability (check in this case that $\pi_{iS} = 1/2$ from (13.101)). This is like a level- k model with type $L0$. Now consider $\mu_0 = 0$ and $\mu_1 = \mu_2 = \mu_3 = \dots = \infty$. This corresponds to a type $L1$ in a level- k model. In this manner, all the types in a level- k model can be recovered.

Rationalizability in the sense of Bernheim (1984) and Pearce (1984) requires that players do not play those strategies that are never a best response to a plausible set of beliefs about the play of the opponents. The final step in the model of NI is to extend this notion to modify best response to a noisy best response, as in (13.101), when beliefs are constructed iteratively, as explained above.

13.7.6 A brief note on some other models

Colman et al. (2014) introduce a set of twelve, 3×3 and 4×4 , games that distinguish between three different solution concepts—level- k models, team reasoning, and *strong Stackelberg reasoning*. The last of these concepts, due to Colman and Bacharach (1997), may not be familiar to many economists. Stackelberg reasoning implies that even in static normal form games, players believe that their opponents will play their best replies to their strategies. Taking into account this one-step behavior of others, players then choose their optimal strategies. The best replies of others may not be unique which limits the domain of such reasoning. Colman et al. (2014) strengthen the concept to strong Stackelberg reasoning that restricts the concept to games where the best replies of others are unique.

Figure 13.36 shows one of the two player, 3×3 experimental games in Colman et al. (2014). Consider the predictions made by the three alternative theories for the row player. Start with level- k models. Suppose that a type $L0$ player randomizes uniformly over the column strategies. Thus, the optimal strategy for a type $L1$ row player is B. Type $L2$ row players believe that the column players are of type $L1$. A type $L1$ column player plays C on the supposition that the row player is of type $L0$. Thus, the best response by a type $L2$ row player is B. Types are truncated at $L2$.

Team reasoning (see Bacharach, 1999, 2006) is a relaxation of the assumption of methodological individualism. Its central insight is that in certain contexts, individuals switch off their preference for selfish own-payoff maximization and choose instead to maximize the payoff of the team. For instance, individual players in a football team may pursue the team objective of winning the game. Of, course players may wish to maximize the team outcome only if they believe that other players will do likewise. Suppose that players maximize the average payoff, as a proxy for the team payoff. In Figure 13.36, the unique outcome under team reasoning is (C,C).

A row player who uses Stackelberg reasoning will choose A because the best response by the column player of the strategies A, B, and C by the row player is, respectively, A, B, and C. Likewise under such reasoning, the column player will also choose A. Thus, the unique outcome under Stackelberg reasoning is (A, A).

The main experimental findings over two sets of experiments (the second set was used to check the robustness of results) are as follows. The choices of players are consistent with type $L1$ players in 37–46% of the cases in 3×3 games and in 46–50% of the cases in 4×4 games.⁸⁵ The percentage of choices consistent with team reasoning increased from 13–20% in 3×3 games to 26–27%

	A	B	C
A	3, 3	1, 0	0, 2
B	1, 1	2, 2	3, 0
C	2, 0	1, 2	2, 5

Figure 13.36 An experimental game from Colman et al. (2014).

⁸⁵ The percentage of choices across all three types of theories can sum up to greater than 100 because the competing theories make identical predictions in some games.

in 4×4 games. Based on raw frequencies, the percentages of choices that are consistent with Stackelberg reasoning in 3×3 games is 38 (the corresponding figures for $L1$ types and team reasoning are 43 and 29). However, there is a significant drop in choices that are consistent with Stackelberg reasoning in 4×4 games to 18% (corresponding figures for type $L1$ players and team reasoning are 46 and 27). The authors conjecture that the higher cognitive effort required in 4×4 games relative to 3×3 games hampers the use of Stackelberg reasoning. Furthermore, it seems that when games get cognitively more challenging, Stackelberg reasoning is abandoned in favour of level- k and team reasoning. Exploring the foundations of such heuristic switches is an exciting and unexplored research area.

We now briefly note a few other equilibrium concepts. Yildiz (2007) considers the possibility of *wishful thinking* in which players partition the set of strategy profiles, then pick their own strategy that corresponds to the highest possible payoff. This is an extreme form of optimism. Halpern and Pass (2012) introduce the concept of *iterated regret minimization*. As the name indicates, this involves the iterated deletion of strategies that do not minimize regret. The authors apply their concept to a range of games where the standard Nash equilibrium concept has proved problematic in explaining the empirical results, such as the traveller's dilemma, centipede games, and Bertrand competition. Cubitt and Sugden (2011) offer another iterative procedure, called the *reasoning-based expected utility procedure*. This procedure typically deletes more strategies than the standard iterated deletion of strategies.

13.8 Behavioral economics of auctions

This section considers the evidence from auctions of a single unit of an object and theoretical attempts to explain the evidence. Our main focus is on common value auctions.

13.8.1 Some basic results in auction theory

We begin by establishing some terminology, definitions, and some basic results in auctions for a single unit of an item. Multi-unit auctions have become more empirically important since the 1990s and have been an important area of theoretical and empirical research. However, for the experimental results on auctions and the behavioral models that we report, the single unit auctions will mostly suffice. The purpose of this section is to build some intuition about the basics of the economics of auctions at a heuristic level.⁸⁶

Suppose that we have n bidders, $i = 1, 2, \dots, n$, for a single indivisible object in an auction. Bidder i observes a private signal, X_i , and some public signal S that is informative about the value of the object (X_i and S can also be vectors). Let the vector of private signals be denoted by $X = (X_1, X_2, \dots, X_n)$. In general, the value of the object for bidder i , v_i , depends on all private signals and the public signal, i.e.,

$$v_i = v_i(X, S).$$

The two main cases considered in the experimental literature are as follows.

1. Independent Private Values (IPV): In this case, bidder i derives utility solely from his own private signal. Furthermore, the private signals are independent, so

⁸⁶ Readers interested in more formal treatments can consult several possible sources, e.g., Krishna (2010) and Milgrom (2004).

$$v_i = v_i(X_i).$$

All bidders know the probability distribution that generates the private signals of all competitors.

2. Common Values (CV): In this case, bidders do not use (or receive) private signals and their value for the object depends solely on the common public signal received, so, for any bidder i ,

$$v_i = v_i(S).$$

AUCTIONS WITH INDEPENDENT PRIVATE VALUES (IPV)

In the *first price sealed-bid auction*, all bidders simultaneously submit bids, $b_1, b_2, \dots, b_n$ and the highest bidder wins. Some tie breaking rule is invoked if there is more than one winning bid, for instance, one among the winning bids may be randomly picked and given the object. The winner pays a price, p^* , equal to the highest bid, so $p^* = b^* = \max \{b_1, b_2, \dots, b_n\}$. Hence, the utility of the winner is given by

$$v_i(X_i) - p^*.$$

In the Vickery or *second price sealed-bid auction*, the winner is the bidder who makes the highest bid. However, the price paid, p^s , equals the second highest bid, b^s . Hence, the utility of the winner is given by

$$v_i(X_i) - p^s.$$

Two important auction formats in actual practice are the English (or ascending) price auction and the Dutch (or descending) price auction. As the names indicate, the English price auction begins with some reserve price, r . The auction price is then gradually raised in discrete steps until only one bidder, who makes the winning bid, remains active. In the Dutch auction, on the other hand, one starts from a high price. The price is then lowered in discrete steps until one of the bidder cries “Mine” who is then declared the winner.

In order to motivate the experimental results, we now give some heuristic insights into some of the properties of the four kinds of auctions that we identify above (first price, second price, English, and Dutch); these results are summarized in Proposition 13.45, below.

Consider, an English auction with the IPV assumption. Starting at some reserve price, an auctioneer elicits increasingly higher bids. Suppose that the value of the object to a bidder is v_i . Then the bidder continues to increase his bids until the time when the bid b_i equals his value for the object, v_i . Any further increase in bids forces him to drop out. Hence, bidding one’s valuation is a dominant strategy.

Now consider a second price sealed-bid auction with the IPV assumption. We claim that it is a dominant strategy for bidder i to bid $b_i^* = v_i$. Suppose that all other bidders bid their valuation, i.e., $b_j^* = v_j, j \neq i$. Suppose $b_i < v_i$, then there is some probability that another individual might bid an amount $b_j^* : b_i < b_j^* \leq v_i$, and win. Since, bidder i can increase profits from bidding his true valuation, hence, $b_i < v_i$ is dominated by $b_i^* = v_i$. Similarly $b_i > v_i$ is dominated by $b_i = v_i$, because there is then some probability that bidder i will win and incur a loss. Thus, in the English and the second price auctions, each bidder bids his/her true valuation, the identity of

the winner is identical and the seller derives the same revenue. This is stated in Remark 13.5b(i), below.

The following example from Milgrom (1989) conveys some of the essential insights on first price sealed-bid auctions under the IPV assumption.

Example 13.23 Suppose that there are two risk-neutral bidders, bidding for one indivisible unit of an object. The first bidder has a valuation of $v_1 = 101$, which is public knowledge. The other bidder's valuation, v_2 , is private information but it is known to be distributed as follows: v_2 equals 50 with probability $\frac{4}{5}$ and 75 with probability $\frac{1}{5}$. Assuming common knowledge of rationality and one dollar as the lowest unit of currency, if bidder 1 bids 76 then he wins for sure, making a profit of $101 - 76 = 25$. If he bids $b_1 = 51$, then his expected payoff is $\frac{4}{5}(v_1 - b_1) = 40$. Thus, in his optimal bid, player 1 wins with probability $\frac{4}{5}$, and bidder 2 wins with probability $\frac{1}{5}$. The two important insights are the following.

- (1) The outcome in this asymmetric information first price sealed-bid auction, unlike the English auction and the second price sealed-bid auction need not be efficient (because bidder 2 wins one out of every five times).
- (2) Bidders bid less than their valuation.

While the outcome in Example 13.23 is not efficient, under certain conditions, first price sealed-bid auctions can produce the efficient outcome. One of the exercises at the end of the chapter shows this to be the case.

Suppose that we are now interested in the question of which auction design, among the four, generates the highest amount of revenue for the seller. In the second price auction, bidders bid their valuation but pay a price to the seller that equals the second highest bid. In first price and Dutch auctions, bidders shade their bids below their valuation, however, they pay a price to the seller that equals their bids (see Example 13.23). Hence, a priori it would seem difficult to decide which auction generates more revenues for the seller. However, a remarkable result, the revenue equivalence theorem, states that under IPV, risk-neutral bidders, and a further set of auxiliary assumptions, all four auction formats yield the same expected revenues for the sellers and same expected payoffs to the buyers.⁸⁷

We now loosely summarize these observations in Remark 13.5. For the precise statement of the result and proofs, see Fudenberg and Tirole (1991), Krishna (2010), and Milgrom (2004).

Remark 13.5

- (a) [Revenue equivalence theorem] Under IPV, when bidders are risk neutral, the four auction formats—first price, second price, English and Dutch—yield the same social surplus and bidders' utility. Additionally, if the valuations are iid, the highest bidder wins in equilibrium, and the lowest bidder gets zero profits, then, the expected payoffs of the seller are identical.
- (b) [Equivalence among auction formats] Under IPV and risk neutrality of bidders, the following two results hold.
 - (b1) The second price auction and the English auction induce identical bidding behavior and revenue.
 - (b2) The first price auction and the Dutch auctions induce identical bidding behavior and revenue.

⁸⁷ See, for instance, Vickrey (1961), Myerson (1981), and Riley and Samuelson (1981).

AUCTIONS WITH COMMON VALUES (CV)

Consider a common value (CV) auction of a single indivisible unit of an object. The most important result that has attracted a large body of empirical work and behavioral explanations is the *winner's curse*, which was first discovered in oil lease auctions. In these auctions, bidders bid for drilling rights for oil on certain tracts of land. The value of the oil is the same for all companies, so in this sense this is a common value auction. However, companies might differ in their estimate of the actual cost, c , of drilling for oil. An estimate of the actual cost by company $i = 1, \dots, n$ is given by $C_i = c + \varepsilon_i$, where the term ε_i is independently and identically distributed across companies and has zero mean.

It follows that the cost estimate of each bidder is unbiased, i.e., $E[C_i] = c$. Since bidders are alike in all other respects in a CV auction, the winner is the most optimistic bidder who has the lowest realization of ε_i . Thus, an unpleasant surprise might await the winner. One of two things might happen when actual costs turn out to be higher than the estimated costs. (1) The bidder might go bankrupt, or (2) the profits might turn out to be lower than expected. These two cases are sometimes known as versions 1 and 2 of the winner's curse.

The source of the problem that leads to the winner's curse is that bidders do not correctly calculate the value of an object or the cost, *conditional on their bid being successful*. Since auctions involve complicated calculations of beliefs about rivals, their rationality, and considerations of strategic uncertainty, it might be useful to illustrate the issues involved in a simpler game. Consider the "Acquire a company" game introduced by Samuelson and Bazerman (1985).

Example 13.24 [*Acquire a company or Takeover game; Samuelson and Bazerman, 1985*]
An acquiring firm (A) bids an amount b to acquire a target firm (T). Firm A announces a bid, which firm T can either accept or reject. Thus, the action set of the target firm is $S_T = \{0, 1\}$, where 0 means reject offer and 1 means accept offer. The value of the firm, v , is private information to T. Firm A knows, however, that v is uniformly distributed in the interval $[0, 100]$. Furthermore, firm A also knows that if acquired, the value of firm T will increase to γv , $\gamma > 1$ (say, because firm A has a commonly known reputation to add value to its acquisitions). On its part, firm T agrees to the bid by firm A if $b \geq v$. How much should A bid?

When $\gamma = 1.5$, experimental results suggest that about 90% of the subjects in their role as firm A, bid in the range 50–75.⁸⁸ The reasoning revealed by subjects in experiments in their role as firm A, is typically as follows. "The average value of the company is 50. By acquiring it, the value increases by 50%, so that post-acquisition, the expected value is 75." The problem with this reasoning is that it ignores the adverse selection problem by making unconditional calculations; it does not calculate the correct value of the firm, conditional on the bid being accepted.

Here is how the optimal bid should be calculated. The expected profit of firm A, for any bid b , is

$$\pi(b) = \Pr(v \leq b) \int_0^b [\gamma v - b] dv, \quad (13.102)$$

where $\Pr(v \leq b)$ is the probability that the bid is no lower than the value of the firm, otherwise firm A's bid is not accepted. If a bid b is accepted, then it reveals that the value of firm T lies uniformly in the interval $[0, b]$, which explains the upper and lower limits on the integral.

⁸⁸ See, for instance, Samuelson and Bazerman (1985), Ball et al. (1991), and Tor and Bazerman (2003).

The optimal, or the rational bid is zero. Formally, since v is uniformly distributed in the interval $[0, 100]$, so $\Pr(v \leq b) = \frac{b}{100}$. Substituting this in (13.102), we get $\pi(b) = \frac{b}{100} \int_0^b [\gamma v - b] dv$. Evaluating this integral we get

$$\pi(b) = \frac{b^3}{100} \left[\frac{\gamma}{2} - 1 \right].$$

For future reference, we write the rational bid as

$$b^r = \begin{cases} 0 & \text{if } 1 < \gamma \leq 2, \\ 100 & \text{if } \gamma > 2. \end{cases} \quad (13.103)$$

The intuition is as follows. If a bid b is accepted, then firm T is worth no more than b if run by the management of firm T. Since the value of firm T is uniformly distributed, each value of firm T below b is equally likely, so, on average, firm T is worth no more than $b/2$. Under the management of firm A, however, the company is worth $\gamma \frac{b}{2}$. For any $\gamma \leq 2$ the expected value of the company is below the bid value, so it is optimal to bid zero.

In contrast to the theoretical prediction of a zero bid, when $\gamma \leq 2$, most subjects in experiments bid between 50 and 75. In other words, they face a *winner's curse*.

13.8.2 Some empirical evidence on the predictions of the rational auctions model

We briefly highlight some of the experimental findings with a view to providing the reader with a flavor of the findings.⁸⁹ Our main focus is on the winner's curse. However, we will first review some findings from the IPV auctions. We will abbreviate the *risk-neutral Nash equilibrium*, for private or common value auctions, by "RNNE."

The predictions of the RNNE in Remark 13.5(b1), (b2) are violated by the experimental findings. Kagel et al. (1987) find that in second price auctions, the bids average 11% more than the dominant strategy, which is to bid one's valuation. Kagel and Levin (1993) find that 62% of the bids are above the dominant strategy and 8% are below it. Furthermore, while the bids converge rapidly to the dominant strategy equilibrium in the English auctions, this is not the case in second price auctions.

There is also evidence of overbidding in first price sealed-bid auctions. Coppinger et al. (1980) give evidence that contradicts Remark 13.5(b2)—the equivalence between first price and Dutch auctions. Goeree et al. (2002) find that for the case of two bidders with six discrete possible values of an object, bidders overbid relative to the predictions of the RNNE in all treatments. Neugebauer and Selten (2006) look at various treatments that are differentiated by the extent of information, e.g., bids of players and the identity of the winner. They also find evidence of overbidding in a first price sealed-bid auction. In one treatment, 75% of the bidders bid above the RNNE, while in another, 41%–48% of the bidders overbid relative to the RNNE.

The tendency to overbid relative to the RNNE does not necessarily vanish with experienced bidders. Garratt et al. (2012) conduct experiments with individuals who are experienced participants in eBay auctions, which have a similarity with second price auctions (although these two auctions are not identical). In experiments that expose experienced bidders on eBay to a standard

⁸⁹ Readers interested in the details can refer to the survey article by Kagel and Levin (2010) that we draw on in this section.

second price sealed-bid auction, 21.2% bid their value, 41.3% under-bid, and 37.5% over-bid. Subjects who had experience with selling on eBay, bid lower as compared to subjects with buying experience on eBay.

The RNNE performs better if one is primarily interested in the signs of the comparative static effects. For instance, an increase in the number of bidders is predicted to increase equilibrium bids. This finds support in the experimental results (Kagel and Levin, 1993). There is also evidence that bidders bid closer to their valuations in second price auctions relative to first price auctions (Kagel and Levin, 2010).

We now turn to the evidence from common value auctions. The first field account of the winner's curse came from three engineers Capen, Clapp, and Campbell (1971). They examined the outcomes of the US Federal government's outer continental shelf oil lease auctions, which have the characteristic of CV auctions. They note that winners of auctions were consistently disappointed with the rates of return. There was wide variability in the bids. Thaler (1988) highlights the following findings from this study and the follow-up study by Mead et al. (1983) that suggests a winner's curse. (1) Restricting oneself to serious bids, the ratio of the highest to the lowest bids is commonly between 5 to 10 and as high as 100. (2) The sum of winning bids in the 1969 Alaska North Slope sale was \$900 million, while the sum of the second highest bids was \$370 million. Furthermore, the winning bid was at least four times the next best bid in 26% of the auctioned tracts and at least two times the next best bid in 77% of the cases. (3) Calculating before-tax returns on 1223 leases over the period 1954–69 in the Gulf of Mexico, only 22% of the leases turned out to be profitable, but the after-tax earnings were not very high; 62% of the leases were dry and another 16% were unprofitable.

Bazerman and Samuelson (1983) provide the first experimental evidence for the winner's curse, using as their subjects, MBA students at Boston University. They conducted 48 first price sealed-bid auctions in 12 classes. In each auction, the number of bidders varied between 4–26. The object for sale was a jar full of coins or nickels or small/large paper clips with a value of \$8. Although all bidders observed the same object, they did not know the exact value of the items in the jar and had to guess the value. Hence, the setting was designed, as far as possible, to be a CV auction. The bid that was closest to the actual value of the item won a \$2 prize. The mean bid across all auctions was \$5.13, which is \$2.87 below the value of the object. This probably reflects risk aversion. However, in contrast to the average overall bid, the average winning bid was \$10.01, which is about \$2 above the actual value. Furthermore, the average winning bid led to losses in half of the auctions. The authors then followed up this game with the Acquire a company game in Samuelson and Bazerman (1985). In this game, the rational bid is zero, however, 90% of the subjects bid between 50–75. These results are suggestive of a winner's curse.

Similar findings of a winner's curse are documented for above-average ability students by Lind and Plott (1991) and also in variations of the game where one bidder knows the value of the object with certainty (Dyer et al., 1989). The finding that inexperienced subjects suffer from a winner's curse and fail to adjust adequately to avoid the winner's curse has been replicated in many other studies. Dyer et al. (1989) ran first price sealed-bid auction experiments with inexperienced subjects and find that only 17% of the winners earn any profits. It also seems that one cannot ascribe these findings to bad luck alone. Examining average and high bids as separate groups, they find that 59% of all bids and 82% of the high bids were greater than the expected value of the object, conditional on winning it.

Explanations of the winner's curse have also been given in terms of “limited liability” or the “joy of winning.” The former explanation, given by Hansen and Lott (1991), argues that the subjects in experiments do not lose more than the cash balances that they start off with, hence, limited liability that is inherent in experimental setups, promotes more aggressive bidding. The

joy of winning explanation simply supposes that subjects get a thrill (or extra utility) from winning the auction, which predisposes them to bid more aggressively. Both these explanations have been countered by experimental results.⁹⁰

The predictions of the standard auction model have been falsified in two other respects. First, theory predicts that in CV auctions, as the number of bidders increases, optimal bids should fall. The intuition is that it is even worse to win in a larger group because the winner's signal of the cost C is then such that the measurement error, ε_i , is more extreme. In contrast, experimental results show that bids do not fall in response to an increase in the number of bidders (Kagel et al., 1995). Second when public information is provided to subjects in experiments about the value of the object, it reduces revenue when a winner's curse is operative. The reason is that bidders subject to a winner's curse bid too aggressively. However, when provided with the information about the true value of the object, they revise their bids downwards. However, theory predicts the opposite. This is because in first price auctions, individuals bid below their valuation and when the true value is publicly announced they should revise their bids upwards. The experimental findings are contrary to the predictions of theory (Kagel and Levin, 1986).

Experienced auction players in lab experiments also exhibit the winner's curse (Dyer et al., 1989). For moderately experienced bidders, Kagel and Levin (1986) find that there is adjustment that takes account of the winner's curse through a "hot stove" learning process. Such bidders reduce their bids with experience, and are able to avoid the winner's curse. However, they do not seem to correctly calculate the expected value of an object, conditional on winning it. When bidders are extremely experienced, greater public information increases revenues in sealed-bid auctions, in line with the theory's predictions. Nevertheless, the profits of these highly experienced bidders still fall below those that would be consistent with the RNNE. The reason is that they bid far too aggressively relative to the predictions of RNNE, although they avoid the winner's curse (Kagel and Richard, 2001). However, Kagel and Levin (2001, pp. 32, 33) caution us in interpreting these results by arguing that the winner's curse is avoided in experimental settings only with strong information feedback that is unlikely to be present in field settings. There are additional reasons, they point out, relating to the incentive and organizational structure, to suspect that other factors in field settings might work in favor of producing the winner's curse rather than removing it.

Harrison and List (2008) conduct two experiments with sports cards dealers; see also Harrison and List (2004). In the first experiment, they use a symmetric and an asymmetric information procedure in which bidders bid for an object. Under symmetric information, all dealers know that the value of the object is drawn randomly from a uniform distribution with a known midpoint. Under asymmetric information, one of the dealers, the insider, knows the objectively true value of the item with certainty, while others believe that it is randomly drawn from a known distribution. Dealers do not suffer from the winner's curse under symmetric information, but under asymmetric information they suffer from the winner's curse in 24–30% of the cases. The authors interpret this result as evidence that in familiar environments (symmetric information case) dealers protect themselves from the winner's curse. In a second experiment, dealers bid on a familiar item, a package of ten sports cards with a known retail value of \$9–\$10. Dealers do not exhibit the winner's curse in this case. In both experiments, more non-dealers than dealers exhibit the winner's curse.

⁹⁰ Kagel and Levin (1991) re-examined the data in Kagel and Levin (1986) and showed that the limited liability argument is not supported and the joy of winning explanation has been rejected by the experimental findings of Holt and Sherman (1994) and Avery and Kagel (1997).

Kagel (2015) argues persuasively that there are alternative and plausible explanations for the results from both experiments reported above. In the first experiment, dealers could simply be using their common heuristic of buying at a low price to sell at a higher price, which protects them from the winner's curse. In the second experiment, there is no scope for a winner's curse because the package of ten sports cards has a publicly known retail value.

The winner's curse has been documented in a variety of settings and not just auctions (see Kagel and Levin, 2010 for the references). Experiments that simultaneously include IPV and CV factors are relatively rare. In one such set of experiments, conducted by Goeree and Offerman (2002), actual bidding behavior is intermediate between the RNNE bids and the naive benchmark in which subjects do not take account of the expected value of winning, conditional on winning the object. The outcome is still relatively efficient because most bidders are subject to the winner's curse, so relatively, the bidder with the highest valuation wins.

13.8.3 *Cursed equilibrium as an explanation of the winner's curse*

We now give an explanation for the winner's curse using the χ -cursed equilibrium of Eyster and Rabin (2005) in Section 13.7.3. Consider the Takeover game in Example 13.24 above, for the case of a fully cursed player, $\chi = 1$. Recall that players in a cursed equilibrium know the distribution of types of the opponent, but ignore the correlation between types and actions. In the context of the Takeover game, types of the target firm, T, are distributed uniformly over $[0, 100]$.

If the acquiring firm A is not cursed, then it knows that the target firm will accept any bid $b \geq v$ and reject any bid $b < v$. Thus, it would know that the probability that a bid b is successful is $\frac{b}{100}$. However, a fully cursed firm A assigns the average action to all types of the target firm. Recalling from Example 13.24 that firm T can either accept or reject the bid ($S_T = \{0, 1\}$), the average strategy of firm T, using (13.98), is $\bar{\sigma}_T = \int_0^b \frac{1}{100} dv + \int_b^{100} \frac{0}{100} dv = \frac{b}{100}$. Thus, a fully cursed firm A believes that any bid b will be accepted with probability $\frac{b}{100}$; if the bid is accepted, the utility of firm A is $\gamma v - b$. These beliefs are not correct because any type of firm T will reject the bid if $b < v$. Thus, a fully cursed firm A maximizes

$$\pi(b; \chi = 1) = \frac{b}{100} \int_0^{100} [\gamma v - b] dv. \quad (13.104)$$

Evaluating the integral, we get $\pi(b; \chi = 1) = 50\gamma b - b^2$. Therefore, the optimal fully cursed bid is $b^c = 25\gamma$. Let us compare it to the optimal bid, b^r , in the absence of cursedness, given in (13.103). When $1 < \gamma \leq 2$, $b^r = 0$ but $b^c \in [25, 50]$, thus, in this case, the fully cursed bidder bids too high. This is an example of the winner's curse. The fully cursed bidder imagines that even when $b < v$ some types of firm T will continue to sell to her and this prevents firm A from lowering the bid to the optimal bid of zero. However, when $2 < \gamma < 4$, $b^r = 100$ but $b^c \in (50, 100)$. In this case, the fully cursed bidder bids too low and fails to realize that by raising the bid, all types of sellers will sell with probability 1.

What if $0 < \chi < 1$? In this case, the profit of a χ -cursed firm A is given by

$$\begin{aligned} \pi(b; \chi) &= \int_0^b \left[(1 - \chi) \times 1 + \chi \frac{b}{100} \right] [\gamma v - b] \frac{1}{100} dv \\ &\quad + \int_b^{100} \left[(1 - \chi) \times 0 + \chi \frac{b}{100} \right] [\gamma v - b] \frac{1}{100} dv. \end{aligned}$$

All types of firm T sell with probability 1 if $b \geq v$. Hence, in the first term, a χ -cursed firm A believes that with probability $(1 - \chi)$ firm T will accept and with probability χ it plays the average strategy $\bar{\sigma}_T = \frac{b}{100}$. But when $b < v$ it knows that with probability $(1 - \chi)$, firm T will not buy (i.e., choose the action $s_T = 0$) and with probability χ it plays the average strategy $\bar{\sigma}_T = \frac{b}{100}$. In each case, the payoff to firm A is $\gamma v - b$ if the bid is accepted.

Example 13.25 [100VT game and shifted 100VT game; Charness and Levin, 2009]: Consider the Takeover game in Example 13.24. Modify it to eliminate firm T in a robot design as follows. A single decision maker, firm A, chooses a bid, b , and then chooses one of 100 cards, numbered 1–100, that are placed face down on a computer screen. If the bid is at least as great as the number, v , on the card, then firm A gets $1.5v - b$ (i.e., $\gamma = 1.5$). Otherwise, the bidder gets zero. The rational bid can be found as in (13.103) and, since $\gamma \leq 2$, it equals $b^r = 0$. The equilibrium bid in a cursed equilibrium maximizes (13.104), so $b^c = 37.5$. Averaging across all 100VT experiments in Charness and Levin (2009), the prediction of the cursed equilibrium is close to the actual values in experiments. Charness and Levin (2009) also consider the shifted 100VT game in which the value of firm T, lies uniformly in the interval $[20, 120]$. In this case, the cursed equilibrium is given by the solution to

$$b^c \in \arg \max \int_{20}^{120} [1.5v - b] \frac{b}{100} dv.$$

A simple calculation shows that the solution is $b^c = 52.5$. This is consistent with the experimental results of Charness and Levin (2009). One might wonder if the robot design in which other players are absent (and so beliefs about other players are absent), is a valid application of a cursed equilibrium? Charness and Levin (2009) interpret Eyster and Rabin's (2005, p. 1632) cursed equilibrium to imply that "in a less literal sense, the notion of cursed equilibrium is not that each player is certain that every other player's action does not depend on her type but rather that they don't look for the correlations this mechanism implies." Crawford et al. (2013, p. 33) disagree with this view. They write: "However, we doubt that such mechanical generalizations would be empirically very useful, because we suspect people use different cognitive routines in games against real other players than in decision problems based on theoretical other players."

Example 13.26 [2VT game; Charness and Levin, 2009] This problem reduces the complexity of the Bayesian updating process in the Takeover game to minimize the scope of other explanations that rely on bounded rationality. Suppose that the value of firm T is equally likely to be 0 or 99 and $\gamma = 1.5$. A rational bidder knows that a bid $b \geq 99$ will be accepted with probability 1 and a bid $0 \leq b < 99$ will be accepted with probability $1/2$. Thus, his expected payoff from bidding $b = 99$ is $\frac{1}{2}(1.5 \times 99 - 99) + \frac{1}{2}(1.5 \times 0 - 99) = -24.75$, while from bidding $b = 0$ it is $(1.5 \times 0 - 0) = 0$. Hence, the rational bid $b^r = 0$.

Suppose that the bidder is fully cursed, so $\chi = 1$. Such a bidder imagines that any bid $b < 99$ is accepted with probability 0.5, the average action of the two likely types of firm T. There is no point in bidding above 99, so by bidding $b = 99$ his payoff is $-24.75 < 0$. On the other hand when he decides to bid below 99, then there is no point in bidding anything more than zero, so his payoff in this case is $\frac{1}{2}(1.5 \times 99 - 0) + \frac{1}{2}(1.5 \times 0 - 0) = 74.25 > 0$. Hence, a fully cursed bidder bids zero, so $b^c = 0$. In this case, the cursed bid coincides with the rational bid. Averaged across the experimental sessions over 60 periods, the experimental results of Charness and Levin (2009) show that between 30–60% of the bids are zero, reducing the extent of the winner's curse relative to the 100VT treatment. The average bid was, however, relatively

Figure 13.37 Actual and fitted bids as a function of the signals.

Source: Eyster and Rabin (2005) with permission of The Econometric Society.

higher in the 2VT design implying that subjects lose money when the rationality requirement is relaxed.

Avery and Kagel (1997) consider two-bidder, second price, common value auctions. The value of the object is not known but each bidder privately receives a signal z_i drawn uniformly from the interval $[1, 4]$. The value of the object to each bidder is $v = z_1 + z_2$. It can be shown that a χ -cursed bidder bids $b_i(z_i) = 2.5\chi + (2 - \chi)z_i$. When $\chi = 0$, $b_i(z_i) = 2z_i$ and when $\chi = 1$, $b_i(z_i) = 2.5 + z_i$, where 2.5 is the average signal of the other player. Figure 13.37 shows a plot of b_i versus z_i for experienced subjects⁹¹ that is much closer to the theory's prediction relative to the plot for inexperienced subjects. Figure 13.37 also shows the various predictions of the model for $\chi = 0, 1, 2$ as well as an OLS fitted curve. Recall that the case $\chi = 0$ gives the Bayesian Nash equilibrium; this is shown as the bold curve in the figure.

In general there is no presumption that cursedness alone explains the bidding behavior of subjects in experiments. The behavior of subjects is much richer than can be explained by cursedness alone. For instance, some subjects play weakly dominated strategies, there appears to be heterogeneity in cursedness across subjects, and subjects play with significant noise around the predicted cursed equilibrium strategies. Relative to inexperienced subjects, experienced subjects are less likely to play weakly dominated strategies and they exhibit lower heterogeneity. However, in both cases, focusing on the Bayesian Nash equilibrium ($\chi = 0$), subjects bid above their best response for low signals and below their best response for high signals. Such behavior is better explained when bidders are cursed, $\chi > 0$. The best fitting value of χ , assuming that subjects play normally distributed noisy best responses is 0.63. In sum, while cursedness alone cannot explain the experimental data on auctions, it fits better than a Bayesian Nash equilibrium.

⁹¹ These are subjects who have experience of 7 practice rounds and 18 actual rounds of the experimental game.

13.8.4 A level- k explanation of the winner's curse

Crawford et al. (2009) and Crawford and Iriberri (2007b) give a level- k analysis of the auction of a single unit of an object with two risk-neutral bidders.⁹² The valuation of each bidder, v_i , $i = 1, 2$, is private information. Each v_i is independently and identically distributed with distribution function $F(v)$ and density $f(v)$. It is useful to distinguish between the two cases of increasing and decreasing densities, subscripted by the alphabets I and D respectively. The increasing density case is given by

$$F_I(v) = v^\gamma; f_I(v) = \gamma v^{\gamma-1}; v \in [0, 1]; \gamma > 1. \quad (13.105)$$

The assumption $\gamma > 1$ ensures that the density is increasing in v . The decreasing density case is given by

$$F_D(v) = \frac{\beta}{\beta - \alpha} \left(1 - \frac{\alpha}{v}\right); f_D(v) = \frac{\alpha\beta}{(\beta - \alpha)v^2}; v \in [\alpha, \beta]; 0 < \alpha < \beta. \quad (13.106)$$

It is obvious that $f'_D(v) < 0$. To derive the benchmark results for the case of fully rational bidders, we first check for Myerson's (1981) *regularity condition*, which requires that $v - \frac{1-F(v)}{f(v)}$ is increasing in v (Fudenberg and Tirole, 1991). For the two cases in (13.105), (13.106), we have

$$v - \frac{1 - F_I(v)}{f_I(v)} = \frac{(1 + \gamma)v}{\gamma} - \frac{1}{\gamma v^{\gamma-1}} \text{ and } v - \frac{1 - F_D(v)}{f_D(v)} = \frac{v^2}{\beta}.$$

Noting that $\gamma > 1$, the distributions satisfy the regularity conditions in both cases. Myerson (1981) showed that if the regularity conditions hold, then the first price auction belongs to the class of optimal mechanisms. For this reason, we will now focus on first price auctions only. We begin by stating the results for the case of fully rational bidders; the proof is omitted because it is standard and readily available (Myerson, 1981; Krishna, 2010). Denote the bids in the increasing and the decreasing density cases by B and b respectively; a superscript star denotes the optimal bid.

Proposition 13.45 (Fully rational bidders benchmark; Crawford et al., 2009):

- (a) *Increasing density case: Consider a first price auction with a reserve price $\rho \in [0, 1]$. For any realization of value $v \geq \rho$, the optimal bid is given by*

$$B^*(v) = \frac{\rho^{1+\gamma}}{(1 + \gamma)v^\gamma} + \left(\frac{\gamma}{1 + \gamma}\right)v. \quad (13.107)$$

And the optimal reserve price is $\rho^* = (1 + \gamma)^{\frac{-1}{\gamma}}$.

- (b) *Decreasing density case: Consider a first price auction with a reserve price $\rho \in [\alpha, \beta]$. For any realization of value $v \geq \max\{\alpha, \rho\}$, the optimal bid is given by*

$$b^*(v) = \frac{v}{v - \alpha} [\rho - \alpha + \alpha (\ln v - \ln \rho)]. \quad (13.108)$$

And the optimal reserve price is $\rho^* = \alpha$.

⁹² We omit here an analysis of *zero-sum betting*. In such games, classical theory predicts that we should not observe any trade. Yet, experimentally, one observes a great deal of trade (Brocas et al., 2014). See Section 5 in Crawford et al. (2013) for more details on a level- k explanation of this phenomena based on a random specification of type L0 players that is independent of the realization of private information of other players.

With the benchmark results in place we can now undertake a level- k analysis of the first price auction model in the two cases, increasing and decreasing densities. It is not clear, a priori, how one might proceed to model the actions of the type L_0 players. Crawford et al. (2009) specify two possibilities.

1. Random L_0 : In this case, type L_0 players simply choose their bids randomly over the relevant support, and any L_k type, $k \geq 1$, is called a “random L_k type.”
2. Truthful L_0 : In this case, type L_0 players truthfully bid their valuations, and any higher L_k type, $k \geq 1$, is called a “truthful L_k type.”

Denote the bid by a type L_k player in the increasing and the decreasing density cases, respectively, by B_k and b_k , with a superscript star denoting an optimal value. For exposition purposes we shall assume that there are only two types of level- k players L_1 and L_2 . Thus, players of type L_0 exist only in the minds of type L_1 players as a model of the type of other players.

THE INCREASING DENSITY CASE WITH LEVEL- k PLAYERS

(a) Random L_k players: Random L_0 types choose their bid, B_0 , uniformly over the interval $[\rho, 1]$, $\rho \geq 0$; bidding over $[\rho, 1]$ appears consistent with the data rather than bidding over $[0, 1]$, hence, this is part of the specification of type L_0 players in the model. If the valuation, v , is lower than the reserve price, ρ , for any of the higher types, they will not bid a positive amount.

Type L_1 players believe that other bidders are of type L_0 . Thus, the perceived probability that the bid B_1 made by a type L_1 player wins is $\frac{B_1 - \rho}{1 - \rho}$. Given that the payoff of type L_1 is his private valuation, v , minus his bid, B_1 , the optimal bid of type L_1 solves the following expected utility problem.

$$B_1^* \in \arg \max \left(\frac{B_1 - \rho}{1 - \rho} \right) (v - B_1).$$

Thus, the optimal bid for a type L_1 player is

$$B_1^* = \frac{\rho + v}{2} \geq B^*(v). \quad (13.109)$$

Since we assume that $v \geq \rho$, so $B_1^* \geq \rho$. A type L_2 bidder believes that the other bidder is of type L_1 who bids according to (13.109). Hence, the probability that the bid of type L_2 , denoted by B_2 , wins, is $\Pr(B_2 \geq B_1^*)$. Using the fact that v is distributed over $[0, 1]$ with distribution function $F_1(v) = v^\gamma$, gives $\Pr(B_2 \geq B_1^*) = \Pr(B_2 \geq \frac{\rho + v}{2}) = \Pr(2B_2 - \rho \geq v) = (2B_2 - \rho)^\gamma$. Hence, the optimal bid of type L_2 , B_2^* , solves:

$$B_2^* \in \arg \max (2B_2 - \rho)^\gamma (v - B_2).$$

Solving the first order condition and noting that bidders will not bid if $v < \rho$, we get

$$B_2^* = \max \left\{ \rho, \frac{\gamma}{1 + \gamma} + \left(\frac{\gamma - 1}{1 + \gamma} \right) v \right\} \leq B^*(v).$$

Thus, type L_2 players underbid relative to the fully rational prediction.

(b) Truthful L_k players: We omit the results here as an exercise for the reader. The bids are typically greater than the fully rational bids, which is consistent with the winner's curse.

THE DECREASING DENSITY CASE WITH LEVEL- k PLAYERS

In this case, the distributional assumptions are given in (13.106). When the valuation exceeds the reservation price, $v \geq \rho$, the equilibrium bids of players are computed as follows.

(a) Random L_k players: In order to facilitate comparison with the fully rational case, assume, as in Proposition 13.45, that $\rho \in [\alpha, \beta]$. Random L_0 types choose uniformly over the interval $[\rho, \beta]$, $\rho \geq \alpha$. Type L_1 players believe that the other bidder is of type L_0 , thus, for any bid they make, B_1 , their probability of winning is $\frac{B_1 - \rho}{\beta - \rho}$. The optimal bid of a type L_1 player, $\rho \leq B_1^* \leq \beta$ can be solved from

$$B_1^* \in \arg \max \left(\frac{B_1 - \rho}{\beta - \rho} \right) (v - B_1).$$

The optimal solution is

$$B_1^* = \frac{v + \rho}{2} \geq b^*(v), \quad (13.110)$$

where the optimal rational bid $b^*(v)$ is defined in (13.108).

Type L_2 players bid an amount B_2 and they believe that the other bidder is of type L_1 who bids according to (13.110). $\Pr(B_2 \geq B_1^*) = \Pr(2B_2 - \rho \geq v)$. Hence, using (13.106), the expected profits of a type L_2 are given by

$$\frac{\beta}{\beta - \alpha} \left(1 - \frac{\alpha}{(2B_2 - \rho)} \right) (v - B_2). \quad (13.111)$$

When $v \geq \rho$, the bid which maximizes (13.111) such that $B_2 \in [\rho, \beta]$ is given by

$$B_2^* = \frac{\rho}{2} + \frac{\alpha}{2} \sqrt{\frac{2v - \rho}{\alpha}} \geq b^*(v), \quad (13.112)$$

where $b^*(v)$ is defined in (13.108). From (13.110), (13.112), the bids by both types of players exceed the fully rational bids. This is consistent with the winner's curse.

(b) Truthful level- k players: We leave this case as an exercise. The main results are similar to the increasing density case.

In the decreasing density case, level- k players overbid relative to the fully rational players because their beliefs are anchored on the play of type L_0 players. Type L_0 players bid uniformly, thus, higher types overestimate the probability of high valuations relative to the actual density (which is decreasing). The intuition for underbidding in the increasing density case is simply the converse of this.

Charness and Levin (2009) test the level- k model and the cursed equilibrium model; these are jointly lumped by them as *belief-based models*. Consider, for instance, the 100VT and the 2VT experiments described in Examples 13.25, 13.26 above. In these games, a bidder faces a computer. Suppose that the bidder imagines the computer to be a type L_0 player and that the bidder is a type L_1 player in a 100VT or 2VT game. Then he believes that the opponent will choose each of her two actions (accept or reject bid) with equal probability, irrespective of the size of the bid. Hence, it is optimal to bid zero. We also saw in Example 13.26 that the cursed bid was also zero in this case. Thus, the level- k models and the cursed equilibrium models cannot explain the winner's curse in these experiments. Charness and Levin (2009) suggest that the winner's curse is caused

by cognitive processes that are not a feature of these two belief-based models. Thus, for instance, the winner's curse is lessened in their experiments when one moves from the 100VT treatment to the less cognitively challenging 2VT treatment. Other such cognitive factors that impact on the degree of the winner's curse in their experiments include the amount of information and instructions provided to subjects in experiments.

Ivanov et al. (2010) provide experimental evidence that casts doubt on belief-based models (they consider cursed equilibrium, level- k , and QRE models). They introduce the maximal game, which is a second price common value auction with n players. Each player in this game receives an iid signal, $x_i \in [0, 10]$, about the common value, V , of the object. The objectively correct common value is the highest value of the signal received, i.e., $V = \max_{i=1}^n x_i$. Players submit simultaneous bids, b_i , and the winner pays the second highest bid. Players can either underbid, $b < x$, overbid $b > x$, or bid the value of their own signal, $b = x$.

Starting from $b < x$ suppose that a bidder raises his bid to $b = x$. Suppose all other players bid equal to their signals, then (1) if at $b < x$ the bidder won the object, then he would still win it and pay the same price (second highest bid), and (2) if at $b < x$ the bidder does not win the object, then he receives a zero payoff. By raising the bid to $b = x$, there is some probability that he will win the object and receive a positive payoff. Hence, underbidding is weakly dominated by $b = x$ for any player. Analogously, the reader can check that $x < b \leq 10$ is also weakly dominated by $b = x$. Thus, bidding one's received signal, i.e., $b_i = x_i$ for all i is a Nash equilibrium in the maximal game; in fact it is the unique equilibrium.

The experimental results of Ivanov et al. (2010) show that the largest proportion of bids satisfies $x < b \leq 10$. Hence, there is a winner's curse. To check for the importance of beliefs, the authors run the experiments in two parts. In part I, bidders participate in two-player bidder auctions (where they suffer from the winner's curse). In part II, they play against a computer that plays according to the bid function of the same individual in part I. So, if the individuals are responding to beliefs, they should realize that they are playing against someone who overbids relative to the signal. Winning against such an individual conveys even worse news. So bids should either stay the same or come down. The experimental results show that individuals do not revise their bids downwards, continuing to bid in a manner that is similar to their bids in part I.

The authors conclude that their results cast doubts on belief-based models of auctions. However, this conclusion has been robustly challenged. Ivanov et al. (2010) select only a subset of subjects whose data is analyzed, based on a selection criterion. Costa-Gomes and Shimoji (2011) raise concerns over the subset of subjects whose data is analyzed. When they analyze the data for all subjects, they find that the overbidding in the part II result is relevant for only a third of the subjects; for half of these subjects, the data is in conformity with belief-based models. A similar method—non-exclusion of subjects—is also employed by Camerer et al. (2012) to re-analyze the data in Ivanov et al. (2010). They find strong support for belief-based models that include cursed equilibrium and cognitive hierarchy models. Furthermore, Crawford et al. (2013, p. 34) raise the objection that the Ivanov et al. data is very noisy with very low signal to noise ratio that can be used to reject any theory.

Crawford and Iriberri (2007b) run a three-horse race between level- k models, cursed equilibrium, and QRE using auction data from three datasets. These datasets are the first and second price common value auctions in Kagel and Levin (1986) and Avery and Kagel (1997), and the independent private values auctions in Goeree et al. (2002) (respectively KL, AK, and GHP). Their interest was in examining data from the early rounds of play.⁹³ Players are assumed to play with logistic noise; both subject-specific and type-specific noise is allowed.

⁹³ For instance, they used the data from AK for inexperienced subjects, while the Eyster and Rabin (2005) results that we examined above, based on the same dataset, were for experienced subjects.

The type distribution of level- k players is fairly stable across the three datasets, particularly when subject-specific noise is considered. This is true to a lesser degree under type-specific noise. With a few exceptions,⁹⁴ the frequency of level- k types is comparable to earlier research (see Section 13.4.5). The frequency of type $L0$ players was quite low—4% in KL first price auctions and 0% in AK second price and GHP first price auctions. For the GHP data with subject-specific noise, level- k models fit the data much better than QRE and can account for some of the deviations from equilibrium that GHP explain by invoking other factors such as “joy of winning” and “risk aversion.”

Interesting, for KL first price and AK second price auctions, when a cursed equilibrium model is used, the Eyster and Rabin (2005) results for experienced subjects are quite similar to the Crawford and Iriberri (2007b) results for inexperienced subjects. Different types of cursed subjects are estimated from the data assuming that $\chi \in [0, 1]$ and types go up in increments of 0.1. There are spikes in the data for estimated cursed types at $\chi = 0$ (equilibrium play) and $\chi = 1$ (fully cursed types). There is a roughly even distribution of types in between (except for spikes at $\chi = 0.2$ in KL second price and $\chi = 0.7$ in AK second price). Except for KL first price auctions, the level- k models fit the data better than cursed equilibrium models.

⁹⁴ In particular, in the KL second price auctions, the estimated frequency of type $L1$ players is too low (21%) and that of type $L2$ is too high (32%), relative to earlier estimates. The authors provide likely explanations for why this might be the case.

Exercise for Part 4

- Recall our discussion of the findings of the two-player game in Beard and Beil (1994) in Section 12.2.1. Goeree and Holt (2001) replicate their findings for an extensive form game shown in Figure 12.1, but with different payoffs as shown in Table 4.E1, which also gives a summary of the results from their replication (q is the actual probability with which a player 2 responds to player 1's choice of R).
 - Recall that p is the conditional probability (in the mind of player 1) of the play of r by player 2, following the play of R by player 1. Compute the threshold probability p_c such that for probabilities greater than p_c , it is optimal for player 1 to play R.
 - Interpret the results in Table 4.E1 and compare these findings to those of Beard and Beil (1994).

Table 4.E1 Goeree and Holt's replication of the Beard–Beil (1994) findings.

Treatment	Numbers of pairs	Payoffs from various strategy combinations			% of Player 1s choosing strategy L	q
		L, l and L, r	R, l	R, r		
1	25	70, 60	60, 10	90, 50	12	1.00
2	25	70, 60	60, 48	90, 50	32	0.53
3	15	80, 50	20, 10	90, 70	13	1.00
4	25	80, 50	20, 68	90, 70	52	0.75
5	25	400, 25	100, 348	450, 350	80	0.80

- (Sefton and Yavas, 1996). Consider the following symmetric two-player strategic form game:

	R	B
R	960, 960	960, 0
B	0, 960	1200, 1200

As in Section 12.2.4, consider an implementation of the strategy profile (B, B) through the Abreu–Matsushima mechanism. Consider three values of T : $T = 4$, $T = 8$, and $T = 12$. The fine is set at $F = 160$. Which of the three cases is implementable with this level of fine? The results in these three cases are shown in Figure 4.E1 with the percentage of all-B play plotted along the vertical axis. Interpret the results.

- Consider the following game from Goeree and Holt (2001).

	Left (26%)	Middle (8%)	Non-Nash (68%)	Right (0%)
Top (68%)	200, 50	0, 45	10, 30	20, -250
Bottom (32%)	0, -250	10, -100	30, 30	50, 40

Figure 4.E1 Percentage of (B, B) choices in various rounds.

Payoffs in the table are in cents and the percentage of row and column players who play each of the strategies is shown in brackets, next to each strategy.

- (a) Find all the Nash equilibria in the game. Why is the majority choice of strategy for the column players, Non-Nash, problematic for a Nash equilibrium?
 - (b) How can the strategy Non-Nash be explained as a maximin choice?
 - (c) How can we rule out loss aversion as a possible explanation of the observed play?
4. (Goeree and Holt, 2001) Consider the sender–receiver game in Table 4.E2. The sender has two possible types, A, B, each with a prior probability of 1/2. The receiver observes the sender's message, either Left, L, or Right, R, and then chooses one of three actions C, D, or E.
- (a) The experimental results indicate the presence of the following outcome. Type A senders send R and type B senders send L. The receivers always play C. Show how this separating equilibrium can be explained by the senders using the *principle of insufficient reason*, namely, that they think each response of the receiver is equally likely.
 - (b) A second possible equilibrium of this game is a pooling equilibrium. In this equilibrium, each sender sends the message L. On receiving a message L, the receiver plays C and on receiving the out-of-equilibrium message R, the receiver plays D. However, the experimental evidence in (a) indicates that the separating equilibrium was played. Does

the pooling equilibrium in (b) survive the Cho and Kreps (1987) intuitive criterion? What can you conclude about the plausibility of the pooling criterion?

(c) Now consider the following change to the payoff matrix. The outcome 500,500 in the southeast corner of the payoff matrix is replaced by 300,300. The experimental results are that 10 of the 13 type A senders choose R and 9 of the 11 type B senders choose L. Hence, we seem to have a separating equilibrium. Is such a separating equilibrium also a perfect Bayesian Nash equilibrium (PBE) in classical game theory? If not then construct a PBE for this game. Are the experimental results consistent with your constructed equilibrium?

5. Consider the Van Huyck et al. (1997) continental divide game in Section 12.4.9. The payoffs are given in (12.7) and the payoff matrix is described in Table 12.17.

(a) Show that the results given in Figure 12.19 can be explained by either of the following two models. (i) A model of myopic best response dynamics in which players play a best response to the observed median in the previous period. (ii) A model of fictitious play (see Part 5 for details) in which players best respond, given the observed frequency of the medians so far. So if the j^{th} median value, M_j , has occurred f_j times, then player i maximizes the following payoff function

$$\sum_j f_j \pi(s_i, M_j),$$

where the payoff function $\pi(s_i, M_j)$ is defined in (12.7).

(b) Show that the myopic best reply dynamics converge within 5 time periods, while the fictitious best reply dynamics converge within 22 periods.

6. Prove Proposition 12.16.
 7. (Jung et al., 1994) Prove Proposition 12.18.
 8. Verify the equilibria claimed in experiments H and J in Table 12.29.
 9. Consider the three two-player games from Goeree and Holt (2001) shown in Figure 4.E2. Five cohorts of ten subjects were randomly matched to play these games. The percentage of players choosing a particular action in each game is shown in brackets, next to the strategy.
 (a) What is the mixed strategy equilibrium for the symmetric matching pennies game? Do you think that the subjects' choices are consistent with this equilibrium?

Symmetric matching pennies game		
	L (48%)	R (52%)
T (48%)	80, 40	40, 80
B (52%)	40, 80	80, 40
Asymmetric matching pennies game		
	L (16%)	R (84%)
T (96%)	320, 40	40, 80
B (4%)	40, 80	80, 40
Reversed asymmetry		
	L (16%)	R (84%)
T (96%)	320, 40	40, 80
B (4%)	40, 80	80, 40

Figure 4.E2 Three simple strategic form games and the choices of players.

Source: Reprinted from *American Economic Review* 91(5): 1402–22. Goeree, J. K. and Holt, C. A. "Ten little treasures of game theory and ten intuitive contradictions." Copyright © 2004, with permission from Elsevier.

(b) Now consider the next two games. The only difference in these games from the symmetric matching pennies game is that the row player's payoff from the strategy profile (T, L) changes (to 320 and 44 respectively). Notice that the column player's payoffs have not altered. What is the new equilibrium prediction? Is the data consistent or inconsistent with classical game theory?

10. Prove Proposition 12.23.
11. Prove Proposition 12.24.
12. (Goeree et al. 2005) Consider the asymmetric matching pennies game in Figure 4.E3 in which $x \geq -1$.

	L	R
U	$x, -1$	$-1, 1$
D	$-1, 1$	$1, -1$

Figure 4.E3 An asymmetric matching pennies game in Goeree et al. (2005).

Label the row player and the column players, respectively, as player 1 and player 2. Denote the probability with which the row player plays U by π_{1U} and the probability with which the column player plays L by π_{2L} .

- (a) Suppose that $x \geq 1$. Denote a regular QRE by (π_{1U}^*, π_{2L}^*) . Derive the conditions on (π_{1U}^*, π_{2L}^*) that are required for a regular QRE.
- (b) Suppose that $-1 < x < 1$. Denote a regular QRE by (π_{1U}^*, π_{2L}^*) . Derive the conditions on (π_{1U}^*, π_{2L}^*) that are required for a regular QRE.
- (c) In (π_{1U}, π_{2L}) space, draw the relevant regions that satisfy the restrictions of a QRE for the two cases: (i) $x = 9$, and (ii) $x = 1$. In the same diagram also indicate the points corresponding to a Nash equilibrium and to random play.
- (d) Show that in a regular QRE, the probability with which the row player plays U is increasing in x and the probability with which the column player plays D is decreasing in x .
13. Consider the properties of responsiveness and monotonicity required for a *regular quantal response function* (Definition 13.8). Consider a decision problem in which there is only one player, player 1, and there are only two actions, s_{11} and s_{12} . Using (13.5), (13.6), the probability that player 1 plays strategy s_{11} is $\pi_{11} = \Pr[\bar{u}_{11} + \varepsilon_{11} \geq \bar{u}_{12} - \varepsilon_{12}] = G(\bar{u}_{11} - \bar{u}_{12})$, where G is the distribution function of $\varepsilon_{12} - \varepsilon_{11}$ and $\bar{u}_{1j}, \varepsilon_{1j}$ are, respectively, the mean payoff and the errors arising from the play of strategy $s_{1j}, j = 1, 2$.
 - (a) Suppose that $G'(x) > 0$ for all x and $G(0) = 3/4$. What can we conclude about the responsiveness and monotonicity of the regular quantal response function?
 - (b) Suppose that $G(x) < 0.5$ for $x < 0$ and $G(x) > 0.5$ for $x > 0$ and there exists some interval $[x_1, x_2] \subset [0, 1]$ over which $G'(x) < 0$. What can we conclude about the responsiveness and monotonicity of the regular quantal response function?
14. Prove part (ii) of Proposition 13.26.
15. (Crawford et al., 2013) Consider the following pursuer–evader game known as the Far Pavilions game. The column player is pursuing the row player (the evader). Each player must simultaneously choose the action, head North (N) or South (S). The payoff matrix is shown in Figure 4.E4. The South route is the easier of the two. If both players head in the same direction, then the row player is caught and has a negative payoff. The payoff is more

	S	N
S	-1, 3	1, 0
N	0, 1	-2, 2

Figure 4.E4 The Far Pavilions Game.

Source: Crawford et al. (2013) with permission from the American Economic Association.

negative when both players head North because of the more difficult route. If both players head in different directions, then the row player gets a non-negative payoff. We wish to consider the wisdom of the following recommendation made by a “mentor” to the row player: “ride hard for the north, since they will be sure you will go southward, where the climate is kinder.”

- (a) Show that the game has a unique mixed strategy Nash equilibrium in which the probability of the mentor’s recommended outcome (N,S) being played out is $9/16$.
 - (b) Show that the recommendation of the mentor to the row player is equivalent to the optimal response of a $L3$ player when the anchoring type $L0$ player randomizes equally between N and S.
 - (c) Suppose that the frequency of types $L0$, $L1$, $L2$, and $L3$ players is respectively 0, 50, 30, and 20. Show that the probability of the outcome (N,S) being played is $2/5$ when the anchoring type $L0$ chooses uniformly randomly between N and S. How does this compare with a situation where (i) all players choose uniformly randomly between their strategies, and (ii) all players play the mixed strategy Nash equilibrium in part (b)?
16. (Crawford and Iriberri, 2007b) Consider the class of zero-sum games in which one player wins by matching actions with the other player, while the other player wins by mismatching actions. Figure 4.E5 shows a zero-sum game of hide-and-seek from Rubinstein (1999).

A hider hides some prize in one of the four boxes marked either A or B, which are ordered as shown in Figure 4.E5. The seeker does not know which box the prize is hidden in. Which box should the hider choose to hide the prize in? Which box should the seeker choose to open? If the seeker guesses the correct box, he gets 1 and the hider gets zero. Otherwise the hider gets 1 and the seeker gets zero.

- (a) Draw the normal form of the game and show that the game has a unique mixed strategy equilibrium. Show that seekers are at a disadvantage in this equilibrium because they can find the prize only 24% of the time.
- (b) Notice that the boxes marked A at both ends are salient/focal. The central box marked B is also salient because it is the only box not marked A. Hence, central A is the least salient location. From experimental results in Rubinstein et al. (1996), central A is a strongly modal choice. Hiders choose central A about 37% of the time and seekers choose to look in it about 46% of the time. Thus, in the experimental results, seekers are able to find the prize much more often than the equilibrium prediction in (a). What should a classical game theorist conclude?

**Figure 4.E5** A zero-sum game of hide-and-seek.

(c) Consider now the explanation of the results in Crawford and Iriberri (2007b) in terms of the level- k model. Each player (hider and seeker) has one of five possible types, $L0, L1, L2, L3, L4$. It does not make sense to assume that type $L0$ (whether hider or seeker) chooses each box with the same probability. The reason is that the labels on the box are an example of non-neutral framing. Suppose, therefore, that type $L0$ chooses the boxes with the following probability. The two end boxes are each chosen with a probability $\frac{p}{2}$, $p > \frac{1}{4}$. The central B box is chosen with a probability $q > \frac{1}{4}$, while the central A is chosen with a probability of $1 - p - q$. Thus, type $L0$ favours the salient locations: end As and the central B. Derive the optimal response of each type ($L0, L1, L2, L3, L4$) of each player (hider and seeker). Is this model able to explain the modal choice of central A for hiders and seekers when the percentages of the types $L0, L1, L2, L3, L4$ are respectively, 0, 19, 32, 24, 25?

(d) Can a quantal response equilibrium explain the modal choice?

17. (Crawford, 2007) Consider the BOS game shown in Figure 13.12 and its analysis in Section 13.4.2 with one round of communication. Make the following amendment to the preplay communication round. Instead of one round of communication, assume now that there are as many rounds of communication as players wish to have (abundant communication). Players in the preplay round simultaneously exchange messages. If they both decide to continue for another round of message exchange they can. However, if one or both players decide to terminate this round, then they choose their respective actions in the BOS game. Assume that players do not draw any inferences about the type of their opponent from the history of message exchange and there is a slight cost of continuing for an extra round of communication. Assume that $a < 2$. Show that with these assumptions, the outcome matrix is as in Proposition 13.31. What do you think happens when $a > 2$?
18. (Ellingsen and Östling, 2010) Derive the analogue of Proposition 13.32 when there is two-way communication in the preplay communication stage and both senders and receivers simultaneously exchange messages. Show that in this case, there is mis-coordination in half the cases when two type $L1$ players meet.
19. (Camerer et al., 2004a) Consider the following stag-hunt game that examines the effect of changes in group size. There are n players who simultaneously choose one of two strategies, L or H. The group choice is H if all players choose H. Otherwise, i.e., if at least one player chooses L, then the group choice is L. The payoffs of any player (row player) against the group average (column player) are shown in Figure 4.E6 and $0 < x < 1$. Thus, for instance, a player receives a payoff of x when he plays L and the group plays L. The Pareto optimal choice is for all players to play H.
 - (a) Consider a two-player stag-hunt game ($n = 2$). Show that if $x < 0.5$, type $L1$ players choose H, otherwise they choose L. Show that any type Lk player, $k > 1$, also behaves exactly like a type $L1$ player.
 - (b) Consider a three-player stag-hunt game ($n = 3$). Show now that type $L1$ players choose H if and only if $x \leq 0.25$ and L otherwise.

	L	H
L	x	0
H	0	1

Figure 4.E6 Payoffs in the n -player stag-hunt game. The column player represents the group average and the row player is any of the n players.

- (c) The experimental results of Van Huyck et al. (1990) show that an increase in group size reduces coordination. Is this consistent with the predictions of the level- k model for the n player stag-hunt game?
20. (Camerer et al., 2004a) Consider game 4 from Binmore et al. (2001) shown in Figure 4.E7. Each of the row and the column players has three strategies.
- (a) Show that the game has a mixed strategy equilibrium in which the row player plays B with probability 0.67 and the column players play R with probability 0.67.
- (b) Show that the predictions of a CH model (see Section 13.3.3) with, say, $\tau = 1.5$, are consistent with the experimental finding of the play of R by 83% of the players.
- (c) The experimental finding is that only 28% of the row players play their part of the Nash strategy profile, B. Why is B not very plausible? In a Nash equilibrium, B is chosen because the column players choose R and strategies and beliefs have to be mutually consistent. Show that the CH model predicts a 25% choice of each of T and M; a prediction that is closer to the experimental findings, relative to the Nash equilibrium.

	L	C	R	data	Nash	CH fit
T	0, 0	2, -2	-1, 1	0.33	0.17	0.25
M	2, -2	0, 0	-1, 1	0.29	0.17	0.25
B	-1, 1	-1, 1	0, 0	0.28	0.67	0.50
data	0.13	0.04	0.83			
Nash	0.17	0.17	0.67			
CH fit	0.08	0.08	0.84

21. (Geanakoplos et al. 1989) Consider the confidence game in Example 13.13. Derive the psychological Nash equilibria in the game.
22. Consider the two-player game Hawk–Dove shown in Figure 4.E8 that was used in Rabin (1993) to illustrate the reciprocity equilibria in a single stage, simultaneous move game. The game is symmetric and each player has two strategies, Hawk (h) and Dove (d). Player 1 is the row player and player 2 is the column player, and $X > 0$ is a scaling factor. The game has two Nash equilibria, (h, d) and (d, h) . Modify the multistage model in Dufwenberg and Kirchsteiger (2004) (see Section 13.5.3) to a single stage in order to compute the psychological equilibria for this game.
23. Prove Proposition 13.36(iii), (iv).

	Hawk	Dove
Hawk	$-2X, -2X$	$2X, 0$
Dove	$0, 2X$	X, X

Figure 4.E8 A hawk–dove game.

Figure 4.E9 A Trust game in extensive form.

Source: Reprinted from *Journal of Economic Theory* 144(1): 1–35. Battigalli, P. and Dufwenberg, M. "Dynamic psychological games." Copyright © 2009, with permission from Elsevier.

24. (Battigalli and Dufwenberg, 2009) Consider the extensive form game shown in Figure 4.E9 (the payoff of the first player is listed first). In the unique backward induction outcome, player 1 plays Don't Trust and ends the game at the first node with the inefficient payoffs (1, 1).
- Now introduce the possibility of guilt. Let player 2 play Share with probability p . Let the first order beliefs of player 1 about p be denoted by b_1^1 and let the beliefs of player 2 about b_1^1 be denoted by b_2^2 . Suppose that guilt takes a particularly simple form. When player 2 plays Grab he faces a reduction in his material payoff by $5b_2^2$. Use a *psychological forward induction* argument to show how the efficient outcome with payoffs (2, 2) can arise [Hint: If player 1 plays Trust, what does this tell player 2 about the lower bound on b_1^1 ?].
25. Consider the results of Charness and Dufwenberg (2006) in Section 13.5.5. Can these results be explained by the following three classes of models?
- Models of inequity aversion, considered in Part 2 of the book, such as those by Fehr and Schmidt (1999), Bolton and Ockenfels (2000), and Charness and Rabin (2002).
 - Models of intentions-based reciprocity, considered in Chapter 13, such as those by Rabin (1993) and Dufwenberg and Kirchsteiger (2004).
 - Models in which there is a fixed cost of lying, such as the model by Gneezy (2005) considered in Part 2 of the book.
26. Prove Proposition 13.42.
27. (Jehiel, 2005) Consider the analogy-based expectations equilibrium (ABEE) of Jehiel (2005). Suppose that we have the two normal form games G1 and G2, shown in Figure 4.E10

	L	M	R	R'		L	M	R	R'
U	5, 2	0, 2	2, 4	0, 0	U	3, 0	4, 2	2, 0	1, 1
D	4, 3	3, 0	1, 0	2, 0	D	0, 2	5, 2	0, 0	2, 4
Game G1					Game G2				

Figure 4.E10 Two normal form games from Jehiel (2005).

Source: Reprinted from *Journal of Economic Theory* 123: 81–104. Jehiel, P. "Analogy-based expectation equilibrium." Copyright © 2005, with permission from Elsevier.

Here we have the following data for the row player (r) and the column player (c): $S_r = \{U, D\}$, $S_c = \{L, M, R, R'\}$, $G = \{G1, G2\}$ and $p(G1) = p(G2) = 0.5$. The analogy partition used by the column player is always fine, i.e., $\Pi_c = \{\{G1\}, \{G2\}\}$. However, the row player has a coarse partition, so $\Pi_r = \{\{G1, G2\}\}$.

Each of the games has a unique Nash equilibrium: (U, R) in game G1 and (D, R') in game G2. Show that in the ABEE of the game, the row player plays D in game G1 and U in game G2 and the respective strategies of the column player are L in game G1 and M in game G2. Does the row player benefit by having a finer partition $\Pi_r = \{\{G1\}, \{G2\}\}$?

28. Prove Proposition 13.44.
29. (al-Nowaihi and Dhami, 2015) This question relates to evidential games in Section 13.7.4. Consider the Nash demand game (Nash, 1950a, 1953). Two players share a cake of size one. Player 1 demands $x \in [0, 1]$ and player 2 simultaneously demands $y \in [0, 1]$. If the demands are feasible, i.e., if $x + y \leq 1$, then each player receives what she demanded. However, if the demands are not feasible, i.e., if $x + y > 1$, then each player gets 0. Any pair, (x, y) , such that $x + y = 1$ is a Nash non-cooperative equilibrium. Thus, the Nash non-cooperative equilibrium concept does not pin down a unique solution in the Nash demand game.
 - (a) Show that if we allow arbitrary social projection functions, then any outcome, (a, b) , such that $a + b = 1$, $a > 0$ and $b > 0$, is an outcome of a consistent evidential equilibrium for the Nash demand game for suitably chosen social projection functions.
 - (b) Show that $(\frac{1}{2}, \frac{1}{2})$ is the unique consistent evidential equilibrium for the Nash demand game under the identity social projection functions: $P_{12}(y|x) = 1 \Leftrightarrow y = x$ and $P_{21}(x|y) = 1 \Leftrightarrow x = y$.
30. Consider two risk-neutral bidders, i, j , participating in a first price sealed-bid auction for one indivisible unit of an object. Both bidders use expected utility to evaluate risky payoffs. Bidders have valuations v_i, v_j that are privately known. Each bidder knows that the valuation of the other is drawn from a uniform distribution $[0, 1]$. The distributions for v_i, v_j are independent and identical. If a bidder wins the object and pays a price p , then the utility of the bidder is $v_i - p$. Suppose that bidders simultaneously submit bids b_i, b_j and the one who makes a higher bid wins. In the event of a tie, both bidders get the object with a probability of $1/2$. The payoff of the loser is zero. We are interested in the Bayesian Nash equilibrium (BNE) of this static game of incomplete information. Consider equilibrium bidding strategies that are linear in one's valuation,

$$b_i(v_i) = \alpha_i + \beta_i v_i; \quad b_j(v_j) = \alpha_j + \beta_j v_j. \quad (4.E1)$$

Notice that in the BNE, we are required to determine the optimal bid for each type of the player; (4.E1) satisfies this requirement with each type of a player associated with a distinct valuation.

- (a) Show that in the unique BNE of the game,

$$b_i = \frac{v_i}{2}; \quad b_j = \frac{v_j}{2}.$$

Notice that unlike the English auctions and the second price auctions, one's optimal bids are below one's valuation.

- (b) Show that when the valuations are uniformly distributed, an equilibrium in linear bidding strategies as in (4.E1) exists and is unique.
- (c) Is the outcome of the first price auction efficient? ■
31. (Crawford et al., 2009)
 - (a) Consider the increasing density case with level- k players in the single price simultaneous bid auction with two risk-neutral players, as in Section 13.8.4. Thus, while the valuation

of each bidder is private information, bidders know the distribution of each other's possible valuations, which is given by (13.105). Show that for truthful level- k players, the bids of types $L1$ and $L2$ are identical and given by

$$B_2^* = \max \left\{ \rho, \left(\frac{\gamma}{1+\gamma} \right) v \right\} \leq B^*(v)$$

where $B^*(v)$ is the optimal rational bid as defined in (13.107) and B_2^* is the optimal bid of a type $L2$ player.

(b) Show that for the decreasing density case, given in (13.106), the optimal bids of types $L1$ and $L2$ are consistent with the winner's curse.

PART 5

Behavioral Models of Learning

INTRODUCTION TO PART 5

In neoclassical economics, one takes preferences as the primitives. Conditional on these preferences, economic actors choose the set of best elements from some well-defined choice set. For instance, consumers may engage in constrained utility maximization, and firms may engage in constrained profit maximization. However, this leaves open the question of the source of these preferences. It is also typical in economics to focus, unlike in biology and physics, mainly on equilibrium analysis. But equilibrium analysis often does not address the question of the time path to an equilibrium. Indeed the temporal learning behavior of economic agents may offer illuminating insights on what sort of equilibria, if any, are likely to be achieved. In Part 5 of the book we address these questions.

Part 5 is split into three chapters. In Chapter 14, we introduce *evolutionary game theory*, and use it to explore the source of human preferences with a focus on *other-regarding preferences* that is the subject matter of Part 2 of the book. In these models, learning typically takes place by random mutations at the level of the gene, as a response to changes in the environment.¹ In some sense, this may be considered the simplest model of learning that is relevant for human choice.

In evolutionary game theory, the animal's genes, or its *genotype*, determine its behavior, or its *phenotype*. In any given environment, the competing phenotypes have different degrees of success. In a Darwinian selection mechanism, more successful phenotypes have greater *fitness*, or reproductive success. Hence, they are more likely to proliferate in the next period. The currently dominant phenotype in the population may be termed as the *resident phenotype*. The basic question in evolutionary game theory is: Can the resident phenotype be invaded by any *mutant phenotype*? If not, then the resident phenotype is known as an *evolutionary stable strategy* (ESS). We provide the motivation for an ESS, and give the necessary criteria, the primary criterion and the secondary criterion, to check if a strategy is an ESS. We also show how the concept of ESS can be extended to asymmetric information about the types of players.

The concept of an ESS is silent about the underlying dynamics that give rise to the equilibrium. An important advance, the *replicator dynamics*, clarified the dynamic process underlying an ESS. The replicator dynamics captures, in a simple model, the idea that fitter phenotypes will have a higher growth rate in the population. We explore the properties of replicator dynamics, and derive the following nested structure. The steady states of replicator dynamics nest the set of Nash equilibria that in turn nest, sequentially, asymptotically stable states of replicator dynamics and ESS.

Within the framework of evolutionary game theory, we ask some fundamental questions. These questions include the following: Why do we observe prosocial human behavior such as altruism, and the desire to cooperate, and accept norms? Why do we observe reciprocity, and other-regarding preferences? If selfishness has higher fitness, how can altruism survive? How is *culture* transmitted across generations? Can self-regarding preferences be a stable outcome of an evolutionary social system?

¹ We omit a discussion of the relation between *molecular genetics* and economics, which supposes that the genetic endowment of individuals can explain the observed individual-level economic outcomes; for a recent survey see Benjamin et al. (2012).

We discuss the inter-generational transmission of culture through a model of *gene-culture co-evolution*. We also consider a range of explanations for prosocial behavior. These include: *kin selection* and *inclusive fitness*, *group selection* and *multilevel selection*, *reciprocal altruism* or *direct reciprocity*, *indirect reciprocity*, *repeated game considerations*, and the *indirect evolutionary approach*. Models of *social imitation* in which humans consciously choose their strategies based on simple principles of *social imitation* and *emulation*, can produce replicator-like dynamics. However, these results are not very robust to changes in the mechanics of social imitation.

One limitation of models of evolutionary game theory is that they cannot explain the rapid rate of learning in experiments because evolution, by its very nature, is a slow and conservative process. In Chapter 15 we explore the theory and empirics of human learning that is much faster relative to learning at the level of the gene. We shall focus on deterministic, and typically stationary, environments. This chapter also allows us to explore the claim that a Nash equilibrium is the product of some underlying learning mechanism. The results of the experiments provide, at best, mixed support for Nash equilibrium. However, in a large number of cases, too large for Nash equilibrium to be taken as the dominant equilibrium concept, play does not conform to a Nash equilibrium. We shall explore exciting new theoretical developments that have made an attempt to organize the learning data.

The most basic learning model that we consider is the *reinforcement model of learning*, also known as *stimulus learning* and *rote learning*. In this model, players begin with some *propensities* to play their pure strategies. They then observe the payoffs from their pure strategies, and update their propensities over time. Propensities are converted into probabilities of play of various strategies. The rationality requirements in this model are rather limited. Strategies that have led to higher payoffs in the past are played with a higher probability, i.e., these are *better replies* rather than *best replies* to the available information. The informational requirements are fairly limited too. Players do not need to know the structure of the underlying game, or even the number of other players, and their strategies.

We consider a wide variety of models of reinforcement learning. Some perform better than others in empirical tests. The main result from the empirical literature is that while reinforcement learning is good at predicting the direction of change, the predicted speed of learning is too sluggish. If the speed of adjustment is increased, then the model fails in other respects. Factors that are not predicted to affect individual choices under reinforcement learning, such as information on the payoffs of others, are often found to be important in experiments. Reinforcement learning is probably most effective when players have a limited understanding of the underlying structure of the game, and they have relatively low information.

A second class of models, models of *belief-based learning*, impose relatively greater rationality. In these models, players form beliefs about others and about the environment around them, and how these beliefs evolve over time. In an important subclass of this model, *fictitious play*, players assign some initial weights to the strategies of opponents, and update the weights as they temporally observe the strategies of the opponents. The relative weights are used to compute the expected probabilities of play of the opponent. The player then plays a best response to these expectations. A special case is *Cournot dynamics*. For 2×2 games, the limiting distribution of play in these models corresponds to a Nash equilibrium. But these results do not hold for 3×3 games.

Existing data does not produce a clear winner in the choice between belief-based models and reinforcement learning models. A range of other variables, not predicted by these theories, such as the optimization premium, and information on market conditions, or about other players, turn out to be important in experiments. Further, a variety of other learning mechanisms, such as imitate the best, learning direction theory, and trial and error learning are also empirically

important. Thus, fictitious play, by itself, is too simple to explain all relevant aspects of human learning.

It turns out that reinforcement learning and fictitious play are special cases of an overarching model, the *experience weighted attraction* (EWA) model. The EWA allows for the incorporation of regret from forgone payoffs, and the depreciation of past experience on account of limited memory, or forgetfulness. EWA also nests a range of other known models such as the Cournot model, *cumulative reinforcement model*, *weighted fictitious play*, and the *average reinforcement model*. The performance of the EWA model is superior to reinforcement learning, and fictitious play, even after taking account of its larger number of parameters.

A more parsimonious alternative to the EWA model is the one-parameter *functional* EWA model or fEWA or *EWA-lite*. The parameters in this model are *self-tuning* in the sense that they respond to changes in the environment. In one comprehensive comparison of the alternative models, based on seven different games, EWA and fEWA do better than reinforcement learning, weighted fictitious play, and quantal response equilibrium.

EWA and fEWA are models of *adaptive play* in the sense that players specify a rule that transforms the history of play into current actions. However, sophisticated players may wish to take account of the information about other players in a way that allows them to outguess others, and improve their payoffs. Such players may also wish to teach other players, and shepherd them in the direction of better payoffs. These are models of *anticipatory learning* and they are supported by the empirical evidence.

Learning direction theory aims to qualitatively predict the direction of change, rather than specify the probabilities with which players play their strategies. The basic theory predicts well the high degree of observed cooperation in repeated prisoner's dilemma game experiments and the direction of bid changes in auction experiments. The theory has been extended to allow for quantitative predictions of the probabilities of play. We consider a range of these extensions, including *impulse matching learning*, *impulse balance equilibrium*, *action-sample learning*, and *payoff-sampling learning*. The emerging evidence makes a strong case for taking these theories seriously, and in many cases, they outperform other standard theories of learning. As our final model in this class, we consider the explanation of the experimental results from *order statistic games*.

Individuals may have to learn in situations in which nature probabilistically draws a game from a set of games, and the *complexity of the learning environment* varies. In order to cope with complexity, players may *categorize games* to reduce the cognitive requirements. For each category, players may apply to each game the average beliefs, or average payoffs for the category, and then play a best response. Greater complexity (larger set of games and lower information) reduces the probability of playing a Nash equilibrium. One also observes learning spillovers across games. Transparency of information on payoffs rather than knowledge of the past play of the opponent is more conducive to the Nash equilibrium being played.

The conditions required for the limiting frequencies of play to be a Nash equilibrium in most plausible learning models are strong. In the presence of enough ex-ante uncertainty about the payoffs of others, there is no guarantee that long-run play is a Nash equilibrium. In more realistic and cognitively plausible models that involve the idea of *regret matching*, the limiting play approaches the set of *coarse correlated equilibria*. This set of equilibria is typically much larger than the set of Nash equilibria.

Chapters 14 and 15 explore various aspects of learning by using deterministic dynamics. In these dynamics, the main object of interest, an *asymptotically stable steady state*, has two properties. First, the outcome is *history dependent*. Second, once the system reaches the basin of attraction of any steady state, it stays there forever. In the final chapter in Part 5, Chapter 16, we consider

stochastic dynamics by introducing a source of *persistent randomness*. The outcome in any period is uncertain; however, we may be able to predict where the stochastic dynamic system is likely to spend most of its time in the long run. The resulting object of interest, a *stochastic steady state*, is able to relax both the steady state properties of deterministic dynamics, namely, history dependence, and the locked-in effect in steady states.

A stochastic steady state may be *ergodic*, i.e., there is a high likelihood that the system spends most of the time in that steady state, irrespective of the history of the system. This gives rise to a powerful argument for choosing among steady states of a deterministic system. Furthermore, we may have *punctuated equilibria*, i.e., once a steady state is achieved, small mutations may accumulate, and may eventually push the system into the basin of attraction of another steady state. The point at which this occurs is called the *tipping point*. A stochastically stable steady state is one in which the basin of attraction is hardest to escape from.

The underlying environment in models of stochastic dynamics has relatively low rationality. Our main vehicle of analysis will be *perturbed Markov chains* that essentially specify adaptive play with memory length T , sample size τ , and error rate ε . Players play a best response to a sample of past observations with a high probability, and with some small probability, ε , they make a mistake, and play randomly. This framework can be used to explain the evolution of institutions and norms as the result of gradual, small, adjustments arising from adaptively learning individuals. The low-rationality adaptive-play environment of *perturbed dynamics* often generates a Nash equilibrium without requiring the stringent epistemic conditions for a Nash equilibrium.

Stochastically stable states may allow for the play of strictly dominated strategies when players use *imitate the best*, rather than play best replies to past observations. For 2×2 games, the stochastically stable state is also the risk dominant state. However, many of the results from 2×2 coordination games do not generalize to 3×3 , or higher dimensional games. A strict risk dominant equilibrium for 3×3 games may not exist, and may not coincide with stochastic stability. However, several of the results generalize for a class of games called *acyclic games*. Stochastic dynamics allow us to pick among alternative norms. The chosen norm may be inefficient, but relatively fair in its distributive implications. This has the potential to explain adherence to moral standards of behavior.

Finally, we briefly consider games played on graphs with boundedly rational players whose direct interaction is local, but indirect interaction is global. We characterize the features of the stochastically stable states, and apply the theory to agrarian contracts.

The applications of stochastic dynamics are interesting and important in their own right. However, it is not clear how one might use this framework to explain the results of experiments in a variety of commonly used games in behavioral economics. For a better evaluation of this line of research, we need to pit these models in a horse race against other models. In contrast to the material that we cover in Chapter 15, insufficient progress has been made in this direction.

A range of Appendices may be useful to interdisciplinary audiences. The material here simply states the relevant results, and is not a substitute for consulting the original sources, and gaining a deeper understanding of the techniques. Appendix A outlines the basics of ordinary differential equations. We consider, briefly, the existence, uniqueness, and stability conditions for linear, and non-linear ordinary differential equations, and systems of such equations. Appendix B considers a model of stochastic utility, and shows that when the preference shocks have an extreme value distribution, the resulting choice of strategies by the players follows a logit model. This material also underpins some of the models considered in Part 4, such as the quantal response equilibrium. Appendix C gives a very condensed guide to the relevant results in unperturbed and perturbed Markov chains.

CHAPTER 14

Evolutionary Game Theory

14.1 Introduction

Evolutionary game theory is based on Darwin's theory of natural selection. The basic idea is that each animal is represented by a *genotype*, or its exact genetic structure. We are using the word genotype in the sense of *alleles*, i.e., any number of alternative forms of the same gene, so there is *heterogeneity* among the genotypes. Each genotype induces a particular behavior that is its phenotype. Hence, animals are *hardwired* to follow certain strategies. By contrast, in classical game theory, strategies, at least as applied to humans, are the product of conscious deliberation. In this chapter, each genotype maps into a unique phenotype, but more generally, a particular genotype may induce a probability distribution of phenotypes.¹

In any period of play, distinct phenotypes have different levels of *fitness*. Fitness is taken to mean the *reproductive success* of the animal. Nature undertakes the following process of *natural selection*. In any period, phenotypes that had higher fitness in the previous period *proliferate* relatively more in numbers. At the same time, phenotypes with lower fitness in the previous period *decay*, or proliferate at a lower rate. The relative fitness of a phenotype depends on (i) its suitability for the current environment, and (ii) the fitness of other phenotypes in the population. New phenotypes arise randomly through a process of *mutation* of the underlying genotype. This is the sense in which we may conceive of learning in evolutionary game theory.

A central question in evolutionary game theory is whether the existing phenotypes, also known as *resident phenotypes*, can survive invasion by other mutant phenotypes. If they can, then they are said to be *evolutionary stable strategies* (ESS). If in an ESS natural selection picks a unique surviving genotype, then the resulting population is said to be *monomorphic*. If there are multiple genotypes in an ESS, then the resulting population is said to be *polymorphic*.

Evolution is an extremely slow and conservative process, occasionally punctuated by the random event of mutation. We also briefly consider the literature on *group selection*, an idea that was initially proposed by Wynne-Edwards (1962). In this view, an individual's reproductive success may be curtailed if this benefits the overall fitness of the group; this idea has not been without controversy.

The speed of learning under evolutionary game theory is slower relative to other learning contexts, such as human learning, in experimental settings (Camerer, 2003). Does this mean that evolutionary game theory is of limited relevance for behavioral economics? This is not the case,

¹ For instance, genes determine that humans have fingerprints. However, the exact fingerprint is unique to each human.

especially if one is interested in exploring the source of the primitives in most economic problems, i.e., preferences and beliefs. For instance, human emotions, visceral influences, the presence of fairness and reciprocity concerns, the nature of time discounting, all have evolutionary explanations.

Section 14.2 reviews some preliminaries, and describes the basic notation.

In Section 14.3, we derive and define an ESS from first principles (Hammerstein and Selten, 1994). We apply the ESS concept to symmetric two-player games in which the players may belong to identical, or different populations. We then derive the *primary* and *secondary* criteria for checking that a strategy is an ESS. These criteria are sometimes also known as *equilibrium* and *stability* conditions, respectively, and considerably simplify the problem of finding an ESS.

In Section 14.4, we establish the relation between ESS and other equilibrium concepts in game theory. For instance, we show that every ESS is a symmetric Nash equilibrium. But the converse does not hold unless the symmetric Nash equilibrium is strict, or we have a symmetric Nash equilibrium in completely mixed strategies (i.e., all pure strategies are played with a strictly positive probability). Hence, ESS is a refinement of Nash equilibrium. The ESS is also a perfect equilibrium, so, in an ESS, no weakly dominated strategies are played.

The concept of an ESS is agnostic about the underlying dynamic process. An important advance, the *replicator dynamics* (Taylor and Jonker, 1978), provides the necessary foundations for an ESS. It is considered in Section 14.5. We describe the rationale for replicator dynamics, and describe its various properties such as proportionality, quotient dynamics, and additive invariance of payoffs.² We also show how the replicator dynamics can be extended to the *asymmetric populations case*. We derive two main properties of the replicator dynamics. First, any asymptotically stable state of the replicator dynamics is a Nash equilibrium. Second, any ESS is an asymptotically stable state of the replicator dynamics.

Section 14.6 considers some applications of evolutionary game theory. These applications make the following main points. First, in the context of a prisoner's dilemma game, we show that ESS can enable us to choose among multiple *monomorphic* steady states of the replicator dynamics. The chosen steady state in ESS typically depends on the initial conditions. Second, while strategies are hardwired in evolutionary game theory, these strategies could be quite complex history-dependent strategies. We examine the evolutionary stability of the *tit-for-tat strategy* for the twice repeated prisoner's dilemma game. Third, in the context of a 2×2 game of chicken, we show that the evolutionary equilibrium could be *polymorphic*, in which both strategies coexist. Fourth, we show that, in the rock-scissor-papers game, there may not be an asymptotically stable steady state even when we allow players to play totally mixed strategies. Fifth, we demonstrate an application of replicator dynamics, and study asymptotic stability using a model of competing and *heterogenous multiple populations*.

In many cases, it is difficult to isolate pairwise interactions among animals for a prize. Rather, it appears that players are *playing the field*, rather than being in direct competition with a particular opponent. The relevant notion of a game in this case is a *population game*. Section 14.7 considers these issues. We define a population game, and define the appropriate notion of an ESS in such a game.

Section 14.8 considers *gene-culture coevolution* (Gintis, 2009b, 2011; Gintis and Helbing, 2014). Environmental changes that are neither too slow, nor too rapid, may be transmitted from one generation to another through *epigenetic transmission*. Epigenetic changes do not alter the structure

² For formal derivations of the replicator dynamics, see Hofbauer and Sigmund (1988) and Gintis (2009a).

of DNA, but they are physiological changes. Examples include beaver dams, and social structures in bee hives; a phenomenon known as *niche construction* (Dawkins, 2006).

In humans, an important form of epigenetic change occurs through the *transmission of culture*; culture may be directly encoded into the brain as distinct from being encoded into the DNA (Gintis, 2011). The physiology of communication in humans is a good example of gene–culture coevolution (Gintis, 2011). As the advantages of communications (a cultural change) became reflected in the greater fitness of the communicators, there were genetic changes that lowered the voice box in the larynx, hence, facilitating even better communication. Other examples that we consider include *evolutionary political economy* (Gintis et al., 2014), the *Westermarck effect* (Wilson, 2012), and *evolutionary prosociality* (Gintis, 2011). We also examine a formal model of cultural transmission in the form of *intergenerational transmission of altruism* despite its lower biological fitness relative to selfishness (Gintis and Helbing, 2014).

Section 14.9 considers the *evolutionary stability of other-regarding preferences* that play a central role in Part 2 of the book. Section 14.9.1 considers models of *kin selection* and *inclusive fitness* (Hamilton, 1964; Maynard Smith, 1964). The idea is that humans may take altruistic actions that are personally costly, say, in term of their own fitness levels, provided the fitness of other kin members, who carry similar genes, can be enhanced. This results in an enduring mathematical inequality, termed as *Hamilton's rule*, which specifies the conditions under which individuals will be prosocial. We work out the implications for evolutionary stability in a prisoner's dilemma game (Nowak, 2006). One drawback of this approach is that it does not explain altruistic human behavior towards genealogically unrelated other humans. However, Hamilton's inequality survives, in a suitably reinterpreted manner, in most of the alternative explanations that we consider.³

Section 14.9.2 considers the conflict between *individual and group selection* (Hamilton, 1964; Price, 1972); these models are also known as models of *multilevel selection*. Consider several competing groups. Within each group, altruism has lower fitness relative to selfishness. However, in competition across groups for scarce resources, groups that have more prosocial traits are likely to be more successful relative to groups of predominantly self-regarding individuals. If this group-selection effect can dominate the first effect (relatively greater fitness of selfishness over altruism in groups), then prosocial preferences may be evolutionarily stable. The benefits of altruism can be enhanced by *assortative matching* of individuals that makes it more likely that altruistic individuals are more likely to meet each other.

Section 14.9.3 considers the notion of *reciprocal altruism* (Trivers, 1971). The idea is that altruism may evolve because individuals reciprocate the previously altruistic choices of others. It was shown that in computer tournaments using the prisoner's dilemma game, the *tit-for-tat strategy* (begin by cooperating, and cooperate in period t if the opponent cooperated in period $t-1$, otherwise defect forever) was the winning strategy relative to pure defection (Axelrod, 1984). However, reciprocal altruism is hard to find in animals and mostly found in humans, and in close relatives, such as chimps. Further the evolutionary stability of strategies such as tit-for-tat is quite sensitive to behavioral errors by players and the size of the group. It also does not explain altruism towards strangers in one-shot games. Empirical evidence for these models, based on the historical record, is not supportive either (Bowles and Gintis, 2011).

³ For an important re-examination of Hamilton's inequality, see Gintis (2014).

Section 14.9.4 considers *altruism* and *spite* towards third parties, based on the indirect transmission of information through, say, gossip and language; this is known as *indirect reciprocity* (Alexander, 1987; Nowak and Sigmund, 1998).

Section 14.9.5 summarizes the objections to using standard repeated game arguments in classical game theory to justify observed prosocial behavior (Bowles and Gintis, 2011; Gintis, 2009b). Indeed, explanations for prosocial behavior based on the folk theorem are so problematic, despite this being offered as the main explanation for cooperation in classical game theory, that Bowles and Gintis (2011) term them as *evolutionary irrelevant equilibria*. Problems include the lack of a specification of the dynamic process towards equilibrium, lack of predictions for the realistic case in which, with a high probability, players receive private signals, lack of foundations for the play of mixed strategies under private signals, and the inability of the purification agenda to apply to many important classes of games including repeated games.

Section 14.9.6 outlines the *indirect evolutionary approach* (Güth and Yaari, 1992; Güth, 1995). In this approach, the preferences of individuals are selected by evolutionary pressures. However, as in neoclassical economics, individuals maximize their utility at each instant in time. When individuals are matched to play a game, they are assumed to recognize the preferences of others, and then play a best response. However, one criticism of this approach is that the recognition of preferences of others, and the associated cues, ought themselves to be endogenous to the evolutionary process (Robson and Samuelson, 2011).

Within the indirect evolutionary approach, we examine the evolutionary stability of the textbook self-regarding preferences (Alger and Weibull, 2013). It turns out that selfishness is wiped out by a form of preferences that they call *homo-moralis*. Indeed, a subset of these preferences, *homo-hamiltonensis*, whose degree of morality is linked to the *degree of assortativity* of matchings, turns out to be the unique evolutionary stable form of preferences. This work illustrates the power and usefulness of the evolutionary approach. We already know from the empirical evidence in Part 2 of the book that prosociality is critical in humans. A demonstration of the evolutionary instability of selfishness is not only consistent with the empirical evidence, it more decisively debunks the neoclassical preference to give center-stage to sociopaths (individuals who have exclusively self-regarding preferences).

In Section 14.9.7, we briefly comment on some assorted issues in reciprocity.

Section 14.10 asks if *models of social learning*, in which individuals are not hardwired to play particular strategies, can produce dynamic processes similar to replicator dynamics. In Section 14.10.1, we consider a two-population model of *social imitation* in which players engage in bilateral meetings. Each period, some players get an opportunity to revise their strategy, and they select the strategy of a randomly chosen player from their population. The dynamics arising from such a process of imitation are also known as *emulation dynamics*. One feature of such models is that they might disproportionately select the median payoff in the population (median enhancing emulation dynamics). In Section 14.10.2, we derive the conditions under which the emulation dynamics are identical to the replicator dynamics. However, the replicator dynamics are not robust to changes in the form of social imitation.

Yet another formulation of the basic Darwinian idea is based on the concept of *payoff monotonicity* that we consider in Section 14.10.3. This requires that strategies that have a higher payoff also have a higher growth rate. Payoff monotone dynamics turn out to have many of the same properties as replicator dynamics. In addition, these dynamics ensure that dominated pure strategies are never played.

14.2 Some preliminaries

In this section, we introduce the notation and review some of the preliminaries for subsequent analysis.⁴ Consider a population of a large number of identical players. In every period, two randomly drawn players from the population play a symmetric, two-player, normal form game.

The set of players is $N = \{1, 2\}$. The pure strategy set of any player is $S = \{s_1, s_2, \dots, s_n\}$. A *pure strategy profile* in any strategic interaction between the two players is $s = (s_i, s_j) \in S \times S$, where s_i is the pure strategy chosen by the first player, and s_j is the pure strategy chosen by the second player.⁵

Player i 's *mixed strategy*, σ_i , is a probability distribution over his pure strategy set, S . We denote by $\sigma_i(s_k) \in [0, 1]$, the probability with which player i plays the pure strategy $s_k \in S$. Sometimes we may need to use the slightly more cumbersome notation $\sigma_i(s_{ik})$ for the probability with which player i plays his k th pure strategy $s_{ik} \in S$. Any pure strategy that is played with a non-zero probability under σ_i is said to belong to its *support*. In particular, a pure strategy $s_k \in S$ for player i , simply corresponds to a degenerate mixed strategy, $\sigma_i(s_k) = 1$. The set of all mixed strategies of player i is denoted by Σ_i . Formally,

$$\Sigma_i = \left\{ \sigma_i = (\sigma_i(s_1), \sigma_i(s_2), \dots, \sigma_i(s_n)) : \sigma_i(s_j) \in [0, 1] \ \forall j \text{ and } \sum_{j=1}^n \sigma_i(s_j) = 1 \right\}. \quad (14.1)$$

A *completely mixed strategy*, σ_i , gives a strictly positive probability weight to all pure strategies, i.e., $\sigma_i(s_j) > 0$ for all $s_j \in S$. The mixed strategy profile of the game $\sigma = (\sigma_i, \sigma_j)$ is an element of the set $\Sigma_i \times \Sigma_j$, $i \neq j$. It will sometimes be convenient to express the mixed strategy profile by $\sigma = (\sigma_i, \sigma_{-i})$, where σ_{-i} is the mixed strategy profile of the player other than player i . The payoff of any player, $i = 1, 2$, is given by the mapping $\pi_i : \Sigma_i \times \Sigma_j \rightarrow \mathbb{R}_+$, $i \neq j$.

Recalling that pure strategies are simply degenerate mixed strategies, the restriction of *symmetric* payoffs is that $\pi_i(s_i, s_j) = \pi_j(s_j, s_i)$ (so player identities are unimportant).⁶ A two-player *normal form*, or *strategic form*, game is denoted by $G(2, S, \pi)$, where $\pi = (\pi_i, \pi_j)$, and each of π_i, π_j is a symmetric payoff function.

It is sometimes convenient to denote the $n \times n$ matrix of payoffs of player i by Π_i . A typical element of this matrix is denoted by $a_{ij} \equiv \pi_i(s_i, s_j)$. The k th row of the payoff matrix Π_i , denoted by Π_{ik} , gives the payoffs to player i when he follows a fixed pure strategy $s_k \in S$, and the opponent successively follows his pure strategies, $s_1, \dots, s_n$.

$$\Pi_{ik} = (a_{k1}, a_{k2}, \dots, a_{kn}). \quad (14.2)$$

⁴ For textbook treatments of evolutionary game theory, see Maynard Smith (1982), Weibull (1995), Vega-Redondo (1996), Samuelson (1997), Hofbauer and Sigmund (1998), Gintis (2009b), and Sandholm (2010).

⁵ While our focus is on random meetings between players, in actual practice one may meet disproportionately many players who play a similar strategy. For instance, altruists might have a network in which they are more likely to meet other altruists. These considerations can be dealt with by using evolutionary graph theory (Lieberman et al., 2005).

⁶ Notice, for instance, that despite the evidence on gender differences that we review in several parts of the book, we do not draw any distinction between strategies played by males and females. Indeed, the dynamic processes in this chapter, such as replicator dynamics, will be typically based on asexual reproduction.

	C	D
C	2, 2	0, 3
D	3, 0	1, 1

Figure 14.1 The two-player prisoner's dilemma game.

We shall assume that a mixed strategy of player i , σ_i , is a *column vector*, and its transpose is denoted by σ_i^T . Then we can write the payoff of player i compactly as

$$\pi_i(\sigma_i, \sigma_j) = \sigma_i^T \Pi_i \sigma_j, i \neq j. \quad (14.3)$$

Example 14.1 Consider the two-player, symmetric, prisoner's dilemma game shown in Figure 14.1. In this case, $S = \{C, D\}$. Denote the row player by 1, and the column player by 2. The payoff matrix of player 1 is given by

$$\Pi_1 = \begin{bmatrix} 2 & 0 \\ 3 & 1 \end{bmatrix}.$$

The payoff matrices are symmetric, so, for instance, $\pi_1(C, D) = \pi_2(D, C) = 0$. Let the corresponding mixed strategies of the players be given by the column vectors

$$\sigma_1 = \begin{pmatrix} p \\ 1-p \end{pmatrix}, \sigma_2 = \begin{pmatrix} q \\ 1-q \end{pmatrix},$$

where p and q are, respectively, the probabilities with which player 1 and player 2 play C. The payoff of player 1 from the mixed strategy profile (σ_1, σ_2) can be written as

$$\pi_1(\sigma_1, \sigma_2) = 2pq + 0 \times p(1-q) + 3(1-p)q + (1-p)(1-q).$$

which can be written in more compact matrix notation as $\pi_1(\sigma_1, \sigma_2) = \sigma_1^T \Pi_1 \sigma_2$.

The next lemma contains two useful results for later application.

Lemma 14.1 Consider the game $G(2, S, \pi)$. Suppose that σ_j is a linear combination of two mixed strategies, σ_j^a and σ_j^b , such that $\sigma_j = \alpha \sigma_j^a + (1-\alpha) \sigma_j^b$, $\alpha \in [0, 1]$.

(a) Then, (14.3) can be written as

$$\pi_i(\sigma_i, \sigma_j) = \alpha \pi_i(\sigma_i, \sigma_j^a) + (1-\alpha) \pi_i(\sigma_i, \sigma_j^b).$$

(b) Suppose that $\sigma_i = \sigma_j$. In this case

$$\pi_i(\sigma_j, \sigma_j) = \alpha \pi_i(\sigma_j^a, \sigma_j) + (1-\alpha) \pi_i(\sigma_j^b, \sigma_j).$$

Proof: The proof follows from a simple application of the distributive laws of matrices. From (14.3)

$$\begin{aligned} \pi_i(\sigma_i, \sigma_j) &= \sigma_i^T \Pi_i (\alpha \sigma_j^a + (1-\alpha) \sigma_j^b) \\ &= \alpha \sigma_i^T \Pi_i \sigma_j^a + (1-\alpha) \sigma_i^T \Pi_i \sigma_j^b \\ &= \alpha \pi_i(\sigma_i, \sigma_j^a) + (1-\alpha) \pi_i(\sigma_i, \sigma_j^b) \end{aligned}$$

which proves part (a). To prove (b) note that

$$\begin{aligned}\pi_i(\sigma_j, \sigma_j) &= \left(\alpha \sigma_j^a + (1 - \alpha) \sigma_j^b \right)^T \Pi_i \sigma_j \\ &= \alpha \left(\sigma_j^a \right)^T \Pi_i \sigma_j + (1 - \alpha) \left(\sigma_j^b \right)^T \Pi_i \sigma_j \\ &= \alpha \pi_i(\sigma_j^a, \sigma_j) + (1 - \alpha) \pi_i(\sigma_j^b, \sigma_j).\end{aligned}$$

This proves part (b). ■

14.3 Evolutionary stable strategies in two-player games

An *evolutionary stable strategy* (ESS) is the standard equilibrium concept in evolutionary game theory. It was introduced in the seminal paper by Maynard Smith and Price (1973). A strategy, or a *phenotype*, is an ESS if starting from a state where it is played by all players in the population, it cannot be invaded by a small fraction of mutants who play an alternative strategy. We apply the definition of ESS only to symmetric two-player normal form games $G(2, S, \pi)$ (see Section 14.2). For an extension to extensive form games, see Section 7 in Hammerstein and Selten (1994).

Suppose that there is an established mixed strategy in the population, $\sigma \in \Sigma$; this could be a pure strategy if σ is degenerate. Now consider the random event of *mutation*. An exogenous fraction, $\lambda > 0$, of the population mutates, and plays a mixed strategy, $\hat{\sigma} \neq \sigma$. The remaining proportion of the population, $1 - \lambda$, continues to play the established strategy σ . Define the average strategy in the population, $\bar{\sigma}$, by

$$\bar{\sigma} = \lambda \hat{\sigma} + (1 - \lambda) \sigma. \quad (14.4)$$

The mixing operation in (14.4) makes use of the usual compounding rule of probabilities.⁷ When random, pairwise, meetings between the players take place, then, on average, one meets an opponent who plays the strategy $\bar{\sigma}$. We would like to see how each of the strategies, $\sigma, \hat{\sigma}$, fare against $\bar{\sigma}$.

Definition 14.1 (*Fitness*): The fitness of the established strategy, σ , and the mutant strategy, $\hat{\sigma}$, is defined as its payoff against the average strategy $\bar{\sigma}$. Hence, the respective fitness levels of the strategies, $\sigma, \hat{\sigma}$, are given by $\pi(\sigma, \bar{\sigma})$ and $\pi(\hat{\sigma}, \bar{\sigma})$. The fitness of the average strategy is given by $\pi(\bar{\sigma}, \bar{\sigma})$.

Measuring biological payoffs in the field is not an easy task. As Hammerstein and Selten (1994, p. 975) write: “Biological critics of evolutionary game theory have argued that it is almost impossible to get empirical access to game-theoretic payoffs [see the open peer commentaries of a survey paper by Maynard Smith (1984)].” See also the discussion following this quote for some attempts to measure biological payoffs and the difficulties in doing so. We will assume away these important problems in our discussion below.

ESS is a static concept, but a better understanding of it can be achieved by considering the time evolution of the mutant strategy. Let time $t = 0, 1, 2, \dots$ be discrete, so that at time t , the

⁷ For instance, suppose that there are only two pure strategies (s_1, s_2) . Let the mixed strategies be $\sigma = (0.6, 0.4)$ and $\hat{\sigma} = (0.2, 0.8)$. If $\lambda = 0.1$, then the average strategy is $\bar{\sigma} = (0.56, 0.44)$.

respective fractions of the mutant and non-mutant populations are λ_t and $1 - \lambda_t$. There are several methods of motivating an ESS; we follow the method in Hammerstein and Selten (1994).

Definition 14.2 (*Growth factors*): The growth factors of the mutant and non-mutant populations are given, respectively, by $\frac{\lambda_{t+1}}{\lambda_t}$ and $\frac{1-\lambda_{t+1}}{1-\lambda_t}$.

Consistent with the Darwinian view of evolution, we assume that the growth rates of phenotypes depend on their respective fitness levels, $\pi(\hat{\sigma}, \bar{\sigma})$, $\pi(\sigma, \bar{\sigma})$, relative to the fitness of the average strategy, $\pi(\bar{\sigma}, \bar{\sigma})$. Hence,

$$\frac{\lambda_{t+1}}{\lambda_t} = \frac{\pi(\hat{\sigma}, \bar{\sigma})}{\pi(\bar{\sigma}, \bar{\sigma})} \text{ and } \frac{1-\lambda_{t+1}}{1-\lambda_t} = \frac{\pi(\sigma, \bar{\sigma})}{\pi(\bar{\sigma}, \bar{\sigma})}. \quad (14.5)$$

Thus, the relative growth rate of the two phenotypes is given by

$$\frac{\left(\frac{\lambda_{t+1}}{\lambda_t}\right)}{\left(\frac{1-\lambda_{t+1}}{1-\lambda_t}\right)} = \frac{\pi(\hat{\sigma}, \bar{\sigma})}{\pi(\sigma, \bar{\sigma})}. \quad (14.6)$$

The growth rate of mutants is greater if they do relatively better against the average strategy. To discover a potential ESS, we are interested in conditions under which the proportion of mutants disappears over time, i.e., $\lambda_t \rightarrow 0$ as $t \rightarrow \infty$. This is the sense in which the existing population strategy cannot be successfully invaded by mutants. We have

$$\lambda_t - \lambda_{t+1} = \left(1 - \frac{\lambda_{t+1}}{\lambda_t}\right) \lambda_t. \quad (14.7)$$

Substituting (14.5) in (14.7), we get

$$\lambda_t - \lambda_{t+1} = \frac{\pi(\bar{\sigma}, \bar{\sigma}) - \pi(\hat{\sigma}, \bar{\sigma})}{\pi(\bar{\sigma}, \bar{\sigma})} \lambda_t. \quad (14.8)$$

Using (14.4) and Lemma 14.1, we get

$$\pi(\bar{\sigma}, \bar{\sigma}) = \pi(\lambda_t \hat{\sigma} + (1 - \lambda_t) \sigma, \bar{\sigma}) = \lambda_t \pi(\hat{\sigma}, \bar{\sigma}) + (1 - \lambda_t) \pi(\sigma, \bar{\sigma}), \quad (14.9)$$

or,

$$\pi(\bar{\sigma}, \bar{\sigma}) - \pi(\hat{\sigma}, \bar{\sigma}) = (1 - \lambda_t) [\pi(\sigma, \bar{\sigma}) - \pi(\hat{\sigma}, \bar{\sigma})]. \quad (14.10)$$

Substituting (14.10) in (14.8) we get

$$\lambda_t - \lambda_{t+1} = \frac{(1 - \lambda_t) [\pi(\sigma, \bar{\sigma}) - \pi(\hat{\sigma}, \bar{\sigma})]}{\pi(\bar{\sigma}, \bar{\sigma})} \lambda_t \quad (14.11)$$

Since payoffs are assumed to be positive (see Section 14.2), $\pi(\bar{\sigma}, \bar{\sigma}) \geq 0$. Phenotype fractions are non-negative, so $\lambda_t \geq 0$. Thus, from (14.11), we get that

$$\lambda_t \geq \lambda_{t+1} \Leftrightarrow \pi(\sigma, \bar{\sigma}) \geq \pi(\hat{\sigma}, \bar{\sigma}). \quad (14.12)$$

Hence, the mutant phenotype grows over time ($\lambda_t < \lambda_{t+1}$) if $\pi(\sigma, \bar{\sigma}) < \pi(\hat{\sigma}, \bar{\sigma})$, i.e., the mutant does relatively better against the average strategy as compared to the dominant phenotype. Conversely, for the mutant to disappear over time, a necessary condition is that $\lambda_t > \lambda_{t+1}$ for all t , i.e., in each period, the dominant phenotype outperforms the mutant against the average strategy. This can be summarized in the following definition.

Definition 14.3 (*Evolutionary stable strategy-I; Taylor and Jonker, 1978*): Consider the symmetric two-player game $G(2, S, \pi)$. Then, a mixed strategy $\sigma \in \Sigma$ is said to be an ESS, if for all mutant strategies $\hat{\sigma} \in \Sigma$, $\hat{\sigma} \neq \sigma$, there exists some “uniform invasion barrier” $0 < \bar{\lambda} < 1$ such that if the mutant population is small enough in the sense that $0 < \lambda < \bar{\lambda}$, then

$$\pi(\sigma, \bar{\sigma}) > \pi(\hat{\sigma}, \bar{\sigma}),$$

where $\bar{\sigma} = \lambda\hat{\sigma} + (1 - \lambda)\sigma$.⁸

A useful way of restating the definition of an ESS arises by eliminating $\bar{\sigma}$ from (14.12). Using Lemma 14.1, and (14.4), we get:

$$\pi(\sigma, \bar{\sigma}) = \lambda_t \pi(\sigma, \hat{\sigma}) + (1 - \lambda_t) \pi(\sigma, \sigma). \quad (14.13)$$

$$\pi(\hat{\sigma}, \bar{\sigma}) = \lambda_t \pi(\hat{\sigma}, \hat{\sigma}) + (1 - \lambda_t) \pi(\hat{\sigma}, \sigma). \quad (14.14)$$

From (14.13), (14.14) we get

$$\pi(\sigma, \bar{\sigma}) - \pi(\hat{\sigma}, \bar{\sigma}) = \lambda_t [\pi(\sigma, \hat{\sigma}) - \pi(\hat{\sigma}, \hat{\sigma})] + (1 - \lambda_t) [\pi(\sigma, \sigma) - \pi(\hat{\sigma}, \sigma)]. \quad (14.15)$$

Substituting (14.15) in (14.12) we get:

$$\lambda_t \geq \lambda_{t+1} \Leftrightarrow \lambda_t [\pi(\sigma, \hat{\sigma}) - \pi(\hat{\sigma}, \hat{\sigma})] + (1 - \lambda_t) [\pi(\sigma, \sigma) - \pi(\hat{\sigma}, \sigma)] \geq 0. \quad (14.16)$$

This gives rise to the following useful observations.

1. Suppose that the fraction of mutants is extremely small, so $\lambda_t \rightarrow 0$. In this case, (14.16) implies that

$$\lambda_t \geq \lambda_{t+1} \Leftrightarrow \pi(\sigma, \sigma) \geq \pi(\hat{\sigma}, \sigma). \quad (14.17)$$

This is called the *primary criterion* for determining an ESS. In particular, the existing strategy σ is an ESS if it does at least as good against itself, relative to how well a mutant strategy does against it.

2. Suppose now that $\pi(\sigma, \sigma) = \pi(\hat{\sigma}, \sigma)$, so the dominant strategy and the mutant strategy are both best replies to the dominant strategy. In this case, (14.16) implies that

$$\lambda_t \geq \lambda_{t+1} \Leftrightarrow \pi(\sigma, \hat{\sigma}) \geq \pi(\hat{\sigma}, \hat{\sigma}). \quad (14.18)$$

⁸ The result on the uniform invasion barrier only holds for two-player games (Vickers and Cannings, 1987).

This is called the *secondary criterion* for determining an ESS. In particular, if $\pi(\sigma, \sigma) = \pi(\hat{\sigma}, \sigma)$, a necessary condition for the mutant to eventually vanish is that in a population that comprises predominantly mutants, strategy σ does better against the mutants relative to how well the mutants do against themselves.

We summarize these observations for future reference.

Definition 14.4 (*Evolutionary stable strategy-II; Maynard Smith and Price, 1973*): Consider a symmetric two-player game $G(2, S, \pi)$. A mixed strategy σ is said to be an ESS, if for any mutant strategy, $\sigma \neq \hat{\sigma}$, any of the following two conditions are satisfied.

- (a) *Equilibrium condition or primary criterion*: $\pi(\sigma, \sigma) > \pi(\hat{\sigma}, \sigma)$.
- (b) *Stability condition or secondary criterion*: If $\pi(\sigma, \sigma) = \pi(\hat{\sigma}, \sigma)$, then $\pi(\sigma, \hat{\sigma}) > \pi(\hat{\sigma}, \hat{\sigma})$.

From Definition 14.4, the primary criterion reveals that an ESS is a Nash equilibrium. However, the secondary criterion proposes a strengthening of Nash equilibrium. Hence, the concept of an ESS is more stringent as compared to a Nash equilibrium.

In 2×2 games, an ESS is guaranteed under fairly mild conditions as we see next, but this result does not generalize to higher dimensional games.

Proposition 14.1 (*van Damme, 1991*): Consider a symmetric two-player game $G(2, S, \pi)$ in which each player has two pure strategies, so $S = (s_1, s_2)$. Suppose that $\pi(s_1, s_1) \neq \pi(s_2, s_1)$ and $\pi(s_2, s_2) \neq \pi(s_1, s_2)$. Then G is guaranteed to have an ESS.

The ESS is a static equilibrium concept and it does not specify the path to the equilibrium. One starts with a candidate ESS strategy and checks that it cannot be successfully invaded by a mutant strategy. Although the ESS is not tied to any dynamic process, the dynamic underpinnings of this concept are considered in Section 14.5 below when we discuss replicator dynamics.

The ESS takes mutations as a rare event. Hence, the evolutionary stability of the existing strategy is checked against invasion by one mutant strategy at a time. It is assumed that once a mutation takes place, the system settles down to a stable state before the next mutation occurs. There is no presumption that an ESS would survive against several simultaneous mutations. In actual practice, however, one may expect mutations to take place on a continual basis, particularly when the mutations are not biological, but, say, cultural. These issues require the introduction of stochastic dynamics, where the relevant equilibrium concept is *stochastic stability*; see Chapter 16. In applications of deterministic evolutionary dynamics, it is a good idea to allow for a large number of initial pure strategies. Extinct strategies stay extinct forever. This will not be a feature of the framework under stochastic dynamics.

An ESS might not exist in certain games, or there could be a multiplicity of ESS for the same game. In the latter case, the history of the game determines which of the two equilibria is stable. This allows evolutionary game theory to provide a powerful equilibrium selection argument in choosing among alternative Nash equilibria. Perhaps surprisingly, the introduction of noise into the underlying dynamics, in the form of persistent mutation, in Chapter 16, allows us to shed this history-dependence. Indeed, with persistent randomness, we shall speak of a limiting ergodic distribution of strategies, irrespective of the history of the system.

While the concept of an ESS is underpinned by the idea of natural selection, it need not maximize the *welfare* of the species. Ex-ante, it is not even clear how one might define the welfare of a species. For instance, is welfare associated with the number of offspring, or the long-term probability of the survival of the species, or its aggregate biomass?

Sometimes a mixed strategy ESS is given two alternative interpretations. First, it could be that players play the same mixed strategy, which is possibly degenerate. In this case, an ESS is said to be played by a *monomorphic population* of players. An alternative interpretation is that all individual players play pure strategies. In a large population, the probability of playing the pure strategy $s_i \in S$ is the fraction of the population that plays the strategy s_i . In this case, an ESS is said to be played by a *polymorphic population* of players. Since the setting in an ESS is static, players who play a mixed strategy have no incentive to mix their pure strategies in the equilibrium proportions. On these grounds, the polymorphic population interpretation is superior. The classic example is the male to female sex ratio of $\frac{1}{2} : \frac{1}{2}$ in most animals with sexual reproduction. In this case, it is clearly polymorphic (or, actually, dimorphic).

14.4 Relation of ESS with other equilibrium concepts

Suppose that in the game $G(2, S, \pi)$, the established strategy in the population is $\sigma \in \Sigma$. The profile (σ, σ) is a Nash equilibrium, if

$$\pi(\sigma, \sigma) \geq \pi(\hat{\sigma}, \sigma) \quad \forall \hat{\sigma} \in \Sigma. \quad (14.19)$$

The degenerate strategy profile (σ, σ) is a strict Nash equilibrium if

$$\pi(\sigma, \sigma) > \pi(\hat{\sigma}, \sigma) \quad \forall \hat{\sigma} \in \Sigma, \quad (14.20)$$

which is simply the primary criterion in an ESS (Definition 14.4). Strict Nash equilibrium arises only in degenerate mixed strategies. However, it is possible that $\pi(\sigma, \sigma) = \pi(\hat{\sigma}, \sigma)$, in which case the secondary criterion in Definition 14.4 may have to be invoked, and we may get a polymorphic equilibrium.

Proposition 14.2

- (a) Every ESS is a Nash equilibrium.
- (b) Any strict Nash equilibrium is an ESS.
- (c) In general, the set of ESS is a strict subset of the set of Nash equilibria. In this sense, ESS is a refinement of Nash equilibrium.

Proof: (a) In an ESS, $\pi(\sigma, \sigma) \geq \pi(\hat{\sigma}, \sigma)$ for all $\hat{\sigma}$, which is also the condition for a Nash equilibrium. Hence, an ESS is a Nash equilibrium.

(b) If we have a strict Nash equilibrium, then for degenerate mixed strategies, we have $\pi(\sigma, \sigma) > \pi(\hat{\sigma}, \sigma)$ for all $\hat{\sigma}$. This is also the primary criterion for an ESS, so σ is also an ESS. Thus, ESS and strict Nash are equivalent.

(c) From (a) and (b), the set of ESS is a subset of the set of Nash equilibria. ■

Proposition 14.3 Suppose that $\sigma \in \Sigma$ is weakly dominated, then it is not an ESS.

Proof: Suppose to the contrary that σ is an ESS, despite being weakly dominated. Then, the primary criterion of ESS: $\pi(\sigma, \sigma) \geq \pi(\hat{\sigma}, \sigma)$ for all $\hat{\sigma}$, is violated. ■

Proposition 14.4 Suppose that $\sigma \in \Sigma$ is a completely mixed ESS. Then it is the unique Nash equilibrium of the game, and $\pi(\sigma, \hat{\sigma}) > \pi(\hat{\sigma}, \hat{\sigma}) \quad \forall \hat{\sigma} \in \Sigma$ such that $\sigma \neq \hat{\sigma}$.

Proof: Since $\sigma \in \Sigma$ is completely mixed, so $\sigma(s_j) > 0$ for all $s_j \in S$. Thus, all pure strategies lie in the support of σ . By the definition of a mixed strategy, we must have $\pi(s_j, \sigma) = \pi(\sigma, \sigma)$. Now pick any other mixed strategy $\hat{\sigma} \in \Sigma$. It follows that

$$\pi(\sigma, \sigma) = \pi(\hat{\sigma}, \sigma). \quad (14.21)$$

By assumption, σ is an ESS. Using, Definition 14.4 and (14.21) we need to invoke the secondary criterion for an ESS, i.e., for all $\forall \hat{\sigma} \in \Sigma, \sigma \neq \hat{\sigma}, \pi(\sigma, \hat{\sigma}) > \pi(\hat{\sigma}, \hat{\sigma})$. It also follows that σ is the unique Nash equilibrium. ■

Consider a strategy $\sigma \in \Sigma$, and denote a ball of radius $\epsilon > 0$ around σ by $B_\epsilon(\sigma)$. The next proposition shows that an ESS is an isolated Nash equilibrium because there is no other strategy in its neighborhood that is a Nash equilibrium.

Proposition 14.5 (Hofbauer and Sigmund, 1998): *A strategy $\sigma \in \Sigma$ is an ESS if there exists some $\epsilon > 0$ such that $\pi(\sigma, \hat{\sigma}) > \pi(\hat{\sigma}, \hat{\sigma})$ for all $\hat{\sigma} \in B_\epsilon(\sigma) \setminus \sigma$.*

Proposition 14.6 (Haigh, 1975): *The game $G(2, S, \pi)$ with a finite strategy set, S , has at most finitely many ESS.*

14.5 Replicator dynamics

Recall that an ESS is a static concept. It would be useful to consider if an ESS arises as a steady state of some dynamic process. There are several dynamic processes, which incorporate the Darwinian idea that more successful strategies in the current period proliferate in the next period, while less successful strategies decay. In this section, we consider a popular adjustment process, the *replicator dynamics*, introduced by Taylor and Jonker (1978).⁹

Suppose that there is a single population. Let us assume that only pure strategies can be inherited from one period to the next. The extension to mixed strategies is non-trivial; see, for instance, Vega-Redondo (1996). If an individual follows a mixed strategy, then he receives the same payoff from all pure strategies in the support of the mixed strategy. Hence, there appears little incentive for him to learn by altering the distribution of his pure strategies. The pure strategy set is given by $S = \{s_1, s_2, \dots, s_n\}$. Suppose that at some instant in time, t , a fraction $x_t(s_i)$ of the population plays the pure strategy s_i . While each individual plays a pure strategy, the state of the system represents frequencies of play of each pure strategy that sum up to one.

Definition 14.5 (State of the system): *At any instant in time, t , the state of the system is denoted by $x_t(s)$. It is a record of the frequency with which each of the pure strategies in the set S is being played, i.e.,*

$$x_t(s) = (x_t(s_1), x_t(s_2), \dots, x_t(s_n)) : x_t(s_j) \geq 0, \forall s_j \in S \text{ and } \sum_{j=1}^n x_t(s_j) = 1.$$

For large populations, the state of the system can be viewed as the mixed strategy profile that a player faces when he is paired against a randomly chosen opponent from the population.

The replicator dynamics specifies how the state of the system evolves over time, and is influenced by the fitness of various pure strategies. The replicator dynamics can be derived in several different ways, but we proceed as follows.¹⁰ Using (14.8), and setting λ_t equal to x_t , we have

⁹ For other adjustment processes, see Hofbauer and Sigmund (1998) and Samuelson (1997).

¹⁰ See, Gintis (2009a) for three alternative methods of deriving the replicator dynamics. We give some microfoundations of replicator dynamics in Section 14.10.2.

$$x_{t+\Delta}(s_i) - x_t(s_i) = \frac{\pi(s_i, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})}{\pi(\bar{\sigma}, \bar{\sigma})} x_t(s_i); s_i \in S, \quad (14.22)$$

where the average strategy $\bar{\sigma}$ is defined as the population weighted average strategy,

$$\bar{\sigma} = \sum_{j=1}^n x_t(s_j) s_j.$$

It is more convenient to work with the continuous time analogue of (14.22). Suppose that the current time is $t \in [0, T]$, where T has the interpretation of terminal time. We use the following standard notation, $\dot{x} = \frac{dx}{dt}$. Let Δ be the interval of time between two successive periods. Hence, we can rewrite (14.22) as follows

$$\frac{x_{t+\Delta}(s_i) - x_t(s_i)}{\Delta} = \frac{[\pi(s_i, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})] \Delta}{\pi(\bar{\sigma}, \bar{\sigma}) \Delta}; s_i \in S, 0 \leq t \leq T. \quad (14.23)$$

The payoff, π , is now the payoff at time t , while the payoff $\pi \Delta$ arises over the interval Δ . The strategies $s_i, \bar{\sigma}$, give, respectively, the i th pure strategy, and the average strategy at time t . Divide both sides of (14.23) by Δ , and take the limits as $\Delta \rightarrow 0$ to get

$$\dot{x}_t(s_i) = \left(\frac{\pi(s_i, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})}{\pi(\bar{\sigma}, \bar{\sigma})} \right) x_t(s_i); s_i \in S, 0 \leq t \leq T. \quad (14.24)$$

The denominator, $\pi(\bar{\sigma}, \bar{\sigma})$, is identical for all pure strategies, hence, it does not affect the relative rates of change of the various pure strategies. Thus, in continuous time, we may consider, instead, the following differential equation.

$$\dot{x}_t(s_i) = [\pi(s_i, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})] x_t(s_i); s_i \in S, 0 \leq t \leq T. \quad (14.25)$$

The *replicator dynamics* are given by the system of n equations in (14.25). At each instant in time, an increase in the number of offspring that are hardwired to play a particular strategy, takes the form of asexual reproduction of *exact replica copies* of itself.¹¹ We use replicator dynamics to model the time path of different strategies; these dynamics can also be used to model the time paths of norms, conventions, and cultural forms.

We now consider some of the properties of the replicator dynamics.

1. (*Proportionality*) The rate of change of the frequency with which a pure strategy is played is *proportional* to its fitness, $\pi(s_i, \bar{\sigma})$, relative to the fitness of the average strategy against itself, $\pi(\bar{\sigma}, \bar{\sigma})$. Strategies that perform worse than the average, decay over time.
2. (*Relation to best response dynamics*) There is no presumption that a strategy which does better than the average is also a *best response*. Thus, the condition $\pi(s_i, \bar{\sigma}) > \pi(\bar{\sigma}, \bar{\sigma})$ implies that s_i is a *better response*, but not necessarily a best response to an opponent who plays $\bar{\sigma}$. This is an important difference between the *replicator dynamics* and the *best response dynamics*. Under replicator dynamics, strategies that are not in the best response set might still grow over an interval of time.

¹¹ This is clearly a very simple view of the inheritance properties, say, of genes, from a parent to an offspring. More realistic inheritance properties comprise the subject matter of *population genetics*; the interested reader may wish to pursue Section 5.3 in Hammerstein and Selten (1994).

3. (*Extinct strategies*) If $x_t(s_i) = 0$ for some $s_i \in S$, then $x_{t'}(s_i) = 0, \forall t' > t$. Thus, once a strategy is extinct, it is extinct forever.
4. (*Time behavior of average payoffs*) Replicator dynamics do not imply that the average payoff in the population will grow over time. In the prisoner's dilemma game (see Figure 14.1), suppose that the established strategy is C (cooperation), but a mutation arises in which the mutants play the strategy D (defection). The payoff to the mutants from D will be higher than the average, so D will grow over time. However, the average payoff will continue to fall, relative to the initial state in which all play C.
5. (*Quotient dynamics*) Suppose that s_i, s_j belong to the support of the average strategy, $\bar{\sigma}$. Using (14.25) we get,

$$\frac{\dot{x}_t(s_i)}{x_t(s_i)} - \frac{\dot{x}_t(s_j)}{x_t(s_j)} = \pi(s_i, \bar{\sigma}) - \pi(s_j, \bar{\sigma}). \quad (14.26)$$

Such dynamics in which the difference in the growth rates of two strategies equals the differences in their respective payoffs, against the average strategy, are referred to as *quotient dynamics*.

6. (*Additive invariance of payoffs*) Recall the payoff matrix for player i , Π_i . Consider row i of this payoff matrix, $\Pi_{i\cdot}$. Suppose that we now consider another payoff matrix for player i , $\hat{\Pi}_i$, in which the payoffs in row i , $\hat{\Pi}_{i\cdot}$, are given by $a_{ij} + c_j$. Simple calculations, that we leave for the reader, give rise to the following expressions.

$$\hat{\pi}_i(s_i, \bar{\sigma}) = \pi_i(s_i, \bar{\sigma}) + \sum_j x(s_j) c_j. \quad (14.27)$$

$$\hat{\pi}_i(\bar{\sigma}, \bar{\sigma}) = \pi_i(\bar{\sigma}, \bar{\sigma}) + \sum_j x(s_j) c_j. \quad (14.28)$$

The equation for the replicator dynamics in (14.25) when the payoff matrix is $\hat{\Pi}_i$, is given by

$$\dot{x}_t(s_i) = [\hat{\pi}(s_i, \bar{\sigma}) - \hat{\pi}(\bar{\sigma}, \bar{\sigma})] x_t(s_i); s_i \in S, 0 \leq t \leq T. \quad (14.29)$$

Substituting (14.27), (14.28) in (14.29) we get

$$\dot{x}_t(s_i) = [\pi(s_i, \bar{\sigma}) - \pi_i(\bar{\sigma}, \bar{\sigma})] x_t(s_i); s_i \in S, 0 \leq t \leq T, \quad (14.30)$$

which is the replicator dynamics with respect to the original payoff matrix Π_i . Hence, the replicator dynamics exhibit *additive invariance of payoffs*.

We now consider the dynamic properties of the replicator dynamics when there is a single population of players. We continue to assume that only pure strategies are inherited from one generation to the next. We use the notation

$$x_t(s) = \sigma \Leftrightarrow (x_t(s_1), \dots, x_t(s_n)) = (\sigma_1, \dots, \sigma_n), \quad (14.31)$$

i.e., σ_i is the proportion of the population at time t , $x_t(s_i)$, that plays the pure strategy $s_i \in S$.

Figure 14.2 Relation between replicator dynamics, evolutionary stable strategies, and Nash equilibria.

Definition 14.6 (*Steady state*): A steady state of the system $\bar{x}_t(s) = (\bar{x}_t(s_1), \bar{x}_t(s_2), \dots, \bar{x}_t(s_n))$ is a solution to $\dot{x}_t(s_i) = 0$ for $i = 1, \dots, n$; it is also sometimes referred to as a “dynamic equilibrium” or a “fixed point” of the replicator dynamics.

Proposition 14.7 Suppose that there exists some symmetric Nash equilibrium, $\sigma = (\sigma_1, \dots, \sigma_n)$, of the game $G(2, S, \pi)$, where $x_t(s_i) = \sigma_i$ for $s_i \in S$. Consider the population state $x_t(s)$, defined in (14.31). Then, the population state $x_t(s)$ is a steady state of the replicator dynamics.

Proof: The average strategy is given by $\bar{\sigma} = \sum_{i=1}^n x_t(s_i) s_i$; if s_i is not in the support of σ then $x_t(s_i) = 0$. For any s_i, s_j in the support of a mixed strategy Nash equilibrium, σ , we have

$$\pi(s_i, \bar{\sigma}) = \pi(s_j, \bar{\sigma}). \quad (14.32)$$

In particular, we also have

$$\pi(s_i, \bar{\sigma}) = \pi(\bar{\sigma}, \bar{\sigma}). \quad (14.33)$$

From the definition of replicator dynamics in (14.25), and using (14.32), (14.33) we get that

$$\dot{x}_t(s_i) = 0, i = 1, \dots, n. \quad (14.34)$$

Using Definition 14.6 and (14.34) we get that $x_t(s) = \sigma$ is a steady state of the replicator dynamics. ■

Proposition 14.7 shows that the set of Nash equilibria is a subset of the set of steady states of the replicator dynamics. However, there are steady states of the replicator dynamics that may not be a Nash equilibrium, so the converse need not be true.

We illustrate the relation between the various concepts in Figure 14.2. We have already shown in Proposition 14.7 that the Nash equilibrium is a subset of the steady states of the replicator dynamics (RD). We will now show below that (i) the *asymptotically stable steady states* of the RD are a subset of the set of Nash equilibria, and (ii) the set of *evolutionary stable* strategies is a subset of the set of asymptotically stable states. Finally, if we were to allow for the inheritance of mixed strategies in RD (we only allow the inheritance of pure strategies), then the asymptotically stable states of RD, and the set of ESS, coincide.

Proposition 14.8 Suppose that there is some asymptotically stable state (see Definition 16.41 in Appendix A) of the replicator dynamics given by

$$x^* = (x^*(s_1), x^*(s_2), \dots, x^*(s_n)).$$

Now define a mixed strategy

$$\sigma^* = x^* : \sigma_i^* = x^*(s_i); i = 1, 2, \dots, n.$$

Then σ^* is a Nash equilibrium of the game.

Proof: We briefly sketch the arguments in the proof, assuming quotient dynamics, which follow from replicator dynamics (see above). Suppose that x^* is an asymptotically stable steady state of the replicator dynamics. However, suppose to the contrary, that the corresponding strategy profile $\sigma^* = x^*$ is not a Nash equilibrium.

Given the continuity of payoffs, there exists¹² (1) some $s_i \in \text{supp}(\sigma^*)$, (2) some pure strategy $s_j \notin \text{supp}(\sigma^*)$, and (3) numbers $\delta > 0$ and $\varepsilon > 0$ such that

$$\pi(s_j, \hat{x}) > \pi(s_i, \hat{x}) + \varepsilon,$$

for all $\hat{x}$ in a δ neighborhood of x^* .

Now consider a path that remains within a δ neighborhood of x^* . Using the quotient dynamics in (14.26) we get that

$$\begin{aligned} \frac{\dot{x}_t(s_j)}{x_t(s_j)} - \frac{\dot{x}_t(s_i)}{x_t(s_i)} &= \pi(s_j, \hat{x}) - \pi(s_i, \hat{x}) > \varepsilon. \\ \Rightarrow \frac{\dot{x}_t(s_j)}{x_t(s_j)} - \frac{\dot{x}_t(s_i)}{x_t(s_i)} &> 0. \end{aligned}$$

Thus, the strategy s_j grows faster than the strategy s_i in the whole neighborhood around x^* . This contradicts the original supposition of an asymptotically stable steady state. ■

Proposition 14.8 shows that the asymptotically stable states of the replicator dynamics provide a refinement of the standard Nash concept. The next proposition gives the relation between asymptotically stable states of the replicator dynamics and the set of ESS. This result can be found in Taylor and Jonker (1978), Hofbauer et al. (1979), and Zeeman (1980).

Proposition 14.9 Suppose that an ESS of the game $G(2, S, \pi)$ is given by $\sigma^* = (\sigma_1^*, \sigma_2^*, \dots, \sigma_n^*)$. Then the population state x^* such that

$$x^* = \sigma^* : \sigma_i^* = x^*(s_i); i = 1, 2, \dots, n,$$

is an asymptotically stable state of the replicator dynamics.

We have shown above that the asymptotically stable steady states of the replicator dynamics are a subset of Nash equilibria of the game and an ESS is a subset of the set of Nash equilibria; this underpins Figure 14.2. Since any strategy that does not survive the iterated deletion of strongly dominated strategies cannot be a part of a Nash equilibrium, the next result is fairly intuitive.

Proposition 14.10 Suppose that $x_t = (x_t(s_1), x_t(s_2), \dots, x_t(s_n))$ is a “completely mixed” trajectory of the replicator dynamics. Suppose that pure strategy s_k is eliminated by iterated deletion of strongly dominated strategies. Then, in the replicator dynamics, $\lim_{t \rightarrow \infty} x_t(s_k) = 0$.

¹² The notation $\text{supp}(\sigma^*)$ means the ‘support of the distribution σ^* ’.

The situation is nuanced for weakly dominated strategies. The next result is stated as Theorem 12.5 in Gintis (2009a).

Proposition 14.11 *Suppose that $x_t = (x_t(s_1), x_t(s_2), \dots, x_t(s_n))$ is a “completely mixed” trajectory of the replicator dynamics. Suppose that some pure strategy s_i is weakly dominated by the pure strategy s_k , so $\pi(s_k, s_j) > \pi(s_i, s_j)$ for some $s_j \in S$. In the replicator dynamics, if $\lim_{t \rightarrow \infty} x_t(s_j) > 0$, then $\lim_{t \rightarrow \infty} x_t(s_i) = 0$.*

REPLICATOR DYNAMICS FOR THE ASYMMETRIC POPULATION CASE

Suppose that there are several populations $p = 1, 2, \dots, P$. Each population, p , has n_p pure strategies. An important issue in setting up the replicator dynamics is the relative sizes of the different populations. Suppose, for instance, that $P = 2$, and the second population is twice the size of the first population. Then, in random pairwise meetings between the two populations, players from the first population will have twice as many matchings as compared to players from the second population. This will clearly have an effect on the population dynamics of each population. We abstract from these issues by assuming that each population is of the same size.

Subscript variables with a p denote the p th population. Suppose that s_{pi} is the i th pure strategy in the p th population, $\bar{\sigma}_p$ is the average strategy in the p th population, and $\bar{\sigma}_{-p}$ is the average mixed strategy profile of all the other populations other than the p th. Then, we can write the replicator dynamics (14.30) as follows.

$$\dot{x}_t(s_{pi}) = [\pi(s_{pi}, \bar{\sigma}_{-p}) - \pi(\bar{\sigma}_p, \bar{\sigma}_{-p})] x_t(s_{pi}); i = 1, \dots, n_p; p = 1, 2, \dots, P; t \geq 0. \quad (14.35)$$

Most of the results for the single population case survive to the multiple populations case. However, an ESS in the asymmetric populations case must be a strict Nash equilibrium; see Gintis (2009a) for a discussion. Section 14.6.4 considers a concrete example for the case of $P = 2$.

14.6 Applications of evolutionary game theory

We now consider several applications of evolutionary game theory in increasingly complicated problems.

14.6.1 Prisoner's dilemma game: monomorphic equilibrium

We consider separately a static and a dynamic version of the game.

STATIC PRISONER'S DILEMMA GAME

Consider the two-player, symmetric, prisoner's dilemma game shown in Figure 14.1, which has a strictly dominated strategy, C . The unique Nash equilibrium of this game is (D, D) . In contrast to classical game theory, individuals in evolutionary game theory are *hardwired* to play either C or D . Suppose that a fraction x of the population plays C , and the remaining fraction $1 - x$ plays D . Thus, the average strategy in the population is given by $\bar{\sigma} = xC + (1 - x)D$. We assume that the population is large, so in pairwise random meetings, it is *as if* any player meets an opponent who plays the mixed strategy $\bar{\sigma}$. The payoff from the respective strategies, C and D , is given by:

$$\pi(C, \bar{\sigma}) = 2x, \pi(D, \bar{\sigma}) = 1 + 2x. \quad (14.36)$$

Figure 14.3 Graph of the replicator dynamics for the PD game.

The payoff of the average strategy against itself is given by

$$\pi(\bar{\sigma}, \bar{\sigma}) = x\pi(C, \bar{\sigma}) + (1-x)\pi(D, \bar{\sigma}) = 1+x. \quad (14.37)$$

The replicator dynamics in (14.25) imply that the time evolution of the fraction of the population that plays strategy C is given by

$$\dot{x} = x[\pi(C, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})]. \quad (14.38)$$

Substituting (14.36), (14.37) in (14.38), we get a first order non-linear differential equation.

$$\dot{x} = f(x) = x(x-1). \quad (14.39)$$

The steady state, $\bar{x}$, is found by solving $\dot{x} = 0 \Leftrightarrow x(x-1) = 0$, which has two solutions shown in Figure 14.3 (recall that x lies between 0 and 1)

$$\bar{x} = 0, \bar{x} = 1. \quad (14.40)$$

The steady state $\bar{x} = 0$ corresponds to an equilibrium in which everyone plays D, while in the steady state $\bar{x} = 1$ everyone plays C.

Recall that the set of ESS is a subset of the set of steady states of the replicator dynamics (see Figure 14.2). We wish to check if either of the two steady states (C, C) or (D, D) is an ESS. Using the *primary criterion* for ESS in Definition 14.4, D is ESS if $\pi(D, D) > \pi(C, D)$, which is true (see the payoff matrix in Figure 14.1), hence, D is an ESS. On the other hand, the state C is neither a Nash equilibrium nor an ESS.

What is the relation of ESS to the asymptotically stable states of the replicator dynamics in this example? Figure 14.3 shows a plot of the replicator dynamics in (14.39). Using the fact that $\frac{1}{x(x-1)} = \frac{-1}{x} + \frac{1}{(x-1)}$, the differential equation in (14.39) can be written in the *variable separable form*.

$$\int \left[\frac{-1}{x} + \frac{1}{(x-1)} \right] dx = \int dt.$$

A simple calculation shows that the solution is given by

$$x(t) = \left[1 - e^t \left(1 - \frac{1}{x(0)} \right) \right]^{-1}. \quad (14.41)$$

Taking the limits on both sides in (14.41) we get that

$$\lim_{t \rightarrow \infty} x(t) = \begin{cases} 0 & \text{if } x(0) > 1 \\ 1 & \text{if } x(0) = 1 \\ 0 & \text{if } x(0) < 1 \end{cases}. \quad (14.42)$$

Equation (14.42) brings out the important role of *history*, or initial conditions, in determining the steady state that the replicator dynamics gravitates towards. Unless all individuals begin with the play of strategy *C* (i.e., $x(0) = 1$), the entire population always drifts off to $x(t) = 0$, i.e., all play *D*. Thus, strategy *C* is an unstable steady state. Alternatively, one may check for stability in the following direct manner. From (14.39), $f'(x) = 2x - 1$, hence, $f'(0) = -1 < 0$, and $f'(1) = 1 > 0$. Using standard stability arguments (see Appendix A), the ESS, $\bar{x} = 0$, is also the stable equilibrium, while $\bar{x} = 1$ is an unstable steady state.

Multiple equilibria are a pervasive problem in standard game theory. Evolutionary game theory provides a *history-dependent refinement* of Nash equilibrium.

DYNAMIC PRISONER'S DILEMMA GAME

In evolutionary game theory, individuals are hardwired to play certain strategies. However, the hardwired strategies can be fairly sophisticated. Furthermore, in repeated games, hardwired strategies, of any complexity, depend on the history of play so far. In order to illustrate this point in a simple example, consider a twice repeated version of the prisoner's dilemma. As usual, in each of the two periods, two players from the population are randomly matched to play the game.

Three possible strategies in the twice repeated game are: always cooperate (*C*), always defect (*D*), or tit-for-tat (*T*); these were examined in a well-known study by Axelrod and Hamilton (1981). An individual who uses strategy *T*, cooperates in the first period, but in the second period, chooses the following history-contingent action: cooperate if the opponent cooperated in period 1, and defect if the opponent defected in period 1 (tit-for-tat). The payoff matrix, shown in Figure 14.4, adapts the single period payoffs in Figure 14.1, to two periods. Intertemporal payoffs are simply the sum of payoffs over the two periods (no discounting is applied).

When two players who are hardwired to play *C* (for both periods) meet, they each get a payoff of $2 + 2 = 4$. Similarly, when two *D* players meet, they each get a payoff of $1 + 1 = 2$. When a *C* player meets a *D* player, the former gets $0 + 0 = 0$, and the latter gets $3 + 3 = 6$. When a *T*

	C	D	T
C	4, 4	0, 6	4, 4
D	6, 0	2, 2	4, 1
T	4, 4	1, 4	4, 4

Figure 14.4 Payoff matrix for the two-period tit-for-tat game.

player meets a C player, then both cooperate in both periods, so each gets $2 + 2 = 4$. When a T player meets an opponent who plays D , then, the T player plays C in the first period, and D in the second period (for a payoff of $0 + 1 = 1$), while the D player simply plays D in both periods for a payoff of $3 + 1 = 4$.

The strategy C is weakly dominated by strategies D , and T , hence, it cannot be an ESS (see Proposition 14.3). Let us focus on the remaining strategies D and T ; the relevant payoffs are given in italics in the symmetric, lower right, 2×2 submatrix in Figure 14.4. There are two Nash equilibria, (D, D) and (T, T) .

We wish to check if T is an ESS, starting from a population in which all play T . Applying the primary criterion for ESS (Definition 14.4), T is an ESS if $\pi(T, T) > \pi(D, T)$. But $\pi(T, T) = \pi(D, T) = 4$, hence, the primary criterion cannot distinguish between the two strategies. The secondary criterion (Definition 14.4) requires $\pi(T, D) > \pi(D, D)$. However, $\pi(T, D) = 1$, $\pi(D, D) = 2$, hence, the strategy T is not an ESS. By contrast, starting from a population in which all play D , let us introduce a small fraction of mutants who play T . In this case, $\pi(D, D) > \pi(T, D)$, hence, the strategy D is the only ESS in the game. Thus, ESS allows us to choose among multiple Nash equilibria.

Consider the replicator dynamics when there are only two strategies, D and T . Suppose that the established strategy is D , and a fraction x of the population mutates to play the strategy T . Thus, the average strategy is $\bar{\sigma} = xT + (1 - x)D$. Individuals are randomly paired, once, to play the sequential two-period prisoner's dilemma game. Players play pure strategies only, either T or D . The payoffs from playing the respective strategies, D and T , against the average strategy are given by,

$$\pi(D, \bar{\sigma}) = 2(1 - x) + 4x = 2(1 + x), \quad (14.43)$$

$$\pi(T, \bar{\sigma}) = (1 - x) + 4x = 1 + 3x. \quad (14.44)$$

The payoff of the average strategy against itself is given by

$$\pi(\bar{\sigma}, \bar{\sigma}) = x\pi(T, \bar{\sigma}) + (1 - x)\pi(D, \bar{\sigma}) = x^2 + x + 2. \quad (14.45)$$

The replicator dynamics are given by

$$\dot{x} = x[\pi(T, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})]. \quad (14.46)$$

Substituting (14.44), (14.45), in (14.46) we have

$$\dot{x} = f(x) = x(1 - x)(x - 1). \quad (14.47)$$

There are two steady states: $\bar{x} = 0$ and $\bar{x} = 1$. Let us now check for the asymptotic stability of these steady states. From (14.47), $f'(x) = -3x^2 + 4x - 1$, hence, $f'(0) = -1 < 0$, and $f'(1) = 0$. Thus, only $\bar{x} = 0$ (where none play T) satisfies the condition for asymptotic stability. The dynamics are shown in Figure 14.5.

In the static and dynamic prisoner's dilemma games, an ESS is a *monomorphic equilibrium*. In our next example, we consider the possibility of a *polymorphic equilibrium*.

Figure 14.5 Dynamics of the tit-for-tat strategy in a repeated prisoner's dilemma game.

	C	M
C	0, 0	-2, 2
M	2, -2	-4, -4

Figure 14.6 Payoff matrix for the game of chicken.

14.6.2 *The game of chicken: polymorphic equilibria*

We now consider the game of chicken. Several versions of the game are given in the literature. In the most common version, two drivers race simultaneously towards a cliff. The one who stops first (strategy C, which is short for “chicken”) loses, and the one who stops last (strategy M, for “macho”) wins.

The symmetric normal form is given in Figure 14.6. There are two pure strategy Nash equilibria, (C, M) and (M, C) , and a mixed strategy Nash equilibrium in which each of the pure strategies is played with probability one half. None of the steady states, (C, C) and (M, M) , satisfy the conditions for an ESS because the set of ESS is a subset of the set of Nash equilibria.

Let us now use the replicator dynamics to look at the evolution of each of the pure strategies in the population. Suppose that initially, the prevalent strategy in the population is C. Consider an invasion by the mutant strategy, M, which is played by a fraction, x , of the population. The average strategy in the population is given by $\bar{\sigma} = xM + (1 - x)C$. We can now compute the following payoffs against the average strategy:

$$\pi(C, \bar{\sigma}) = -2x; \pi(M, \bar{\sigma}) = 2(1 - 3x). \quad (14.48)$$

$$\pi(\bar{\sigma}, \bar{\sigma}) = (1 - x)\pi(C, \bar{\sigma}) + x\pi(M, \bar{\sigma}) = -4x^2. \quad (14.49)$$

Using the replicator dynamics, we get

$$\dot{x} = x[\pi(M, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})]. \quad (14.50)$$

Substituting (14.48), (14.49) in (14.50), we get

$$\dot{x} = f(x) = x(4x^2 - 6x + 2). \quad (14.51)$$

Figure 14.7 A plot of the dynamic equation of motion in the game of chicken.

A plot of $f(x)$ is shown in Figure 14.7. There are three steady states, $\bar{x} = 0$, $\bar{x} = 0.5$, and $\bar{x} = 1$. To check for stability, note that $f'(x) = 12x(x - 1) + 2$. Hence, $f'(0) > 0$, and $f'(1) > 0$, but $f'(0.5) < 0$, thus, the only stable steady state is $\bar{x} = 0.5$.

The asymptotic solution is a polymorphic equilibrium in which half the individuals play C , while the other half play M . The monomorphic equilibrium in which all play C ($\bar{x} = 0$) is unstable because a small number of mutants who play M will be very successful; they get $2 > 0$. Analogously, the monomorphic equilibrium in which everyone is macho is unstable. In this case, there are too many people who are headed for the cliff, and each gets a payoff of -4 ; an encroachment by a small number of mutants who play C will ensure a payoff $-2 > -4$. Thus, the only stable equilibrium is an interior one.

So far, we have restricted attention only to pure strategies. Now consider the mixed strategy W that puts equal weight on the pure strategies C and M , so $W = \frac{1}{2}C + \frac{1}{2}M$. We now wish to check if W is an ESS, when W is the initially prevalent strategy. First check if W can be invaded, sequentially, by a mutant population that plays the pure strategy M or C ; the fraction of the mutant population at time t is x_t . A simple calculation gives the following payoffs.

$$\pi(W, W) = \frac{1}{2} \left\{ \frac{1}{2}\pi(C, C) + \frac{1}{2}\pi(C, M) \right\} + \frac{1}{2} \left\{ \frac{1}{2}\pi(M, C) + \frac{1}{2}\pi(M, M) \right\} = -1. \quad (14.52)$$

$$\pi(W, M) = \frac{1}{2}\pi(C, M) + \frac{1}{2}\pi(M, M) = -3. \quad (14.53)$$

$$\pi(W, C) = \frac{1}{2}\pi(M, C) + \frac{1}{2}\pi(C, C) = 1.$$

$$\pi(M, W) = \frac{1}{2}\pi(M, C) + \frac{1}{2}\pi(M, M) = -1. \quad (14.54)$$

$$\pi(C, W) = \frac{1}{2}\pi(C, C) + \frac{1}{2}\pi(C, M) = -1. \quad (14.55)$$

Let us first check if W is an ESS. W is an ESS against M if $\pi(W, W) > \pi(M, W)$. But $\pi(W, W) = \pi(M, W)$, hence, the primary criterion is not decisive. A similar issue arises when

the mutants play C because $\pi(W, W) = \pi(C, W)$. Thus, we need to resort to the secondary criterion. For mutations involving pure strategies M, C , one at a time, we can check the following.

$$W \text{ against } M : \pi(W, M) > \pi(M, M) \Leftrightarrow -3 > -4.$$

$$W \text{ against } C : \pi(W, C) > \pi(C, C) \Leftrightarrow 1 > 0.$$

Based on the secondary criterion, W is an ESS against successive mutations to strategies M and C .

14.6.3 Non-existence of an asymptotically stable equilibrium

In evolutionary game theory, an asymptotically stable steady state may not exist if there are more than two strategies, even when players play *completely mixed strategies* (i.e., all pure strategies are played with a strictly positive probability). Consider, for instance, a two-player zero-sum game, the *rock-scissors-paper game*. The normal form is shown in Figure 14.8.

There are three strategies, rock (R), paper (P), and scissors (S). When players who play identical strategies meet, the payoffs are $(0, 0)$; see the payoffs along the diagonal. When strategies are different, one strategy wins, for a payoff of 1, and the other loses, for a payoff of -1 . R wins against S , S wins against P , and P wins against R .

There are no pure strategy Nash equilibria in this game. Denote the probability of play of R, S , and P , respectively, by σ_1, σ_2 , and $1 - \sigma_1 - \sigma_2$. In the unique Nash equilibrium in mixed strategies, each of the three strategies is played with equal probability, so

$$\sigma^N = (\sigma_1, \sigma_2, 1 - \sigma_1 - \sigma_2) = \left(\frac{1}{3}, \frac{1}{3}, \frac{1}{3}\right).$$

We have already shown that asymptotically stable steady states of the replicator dynamics and the ESS are both subsets of Nash. Thus, the unique Nash equilibrium, σ^N , is the only candidate strategy profile that could be both an ESS and an asymptotically stable state. Let the population proportions playing the three strategies, R, S , and P , at time t be, respectively $x_t(R)$, $x_t(S)$, and $1 - x_t(R) - x_t(S)$. The average population strategy, $\bar{\sigma}$, is given by

$$\bar{\sigma} = x_t(R)R + x_t(S)S + (1 - x_t(R) - x_t(S))P.$$

Since we have a zero-sum game, for any pair of strategies, the payoff from the average strategy against the average strategy is zero, i.e., $\pi(\bar{\sigma}, \bar{\sigma}) = 0$. Also note that

$$\pi(R, \bar{\sigma}) = x_t(S) - [1 - x_t(R) - x_t(S)], \quad (14.56)$$

	R	S	P
R	0, 0	1, -1	-1, 1
S	-1, 1	0, 0	1, -1
P	1, -1	-1, 1	0, 0

Figure 14.8 The rock-scissors-paper game.

$$\pi(S, \bar{\sigma}) = -x_t(R) + [1 - x_t(R) - x_t(S)]. \quad (14.57)$$

The replicator dynamics is given by the following system of two differential equations.¹³

$$\dot{x}_t(R) = x_t(R) [\pi(R, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})]. \quad (14.58)$$

$$\dot{x}_t(S) = x_t(S) [\pi(S, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})]. \quad (14.59)$$

Using $\pi(\bar{\sigma}, \bar{\sigma}) = 0$, and (14.56), (14.57), we can rewrite (14.58), (14.59) as follows.

$$\dot{x}_t(R) = f_1(x_t(R), x_t(S)) = x_t(R) [2x_t(S) + x_t(R) - 1]. \quad (14.60)$$

$$\dot{x}_t(S) = f_2(x_t(R), x_t(S)) = x_t(S) [-2x_t(R) - x_t(S) + 1]. \quad (14.61)$$

To find the interior steady state of the system, set $\dot{x}_t(R) = \dot{x}_t(S) = 0$. This gives us two equations in two unknowns, $2x_t(S) + x_t(R) - 1 = 0$ and $-2x_t(R) - x_t(S) + 1 = 0$. The solution to these equations gives the steady state:

$$\mathbf{x}^* = (x^*(R), x^*(S), x^*(P)) = \left(\frac{1}{3}, \frac{1}{3}, \frac{1}{3}\right).$$

(14.60), (14.61) is a system of two non-linear differential equations. To check for the stability of the steady state, we need to evaluate the Jacobian of $\mathbf{f} = (f_1, f_2)$ at the steady state $\mathbf{x}^*$:

$$D\mathbf{f}(\mathbf{x}^*) = \begin{bmatrix} \frac{\partial f_1(\mathbf{x}^*)}{\partial x_t(R)} & \frac{\partial f_1(\mathbf{x}^*)}{\partial x_t(S)} \\ \frac{\partial f_2(\mathbf{x}^*)}{\partial x_t(R)} & \frac{\partial f_2(\mathbf{x}^*)}{\partial x_t(S)} \end{bmatrix} = \begin{bmatrix} \frac{1}{3} & \frac{2}{3} \\ -\frac{2}{3} & -\frac{1}{3} \end{bmatrix}.$$

To find the eigenvalues, solve for $|D\mathbf{f}(\mathbf{x}^*) - \lambda I| = 0$. This gives the equation $9\lambda^2 + 3 = 0$. The two complex roots are $0 \pm i\sqrt{\frac{1}{3}}$. When the real part of the eigenvalue is zero, the steady state of the system is given by a neutrally stable center. Furthermore, the center is surrounded by closed orbits. This is shown in Figure 14.9. So, unless the dynamical system starts off in the steady state, it will never approach the steady state. Thus, there are no asymptotically stable steady states. Since the set of ESS is a subset of these states, an ESS does not exist in this case. It turns out that a small amount of noise in the payoffs can alter these results. One of the exercises asks you to solve such a problem.

14.6.4 A two-population model of coordination

Consider the coordination game shown in Figure 14.10. Two players, the row player (player 1) and the column player (player 2), can choose either action A or D . If the players coordinate on the same action, they have a payoff of 1, otherwise they get a payoff of 0. There are two Nash equilibria in the game, (A, A) and (D, D) . There is also a mixed strategy Nash equilibrium in which both players play A and D with equal probability

¹³ The time path of the evolution of $x_t(P)$ can be found residually from $x_t(P) = 1 - x_t(R) - x_t(S)$.

Figure 14.9 Orbits for the rock-scissors-paper game.

	A	D
A	1, 1	0, 0
D	0, 0	1, 1

Figure 14.10 A two-player coordination game.

Suppose that there are two separate populations of players 1 and 2, who are randomly matched each period. The respective fractions of populations 1 and 2 who play A are x and y . Thus, the average strategies of the two populations are $\bar{\sigma}_1, \bar{\sigma}_2$:

$$\bar{\sigma}_1 = xA + (1-x)D, \quad \bar{\sigma}_2 = yA + (1-y)D.$$

Let π_1 and π_2 denote the payoffs in populations 1 and 2. Using (14.35), the replicator dynamics for the case of two populations is written as:

$$\dot{x}_t = x_t [\pi_1(A, \bar{\sigma}_2) - \pi_1(\bar{\sigma}_1, \bar{\sigma}_2)]. \quad (14.62)$$

$$\dot{y}_t = y_t [\pi_2(A, \bar{\sigma}_1) - \pi_2(\bar{\sigma}_2, \bar{\sigma}_1)]. \quad (14.63)$$

We can now compute the following payoffs in both populations.

$$\pi_1(A, \bar{\sigma}_2) = y, \quad \pi_1(D, \bar{\sigma}_2) = 1 - y, \quad \pi_2(A, \bar{\sigma}_1) = x, \quad \pi_2(D, \bar{\sigma}_1) = 1 - x. \quad (14.64)$$

$$\pi_1(\bar{\sigma}_1, \bar{\sigma}_2) = x\pi_1(A, \bar{\sigma}_2) + (1-x)\pi_1(D, \bar{\sigma}_2) = 1 - x - y(1 - 2x). \quad (14.65)$$

$$\pi_2(\bar{\sigma}_2, \bar{\sigma}_1) = y\pi_2(A, \bar{\sigma}_1) + (1-y)\pi_2(D, \bar{\sigma}_1) = 1 - x - y(1 - 2x). \quad (14.66)$$

Substituting (14.64)–(14.66) in (14.62) and (14.63), we get.

$$\dot{x}_t = f_1(x_t, y_t) = x_t(2y_t - 1)(1 - x_t). \quad (14.67)$$

$$\dot{y}_t = f_2(x_t, y_t) = y_t(2x_t - 1)(1 - y_t). \quad (14.68)$$

Figure 14.11 Coordination game in the two-population case.

Setting $\dot{x}_t = \dot{y}_t = 0$, we can find the following steady states of the system.

$$(\bar{x}, \bar{y}) = (0, 0), (1, 0), (0, 1), (1, 1), \left(\frac{1}{2}, \frac{1}{2}\right).$$

To determine the asymptotic stability of the steady states, we first form the Jacobian of the appropriate matrix.

$$Df(\bar{x}, \bar{y}) = \begin{bmatrix} \frac{\partial f_1(\bar{x}, \bar{y})}{\partial x_t} & \frac{\partial f_1(\bar{x}, \bar{y})}{\partial y_t} \\ \frac{\partial f_2(\bar{x}, \bar{y})}{\partial x_t} & \frac{\partial f_2(\bar{x}, \bar{y})}{\partial y_t} \end{bmatrix} = \begin{bmatrix} (2y_t - 1)(1 - 2x_t) & 2x_t(1 - x_t) \\ 2y_t(1 - y_t) & (2x_t - 1)(1 - 2y_t) \end{bmatrix}.$$

We now check the stability of each of the steady states, using the relevant stability conditions.

1. $(\bar{x}, \bar{y}) = (0, 0)$: The two repeated eigenvalues are $r_1 = -1$ and $r_2 = -1$, hence, this is an asymptotically stable steady state.
2. $(\bar{x}, \bar{y}) = (1, 0)$: The two repeated eigenvalues, $r_1 = 1$ and $r_2 = 1$, are positive. Thus, the state $(1, 0)$ is asymptotically unstable.
3. $(\bar{x}, \bar{y}) = (0, 1)$: The two repeated eigenvalues are $r_1 = 1$ and $r_2 = 1$, so the state $(1, 0)$ is asymptotically unstable.
4. $(\bar{x}, \bar{y}) = (1, 1)$: The two repeated eigenvalues are $r_1 = -1$ and $r_2 = -1$, hence, this is an asymptotically stable steady state.
5. $(\bar{x}, \bar{y}) = (\frac{1}{2}, \frac{1}{2})$: The two eigenvalues are $r_1 = \frac{1}{2}$ and $r_2 = -\frac{1}{2}$. One of the eigenvalues is positive, and the other is negative, so we have a saddle point.

Figure 14.11 shows some representative trajectories of the dynamic system. The $\dot{x} = 0$ locus is shown as the horizontal line at $y = 1/2$, and the $\dot{y} = 0$ locus is shown as the vertical line at $x = 1/2$. The direction of motion is shown by arrows in each of the resulting four regions. If the proportion of any population that plays A exceeds $1/2$, then the proportion of the other population that plays A is also growing. Hence, in the region $x > 1/2$ and $y > 1/2$, the proportion of each population playing A is growing. In this case, one converges to the stable steady state $(1, 1)$. In the opposite case, $x < 1/2$ and $y < 1/2$, one converges to the stable steady state $(0, 0)$. Finally, the unique saddlepath is shown as the SS curve, which converges to the steady state $(\frac{1}{2}, \frac{1}{2})$.

14.7 Playing the field

In some animal interactions, it is not possible to isolate pairwise interactions, and it appears that animals are playing against all other animals in the population. Animals are then said to be *playing the field*. Our brief formalization here follows Hammerstein and Selten (1994). Suppose that Σ is the convex hull of finitely many points. Elements of Σ may be mixed strategies (as in this chapter), but more generally they could also be interpreted as vectors of biological parameters. For consistency with the rest of the chapter, we refer to elements of Σ as strategies.

Suppose that we are interested in the monomorphic stability of some strategy $p \in \Sigma$. Let there be an invasion by a fraction $\varepsilon \in [0, 1]$ of mutants who play another strategy, $q \in \Sigma$. Consider a *bimorphic population state* $z = (1 - \varepsilon)p + \varepsilon q \in \Sigma$.

Definition 14.7 (*Population game*): A population game $G = (n, \Sigma, \pi)$ is a triplet that specifies the number of players in the population n , the set Σ , and a payoff function π with the following properties.

- (i) The set Σ is the convex hull of finitely many points.
- (ii) The payoff function $\pi : \mathbb{R}^m \times \mathbb{R}^m \rightarrow \mathbb{R}$. $\pi(r, z)$ is the payoff to a player who follows strategy $r \in \Sigma$ and plays against a field where the average strategy is $z = (1 - \varepsilon)p + \varepsilon q \in \Sigma$, $\varepsilon \in [0, 1]$. We require that $\pi(r, z)$ be defined for all $r, z \in \Sigma$.
- (iii) For $\varepsilon = 0$ we have $z = p$. We require that $\pi(r, p)$ does not depend on q .

The strategy $r \in \Sigma$ is a best response to $p \in \Sigma$ if $\pi(r, p) \geq \pi(q, p)$ for all $q \in \Sigma$. If r is the unique best response, then it is a strict best reply to p .

Definition 14.8 (*ESS in the population game; Hammerstein and Selten, 1994*): Consider the population game $G = (n, \Sigma, \pi)$ (Definition 14.7). A strategy $p \in \Sigma$ is an evolutionary stable strategy if:

- (a) *Equilibrium condition or primary criterion*: $\pi(p, p) > \pi(q, p)$ for all $q \in \Sigma$.
- (b) *Stability condition or secondary criterion*: Consider the set of best replies to p that are different from p , $BR(p) = \{r \neq p : \pi(p, p) = \pi(r, p), r, p \in \Sigma\}$. For any $r \in BR(p)$ there exists ε_r such that

$$\pi(p, (1 - \varepsilon)p + \varepsilon r) > \pi(r, (1 - \varepsilon)p + \varepsilon r) \text{ for all } \varepsilon \in (0, \varepsilon_r).$$

The ESS result in Definition 14.8 can be stated for a uniform invasion barrier in which ε_r is independent of $r \in BR(p)$. This requires suitable restrictions on the payoff function.¹⁴ For a further discussion of these issues the reader may consult Hammerstein and Selten (1994).

14.8 Gene-culture coevolution

Part 2 of the book considered a range of human prosocial behaviors. What accounts for such prosocial concerns among humans? Why are *character virtues* possessed by many humans, and valued by most? Two sorts of contrasting answers were given to these questions in two different behavioral sciences. Economics provided an account based on models of self-interest that form

¹⁴ For instance, $\pi(r, p)$ is required to be linear in the first argument; see Crawford (1990a,b).

the basis of neoclassical economics. There is now compelling evidence against the purely self-interested approach that is reviewed in Part 2.

At the other extreme, sociology advocated the *cultural hegemony model* in which individuals passively accepted the dominant culture that is the source of the relevant norms associated with various social roles; the dominant culture may have been put into place by the ruling or dominant class. The predictions of this model too are not consistent with the evidence. There are many instances in which the dominant cultures are replaced by minority counter cultures, or even assimilated by them. For instance, African Americans in the era of the civil rights movement, or the failed attempts to indoctrinate people into socialist morality in the former Soviet Union; see Gintis et al. (2014).

An alternative is the model of *gene-culture coevolution*, which is the study of the transmission of genes and culture from one generation to the next, as well as the interaction between them.

14.8.1 Basics of gene-culture coevolution

Bowles and Gintis (2011, p. 13) define *culture* as “the ensemble of preferences and beliefs that are acquired by means other than genetic transmission.” Wilson (2012, p. 213) defines culture thus: “culture is the combination of traits that distinguishes one group from another. A cultural trait is a behavior that is either first invented within a group, or else learned from another group, then transmitted among members of the group.” These definitions can be used to identify the presence of cultures in other animals as well. Culture is typically transmitted by imitation. Examples include: Chimpanzees that use a branch of a tree, stripped of its leaves, poke it into a termite mound, and then eat the soldier termites that stick to the branch; or the fishing practices of dolphins.

Interestingly, the Neanderthals exhibited very little culture in the form of art and ornaments, in contrast to their close relatives, *Homo sapiens*, despite having a larger brain size. Yet, it appears that *Homo sapiens* overpowered, and probably eliminated the Neanderthals (Wilson, 2012). What accounts for the success of *Homo sapiens* relative to other related species, and their unprecedented increase in brain size over time? Several factors have been suggested.

An influential line of research, associated mainly with the names of J. Tooby, L. Cosmides, and S. Pinker, advances the *cognitive niche hypothesis*.¹⁵ In this view, non-human animals typically possess *domain-specific* or *dedicated intelligence* that is suitable for adapting to the particular environment that the animal lives in. In contrast, humans possess *improvisational intelligence*, which implies sufficient learning flexibility in the brain that allows them to adapt quickly to new and strange environments. Such adaptation, a form of culture, is then quickly shared with others who avoid the information acquisition costs of adaptation.

Another important element behind the success of *Homo sapiens* may well be their willingness and instinct to engage in cooperative activities and shared goals. For instance, bipedalism, the development of fire, establishments of campsites, agriculture, and the development of *eusociality*. This has been termed as the *cultural intelligence hypothesis* in which the development of language played a key role; see, for instance, Tomasello (1999).¹⁶

Boyd et al. (2011) do not deny the importance of superior human cognitive abilities embodied in the cognitive niche hypothesis. However, they argue that by itself this cannot provide an adequate explanation of human adaptability. They argue instead for the *cultural niche hypothesis* in

¹⁵ See, for instance, Barrett et al. (2007), Tooby and Cosmides (1992), and Pinker (2010).

¹⁶ For a fascinating account of the development of language, see Wilson (2012, ch. 22).

which humans learn over many generations, and evolve culturally transmitted bodies of knowledge in which the causal link between variables is often unknown. Consider the following two examples.

Children are programmed to learn by imitation. In experiments, even when learning involves irrelevant steps that are clearly identified as unnecessary by visual inspection, children copy all steps, including the irrelevant steps, but chimpanzees omit the irrelevant steps. Humans have also learned to use chilli peppers in meat, despite their unpalatable taste, to protect themselves against food-borne pathogens. However, this occurred prior to an understanding of the causal mechanism. Boyd et al. (2011, p. 10924) close with the quote: “So it does not make sense to ask, does culture overcome biology? The right question to ask is, how do genetic and cultural inheritance interact to produce the observed patterns of human psychology and behavior?”

There is now a compelling case for *gene–culture coevolution*.¹⁷ To motivate the theory, one may distinguish between three kinds of changes in the environment, and our response to them.

1. Adaptability to extremely slow changes in the environment are directly encoded into our DNA.
2. It is not efficient to code extremely rapid changes in the environment directly into the DNA. Genetic changes are slow and conservative. In humans, the ability to respond to rapid environmental change is incorporated into brain structures that allow for a flexible capacity to deal with novel situations as a form of problem solving.
3. For environmental changes that are neither very rapid nor very slow, a third form of response is optimal. This takes the form of non-genetic or *epigenetic changes*. These are physiological developments that are not genetically hardwired; neither are they involuntary reflexes such as eyeblinks; for a review see Gintis (2009b).

Wilson (2012, p. 194) gives a cogent introduction to epigenetic changes: “The behaviors created by epigenetic rules are not hardwired like reflexes. It is the epigenetic rules instead that are hardwired, and hence compose the true core of human nature. These behaviors are learned, but the process is what psychologists call “prepared.” In prepared learning, we are innately predisposed to learn, and thereby reinforce one option over another.” For instance, children learn a fear of snakes very rapidly, but do not a fear pigeons or rabbits. *Prepared learning* allows us to find a landscape as beautiful, but we would not classify an open waste pit as beautiful.¹⁸ This view is in contrast to the *blank slate view of the human mind* in which language and culture are learned through the environment.

A prominent example of an epigenetic transmission mechanism is *culture*. Humans, over their evolutionary history, are *predisposed* to learn various aspects of culture, e.g., language, through three channels. The *vertical channel* (parents to children), the *oblique channel* (from non-parent elders to younger people), and the *horizontal channel* (between peers). This is a form of epigenetic transmission because no changes of the human DNA are involved. For instance, no gene that is exclusively responsible for cooperative behavior has been discovered. Bowles and Gintis (2011, p. 16) write: “the idea of one to one mapping between genes and behavior is unlikely given what is now known about gene expression, and is implausible in light of the complexity

¹⁷ For early, and pioneering, work on gene–culture coevolution, see Lumsden and Wilson (1980, 1981). For a fascinating, authoritative, and non-technical, introduction, see Wilson (2012). For a focus on cultural evolution, see Cavalli-Sforza and Feldman, (1982), Boyd and Richerson (1985), Dunbar (1993), and Richerson and Boyd (2004).

¹⁸ Lumsden and Wilson (1980, 1981) stressed the importance of the human instinct, as arising through prepared learning.

and cultural variation of cooperative behaviors.” For these reasons, we interpret culture at the level of the observed phenotype rather than the unobserved genotype.

The evidence suggests that culture is directly encoded in the brain (Gintis, 2011, pp. 379–80). For instance, the prefrontal cortex is associated with human morality. Individuals with a damaged prefrontal cortex engage in several kinds of antisocial, and even sociopathic behaviors. Many of the brain structures associated with culture are either unique to humans, or are best developed in them relative to close primate relatives.

The ideas are best conveyed by examples.

Example 14.2 (*Niche construction*) *Niche construction refers to the ability of an organism to influence the environment around it, and to epigenetically transmit this information from one generation to the next. As examples, Dawkins (2006) noted environmental constructs such as beaver dams, transmission of the social structure of bee hives across generations of bees, and species-specific hunting/mating practices of animals. An example of niche construction in humans is lactose tolerance (Wilson, 2012, ch. 20). In most of human evolutionary history, the production of the enzyme lactase that allows the digestion of milk, took place only among infants. However, with the development of herding, 9000 to 3000 years ago, a mutation that allowed for lactose tolerance in adults took place, and rapidly spread through the human population. In this example, the niche was the advent of domestication of cattle.*

Example 14.3 (*Cooperation and prosociality; Gintis, 2011*) *Unrelated or loosely related individuals in hunter-gatherer societies typically cooperated with each other in hunting, defence, and territorial acquisition. As Gintis (2011, p. 879) notes: “While some contemporary biological and economic theorists have attempted to show that such cooperation can be supported by self-regarding rational agents,¹⁹ the conditions under which their models work are implausible even for small groups.²⁰ Rather, the social environment of early humans was conducive to the development of prosocial traits, such as empathy, shame, pride, embarrassment, and reciprocity, without which social cooperation would be impossible.²¹” Such cooperative behavior is an epigenetic change that appears to have improved the fitness of the human species in that environment. This conclusion is supported by neuroscientific studies that identify particular brain regions that are responsible for these functions (such as empathy and prosociality).*

This view of human sociality is in contrast to the view that human altruism is a maladaptation in which humans mistakenly apply repeated game heuristics to static situations and/or mistake anonymous interactions for publicly observed interactions.²² There are two issues here. One is the evidence on the accuracy of this historical account. On this, Gintis (2011, p. 882) writes: “However, our understanding of contemporary hunter-gatherer societies indicates the lack of credibility of this argument, as do analyses of trade and migration patterns in Pleistocene.”²³ The second issue is the evidence from experimental games, which shows that human behavior in static and repeated games is quite different. Part 2 of the book explores this evidence in some detail. Furthermore, the evidence from the experiments of Andreoni

¹⁹ See, for instance, Alexander (1987), Fudenberg et al., (1994), and Trivers (1971).

²⁰ See, for instance, Boyd and Richerson (1988) and Gintis (2009b).

²¹ See, for instance, Sterelny (2011).

²² See, for instance, Haley and Fessler (2005), and Hagen and Hammerstein (2006).

²³ See, for instance, Bowles and Gintis (2011) and Fehr and Joseph (2004).

and Miller (2002) (see Part 2) shows that altruistic giving in dictator games does not arise from confusion; economic agents vary the amount of giving as the price varies.²⁴

Example 14.4 (*The physiology of communication; Gintis, 2009b, 2011*): In one of the most dramatic examples of gene–culture coevolution, the cultural development of oral communication, and the resulting fitness advantages, were supported by genetic changes that facilitated richer communication. Gintis (2011, pp. 380–1) outlines the relevant changes. These include: Expansion in the motor cortex region to facilitate speech production; development of brain regions such as Brocas and Wernicke’s areas, unique to humans, that facilitate grammatical speech; a gradual lowering of the larynx to increase the range and resonance of sounds; anatomical changes and developments in the tongue muscles that facilitate more precise speech; and changes in facial nerves and musculature that allowed a richer range of emotions to be displayed in a complementary manner with speech.

Example 14.5 (*The Westermarck effect; Wilson, 2012*) Humans instinctively avoid incest with others that they have been in contact with in early life, a phenomenon known as the Westermarck effect. Human children raised together up to the age of about 30 months avoid partnering to produce offspring. This tendency is shared with primate relatives such as chimpanzees and baboons. In humans, this tendency arises even if one is raised in early life with non-biological siblings. Wilson (2012, p. 202) writes: “it is evident that the human brain is programmed to follow a simple rule of thumb: Have no sexual interest in those whom you knew intimately during the earliest years of your life.” This is a cultural practice, and it is reinforced by taboos and social sanctions. Yet there are well-known genetic advantages from avoiding inbreeding. Hence, this is an example of gene–culture coevolution.

Example 14.6 (*Evolutionary political economy; Gintis et al., 2014*) Gintis et al. (2014) give a fascinating discussion of the gene–culture coevolution of dominance seeking, coalition formation, and the role of leadership in humans.²⁵ We encourage the interested reader to pursue the relevant references in their paper; what follows is a flavor of some of these fascinating issues.

The authors describe shared human evolutionary history with related primates, and demonstrate that humans have a genetic predisposition towards dominance seeking, and coalition formation. Most primate societies, except our closest relatives, the chimpanzees, do not engage in organized collective action, so they do not need leaders to coordinate their actions. Rather, in most primate societies, leadership is based on physical prowess, and the leader’s main role is to keep the peace between warring factions in the group.

Chimpanzees engage in two kinds of coalition building, rank changing and leveling. Rank changing coalitions arise when an individual takes over the leadership of a group, not necessarily because he is the strongest, but perhaps because he has a comparative advantage in coalition building. Leveling coalition formation occurs when males who are situated lower down in the chimp hierarchy, form a coalition to counter the resource appropriating tendency of the current leader. This is also known as reverse dominance hierarchy. For instance, one observes that female chimps in captivity make an attempt to neutralize “alpha-male bullies.” At least two factors played a role in the development of leadership in humans that was based not on physical prowess, but rather on the ability to motivate and persuade others. These

²⁴ However, the evidence from dictator games also shows that humans may be reluctant altruists and are less likely to give if they are guaranteed anonymity. We refer the reader to Part 2 for the details.

²⁵ Another lucid and fascinating source is Wilson (2012).

factors were: (1) The emergence and formation of leveling coalitions. (2) Humans developed lethal weapons so that there was a real threat to the life of the dominant male from other non-dominant males. By contrast, even in chimps, it is very difficult, without lethal weapons to kill the leader. Gintis et al. (2014, p. 24) give the determinants of the quality of persuasion among leaders: “Persuasion depends on clear logic, analytical abilities, a high degree of social cognition (knowing how to form coalitions and motivate others), and linguistic facility.” These leadership qualities (despite lacking superior physical prowess) are absent in other animals, although chimps seem to possess them in a more rudimentary form.

14.8.2 A formal model of cultural evolution

We now consider a formal model of cultural evolution (Gintis and Helbing, 2014).²⁶ Consider a single population of individuals, and a single cultural norm, A (short for *altruism*), that can be adopted, or not adopted. Suppose that at time t , the population is split into two categories. A fraction x_t adopts the norm A, and has fitness $1 - s$, $s \in (0, 1)$, while the remaining population fraction, $1 - x_t$, follows the alternative norm B (short for *selfishness*, or not A) and has fitness 1. Thus, the fitness of the selfish trait is higher than the fitness of the altruistic trait. The puzzle is to explain why, despite this fact, one observes the altruistic trait in humans.

In the initial period, there are n males and n females, so denote the total population size at time t by

$$P_t = 2n. \quad (14.69)$$

Males and females are randomly matched to produce offspring, so, depending on the categories of the matched pairs, these matching can be of the form AA, AB, BA, or BB.

Cultural transmission takes the following form.

1. In the *vertical channel* (parents to children), the offspring of AA parents are of type A, and the offspring of BB parents are type B. When parents are of mixed types (AB or BA), then half the offspring are type A, and half are type B.
2. In the *oblique channel*, a fraction $\gamma \in (0, 1)$ of type B children (of type AB, BA, and BB parents) are persuaded by *institutions*, or *other elders* who promote altruistic norms, to convert to type A. Anecdotal evidence supports the existence and strength of this channel. For instance, people typically encourage children to engage in moral, not immoral acts; to help others, not to steal from others; to tell the truth, and not lie. Institutions reward acts of bravery, not cowardice; the tax system gives tax deductions on charitable contributions, but imposes penalties for tax evasion. This channel is critical to the results below.
3. We also allow some players of type A to switch to type B in any period, on account of the higher fitness of the selfish trait (see below).

Recalling that the fractions of types A and B in the population are, respectively, x_t and $1 - x_t$, the number of distinct unions of each type are shown in Table 14.1.

²⁶ There is a rich literature on cultural transmission that typically uses a different transmission mechanism to the one we use here. For a model of cultural transmission motivated by an explanation of the inter-marriage rates and socialization among Protestants, Catholics, and Jews, see Bisin et al. (2004). For a survey of similar themes, see Bisin and Verdier (2011). Mengel (2008) considers cultural transmission of a norm of cooperation in a repeated prisoner's dilemma game in which not everybody adheres to a norm.

Table 14.1 Number of conjugal unions of each type.

	A	B
A	nx_t^2	$nx_t(1 - x_t)$
B	$nx_t(1 - x_t)$	$n(1 - x_t)^2$

Table 14.2 Number of offspring for each conjugal pair.

	A	B
A	$nx_t^2(1 - s)^2\beta$	$nx_t(1 - x_t)(1 - s)\beta$
B	$nx_t(1 - x_t)(1 - s)\beta$	$n(1 - x_t)^2\beta$

Each conjugal pair in Table 14.1 produces a new generation of offspring. Once a new generation is born at the end of the period, the previous generation dies. Let β be a parameter to be determined later, which ensures that the population grows at some rate $g(x_t)$ that depends on the fraction of altruists, x_t , at time t . Thus, the total population in the next time period, $t + 1$, equals

$$P_{t+1} = 2n(1 + g(x_t)).$$

In keeping with the idea of Darwinian fitness, the number of offspring of each conjugal pair in Table 14.1 is proportional to the product of the biological fitness of each pair of parents; see Table 14.2. For instance, the product of biological fitness of (i) AA parents is $(1 - s)^2$, (ii) AB or BA parents is $(1 - s)$, (iii) BB parents is 1. The multiplication by the parameter β allows one to capture the one-period population growth rate in each category.

The total number of offspring at time t , which equals the population at time $t + 1$ (because the previous generation dies off at the end of the period), is given by

$$P_{t+1} = nx_t^2(1 - s)^2\beta + 2nx_t(1 - x_t)(1 - s)\beta + n(1 - x_t)^2\beta. \quad (14.70)$$

The parameter β can now be found from the definition of the growth rate of population between periods t and $t + 1$

$$g(x_t) = \frac{P_{t+1} - P_t}{P_t}. \quad (14.71)$$

Substituting (14.69) and (14.70) into (14.71), we get

$$\beta = \frac{2(g(x_t) + 1)}{(1 - sx_t)^2}. \quad (14.72)$$

We can now find the fraction of offspring of each conjugal pair in Table 14.2. For instance, the proportion of offspring of AA parents is $\lambda_{AA} = \frac{nx_t^2(1-s)^2\beta}{P_{t+1}} = \frac{nx_t^2(1-s)^2\beta}{2n(1+g(x_t))}$. Substituting the value of β from (14.72), we get $\lambda_{AA} = \frac{x_t^2(1-s)^2}{(1-sx_t)^2}$. Proceeding in this manner, a simple calculation shows that the fractions of offspring of all types of conjugal pairs are given as follows.

$$\lambda_{AA} = \frac{x_t^2(1-s)^2}{(1-sx_t)^2}; \lambda_{AB} + \lambda_{BA} = \frac{2x_t(1-x_t)(1-s)}{(1-sx_t)^2}; \lambda_{BB} = \frac{(1-x_t)^2}{(1-sx_t)^2}. \quad (14.73)$$

We now wish to determine the fraction of altruists at time $t + 1$. We do this in a series of steps.

1. The vertical transmission channel ensures that the fraction λ_{AA} is comprised of all altruists because both parents are altruistic.
2. Consider now the offsprings of parents of types AB and BA. The fraction $\frac{1}{2}(\lambda_{AB} + \lambda_{BA})$ of offspring is altruistic by birth (vertical channel) and the remaining fraction, $\frac{1}{2}(\lambda_{AB} + \lambda_{BA})$ is selfish by birth (vertical channel). However, of the latter fraction that is selfish by birth, a fraction $(\gamma x_t) \frac{1}{2}(\lambda_{AB} + \lambda_{BA})$ is converted to the altruistic type on account of the oblique channel, where $\gamma \in (0, 1)$ is time invariant. Thus, the greater the fraction of altruists, x_t , in the population, the higher is the rate of conversion.
3. Finally, the fraction of individuals λ_{BB} are all selfish because both parents are selfish (vertical channel). Of this, a fraction $(\gamma x_t) \lambda_{BB}$ are converted to altruistic types on account of the oblique channel; the rate of conversion depends on the fraction of altruists, x_t , in the population.

Thus, the change in the fraction of altruists between time t and $t + 1$ is

$$x_{t+1} - x_t = \left[\lambda_{AA} + \frac{1 + \gamma x_t}{2} (\lambda_{AB} + \lambda_{BA}) + \gamma x_t \lambda_{BB} \right] - x_t. \quad (14.74)$$

Substituting (14.73) in (14.74), we get

$$x_{t+1} - x_t = \frac{x_t(1-x_t)(\gamma-s)}{(1-sx_t)}. \quad (14.75)$$

While it has been pedagogically simpler to outline the model in discrete time, it is easier to work in continuous time once the dynamic equation has been derived. The continuous time analog of (14.75) is given by the first order, non-linear, differential equation.

$$\dot{x}_t = \frac{x_t(1-x_t)(\gamma-s)}{(1-sx_t)}. \quad (14.76)$$

We now consider our second transmission channel. The fitness level of the selfish types is greater than the altruistic types. So should not an individual of type A wish to imitate the selfish trait of an individual of type B? To take account of this possibility, suppose that each individual i randomly samples the fitness of another member j , and switches to j 's type if the fitness of j is higher. Thus, only altruistic types switch to selfish types because their fitness is relatively lower ($1 - s < 1$).

There might be *informational* or *observational frictions* about the payoffs of others. Thus, the probability that any member of type A switches to type B, denoted by p , is directly proportion to the fitness difference between the two types, so $p = \sigma s$, where $\sigma \in (0, 1)$. The leakage of some A types to B types, through this channel, reduces the growth rate of altruistic types. In a large population, the probability that a type A player randomly meets a type B player is $x_t(1-x_t)$. Such a meeting results in a conversion of type A to B with probability p . Hence, once this imitation channel works itself out, the change in the altruistic population is given by a modification of (14.76)

$$\dot{x}_t = \frac{x_t(1-x_t)(\gamma-s)}{(1-sx_t)} - \sigma sx_t(1-x_t). \quad (14.77)$$

The two terms on the RHS in (14.77) represent two channels through which the altruistic types evolve over time. The first is the *cultural transmission mechanism* (vertical and oblique) that favors the altruistic norm. The second is the *standard replicator dynamics* that favors the relatively fitter cultural trait of selfishness. Let us rewrite (14.77) in a manner that makes the steady states fairly transparent.

$$\dot{x}_t = f(x_t) = x_t(1-x_t) \left[\frac{(\gamma-s)}{(1-sx_t)} - \sigma s \right]. \quad (14.78)$$

Proposition 14.12 Consider the first order non-linear differential equation given in (14.78).

(a) The three steady states are

$$\bar{x} = 0, \bar{x} = 1, \text{ and } \bar{x} = \frac{1}{s^2\sigma} (s + s\sigma - \gamma). \quad (14.79)$$

(b) For $s < s_c = \frac{\gamma}{1+\sigma}$, the unique stable steady state is $\bar{x} = 1$ where all individuals are altruistic.

(c) For intermediate levels of s : $s_c < s < s_-$, where s_- is defined in (14.80)

$$s_- = \frac{(1+\sigma) - \sqrt{(1+\sigma)^2 - 4\sigma\gamma}}{2\sigma}, \quad (14.80)$$

both $\bar{x} = 0$, and $\bar{x} = 1$ (all play A and all play B) are locally stable. In this case, $\bar{x} = \frac{1}{s^2\sigma} (s + s\sigma - \gamma)$ is an unstable equilibrium that separates the basins of attraction of the two stable equilibria.

(d) If $s_- < s$, then $\bar{x} = 0$ is the unique stable steady state.

Proof: (a) Set $f(x_t) = 0$ in (14.78) and solve out for the three roots to get (14.79).

(b) Differentiating $f(x_t)$ in (14.78), we get

$$f'(x_t) = \frac{-1}{(sx-1)^2} (s(1+\sigma)-\gamma + 2x(\gamma-s(1+\sigma+s\sigma))+sx^2(s+4s\sigma-\gamma+s^2\sigma)-2s^3x^3\sigma).$$

Let us evaluate f' at the three steady states in (14.79).

$$f'(0) = \gamma - s(1+\sigma). \quad (14.81)$$

$$f'(1) = \frac{-1}{(1-s)} (s^2\sigma - s(1+\sigma) + \gamma). \quad (14.82)$$

$$f'\left(\frac{1}{s^2\sigma} (s(1+\sigma) - \gamma)\right) = \frac{-1}{s(s-\gamma)} (\gamma - s(1+\sigma)) (\gamma - s(1+\sigma) + s^2\sigma). \quad (14.83)$$

We now sequentially check the stability condition, $f'(\bar{x}) < 0$, for the three steady states.

(bi) Steady state $\bar{x} = 0$: First note that

$$\gamma - s(1 + \sigma) \begin{matrix} \geq \\ \leq \end{matrix} 0 \text{ if } s_c = \frac{\gamma}{1 + \sigma} \begin{matrix} \geq \\ \leq \end{matrix} s. \quad (14.84)$$

Using (14.81) and (14.84), we get

$$\begin{cases} s < s_c & \Rightarrow \bar{x} = 0 \text{ is unstable.} \\ s > s_c & \Rightarrow \bar{x} = 0 \text{ is stable.} \end{cases}$$

(bii) Steady state $\bar{x} = 1$: The roots of the quadratic equation in s

$$s^2\sigma - s(1 + \sigma) + \gamma = 0, \quad (14.85)$$

are given by $s = \frac{(1+\sigma) \pm \sqrt{(1+\sigma)^2 - 4\sigma\gamma}}{2\sigma}$. Since $\sigma, \gamma \in (0, 1)$, we have $(1 + \sigma)^2 - 4\sigma\gamma > 0$, thus, both roots are real. Denote the smaller root by s_- ; this is given in (14.80). The larger root $s_+ = \frac{(1+\sigma) + \sqrt{(1+\sigma)^2 - 4\sigma\gamma}}{2\sigma} > 1$ is not feasible because $s \in (0, 1)$, so we shall ignore it. One can show that $s_- > s_c$. Since, the coefficient of s^2 in (14.85), $\sigma > 0$, so for any $s < s_c$ we have $s^2\sigma - s(1 + \sigma) + \gamma > 0$. Using (14.82) we have $f'(1) < 0$. Thus, $\bar{x} = 1$ is a stable steady state for $s < s_c$.

(biii) Steady state $\bar{x} = \frac{1}{s^2\sigma}(s + s\sigma - \gamma)$. One can check that in this case, for any $s < s_c$, we have $\bar{x} < 0$, which is not feasible.

Putting together (bi)–(biii), the only stable steady state when $s < s_c$ is $\bar{x} = 1$.

(c) Simple calculations show in this case that $f'(0) < 0$, and $f'(1) < 0$, so the intermediate steady state must satisfy $f'\left(\frac{1}{s^2\sigma}(s(1 + \sigma) - \gamma)\right) > 1$. Thus, the two extreme steady states are locally stable, while the intermediate steady state is unstable, and it separates the basins of attraction of the two stable equilibria.

(d) In this case $\bar{x} = \frac{1}{s^2\sigma}(s + s\sigma - \gamma) > 1$ is not feasible, and $f'(0) < 0$, but $f'(1) > 0$. Thus, $\bar{x} = 0$ is the only stable steady state. ■

Proposition 14.13 (*Fundamental Theorem of Sociology; Gintis and Helbing, 2014*) *In the model described above, altruistic norms persist in a cultural equilibrium only if there is a strictly positive rate of cultural transmission of altruism via social institutions, i.e., $\gamma > 0$.*

Proof: Suppose that there is an absence of cultural transmission of altruism through the oblique channel, so $\gamma = 0$. Substitute $\gamma = 0$ in (14.81), (14.82), and (14.83), and we have $f'(0) < 0$, but $f'(1) > 0$, and $f'\left(\frac{1}{s^2\sigma}(s(1 + \sigma))\right) > 0$. Thus, $\bar{x} = 0$ (all play B) is the unique stable steady state in which all individuals are selfish. ■

Proposition 14.12 reflects the opposing forces of altruistic cultural transmission, and the standard replicator dynamics that favors selfishness because it is relatively fitter. When the fitness advantages of the selfish trait are weak in the sense of low enough s , then everyone is altruistic (Proposition 14.12(b)). At the other extreme, when s is high enough, then the effect arising through replicator dynamics is so strong that cultural transmission is unable to have any effect in the stable steady state (Proposition 14.12(d)). However, in the absence of any cultural transmission $\gamma = 0$, everyone is selfish (Proposition 14.13). Thus, we have the important result that *cultural transmission is a necessary, but not sufficient condition for altruism to emerge in society.*

In this book we have, in many instances, reported the effect of cultural factors on empirical results. For instance, there are quite dramatic cultural effects in the ultimatum game results when it is played in diverse cultures (Henrich et al., 2001). The formal model of cultural transmission in this section is admittedly simple in that it treats two polar extremes of altruism and

selfishness. By modifying this model to consider a range of altruistic strategies, say, $A_1, \dots, A_m$, and allowing for a range of parameter values, one may be able to explain the cultural richness of the experimental results arising from various games. This model can also be used to underpin the emergence of social norms (see Part 4 of the book and Chapter 16) and various forms of other-regarding preferences and character virtues (see Part 2 of the book).

14.9 The evolution of altruism and reciprocity

Bowles and Gintis (2011) provide an authoritative evolutionary treatment of human cooperation. Their thesis rests on three main arguments, all backed by good evidence. First, humans have evolved institutions and cultural practices to (i) protect altruistic members from being exploited by selfish members, and (ii) to promote altruism. In addition to the role of leveling coalitions that we mention above, other methods include ostracism and punishment of deviants and free-riders who violate the cooperative norm, tax deductibility of charitable giving, awards for altruism and other character virtues. Second humans have internalized the norm of cooperation; the mechanism is similar to the evolutionary stability of the culturally transmitted altruistic strategy in Section 14.8.2 above. Third, competition for scarce resources favors groups who are relatively better at coordinating the acquisition of resources, e.g., territorial conquests.

Now we examine the evolutionary origins of cooperation, using a taxonomy suggested by Nowak (2006). Many other areas of behavioral economics are not as well underpinned by evolutionary foundations, hence, we omit a discussion of these. However, for non-exponential time preferences, see Sozou (1998) and Dasgupta and Maskin (2005), although only the latter can explain hyperbolic discounting. For a nice discussion of these issues, see Robson and Samuelson (2011).

The usage of the terms direct reciprocity, indirect reciprocity, and reciprocal altruism in this section follows the standard usage in biology. This usage is sometimes different from that in Part 2 in order to maintain coherence with the relevant literature.

14.9.1 *Kin selection and inclusive fitness*

The idea behind *inclusive fitness*, introduced by Hamilton (1963, 1964), comes from observations on the behavior of animals in which they provide costly assistance to other animals of the same species. For instance, a member of Belding's ground squirrels will typically emit a cry to warn other animals in the group about the presence of a predator, but in the process, put itself into extreme danger by identifying itself to the predator. Maynard Smith (1964) referred to this idea as *kin selection*, which is a narrower concept than inclusive fitness because it refers only to interaction between genealogical relatives. We may take inclusive fitness as a broader concept that deals with the observed prosocial behavior among humans, even towards those who are not related by kin. Sometimes in common usage, the related ideas of kin selection and inclusive fitness are used interchangeably.

Suppose that an individual confers an altruistic benefit b to another individual at some personal cost c , and the *degree of relatedness* (or probability of sharing a gene) of the other individual is r . For instance, $r = 1/2$ for siblings, $r = 1/4$ for nieces/nephews, $r = 1/8$ for cousins, and so on. Benefits b and cost c are measured in units of fitness. Individuals may be willing to engage in altruistic acts towards relatives and this willingness may be increasing in the degree of relatedness. This is nicely captured in a quote attributed to J.B.S. Haldane: "I will jump into the river to save two

brothers, or eight cousins." In a seminal contribution, Hamilton (1964) proposed the following inequality for altruism to be favored by natural selection

$$rb > c \Leftrightarrow r > \frac{c}{b}. \quad (14.86)$$

Rewriting (14.86) as $\frac{b}{c} > \frac{1}{r}$, the required ratio of benefits to cost can be quite high as the degree of relatedness decreases. Gintis (2014) shows that Hamilton's original inequality is consistent with both prosocial and antisocial behavior, and proposes important amendments to this inequality.

Consider the one-shot prisoner's dilemma game shown in Figure 14.12. Suppose that there are two traits in the population, A (altruism) and B (selfishness). Suppose that there are random binary meetings between members of the population. An individual with trait A confers a benefit b to the other in the binary meeting, at a cost c , such that $b > c > 0$. However, individuals with trait B neither incur the cost nor impart benefits to others.

In the presence of inclusive fitness, we may modify the strategic form game in Figure 14.12 as follows. Suppose that the average degree of relatedness in the population is $r \in (0, 1)$. The main implication of inclusive fitness is that one internalizes the payoffs of relatives (benefits and costs) in a proportion that depends on r . This is reflected in the modified strategic normal form game shown in Figure 14.13.

We leave the proof of the next proposition as an exercise. It shows that Hamilton's inequality in (14.86) has two desirable properties.

Proposition 14.14 (Nowak, 2006): *Consider the strategic normal form game shown in Figure 14.13. Cooperation (trait A) is an evolutionary stable strategy as well as a risk dominant strategy if (14.86) holds.*²⁷

²⁷ See the Appendix on game theory for the definition of a risk dominant strategy.

14.9.2 Group selection or multilevel selection

Hamilton's inequality shows that the explanation of prosocial behavior towards non-kin members (very low r) requires an unrealistically high benefit to cost ratio of prosocial behavior. In the quest to explain cooperation, one is then led to the idea of *group selection*, sometimes known as *multilevel selection*. The basic idea here is that over human evolutionary history (Wilson, 2012): (i) people have lived in small groups, (ii) there was inter-group competition for scarce resources, and (iii) cooperation among more prosocial groups results in higher success in inter-group competition.

Within each group, certain prosocial traits such as altruism/cooperation may have lower fitness relative to selfishness. So if each group lived in isolation, prosocial traits may never have been evolutionarily stable. However, in the struggle between groups, groups with more cooperative traits are likely to prevail over others in the competition for scarce resources. This imparts higher group-level fitness to such prosocial traits. Whether prosociality survives, depends on the relative strengths of these two opposing effects. Haldane (1932) proposed an initial transmission mechanism for how group selection may operate. Price (1972) gave a more formal account of such a mechanism. We give a flavor of the argument; the interested reader can consult Bowles and Gintis (2011) for the details.

Consider the prisoner's dilemma game shown in Figure 14.12. The population is divided into several groups. Denote the fraction of individuals in group j by λ_j . Let i index an individual in group j and let the expected fitness of this individual be denoted by π_{ij} . Let d_{ij} be a dummy variable that equals 1 if the individual has trait A, otherwise $d_{ij} = 0$. Denote the fraction of individuals in the entire population with trait A at time t by x_t and the fraction with trait A in group j by x_{jt} . Suppose that fitness takes the following form.

$$\pi_{ij} = \beta_0 + \beta_g x_{jt} + \beta_i d_{ij}. \quad (14.87)$$

In (14.87), fitness, π_{ij} , depends, in an additively separable manner, on the fraction of other altruists in the same group, x_{jt} , and whether the individual is altruistic or not, d_{ij} . β_g and β_i measure, respectively, the marginal effects of these variables and β_0 considers the effect of omitted variables. The *Price equation* can then be shown to take the following form²⁸

$$\Delta x_t = x_{t+1} - x_t = (b - c) \text{var}(x_{jt}) - c \overline{\text{var}}(d_{ij}), \quad (14.88)$$

where Δx_t is the change in the fraction of altruists in the population, $\text{var}(x_{jt})$ is the between-groups genetic variance of the trait A, and $\overline{\text{var}}(d_{ij}) = \sum_j \lambda_j \text{var}(d_{ij})$ is the average within-groups variation of the trait A. A higher variation between-groups suggests that there is greater sorting of groups into high A and low A types. In high type A groups, the fitness of the altruistic strategy is high because altruistic types are more likely to run into other altruistic types, hence, the payoff, $b - c$ (see Figure 14.12), is high; this is reflected in the higher reproductive success of these altruistic types. In binary meetings across groups, however, the altruistic trait has a lower fitness compared to the selfish trait (second term in (14.88)).

Let $P(A | A)$ and $P(A | B)$ denote the probability that individuals with traits A and B, respectively, encounter an individual with trait A. For the prisoner's dilemma game in Figure 14.12, Bowles and Gintis (2011) use this framework to derive a critical condition for the steady state

²⁸ For a derivation, see Appendix A10 in Bowles and Gintis (2011).

$$\Delta x_t \begin{matrix} \geq \\ \leq \end{matrix} 0 \Leftrightarrow P(A | A) - P(A | B) \begin{matrix} \geq \\ \leq \end{matrix} \frac{c}{b}. \quad (14.89)$$

Notice the similarity of (14.89) with Hamilton's rule in (14.86) if we interpret $P(A | A) - P(A | B) = r$. Thus, the fraction of altruists is expected to increase if the probability that altruists meet other altruists is high, the cost of altruism is low, and the benefits to the other party of altruism are high.

Readers may wonder if these sorts of models pass the empirical test of describing the long sweep of human evolutionary history. We leave the reader to consult Chapter 6 in Bowles and Gintis (2011) for the details. They find that, on average, r is unlikely to exceed 0.10. Thus, models of kin-based selection (see (14.86)) require b to exceed c by a factor of about 10, which is unlikely. However, for individual actions on which the survival of the group may be at stake, as could be the case in models of group or multilevel selection, it is possible that such a relationship holds. Hence, the claim of the group selection model is that it describes better the emergence of altruism.

More generally, group selection can also explain the development of human morality. While selfish traits enhance individual fitness, group fitness may be enhanced by moral actions toward others. Furthermore, unless one is a sociopath, the human mind appears predisposed to accept and imitate moral actions.

Nowak et al. (2010) argued that group selection is a more persuasive explanation for human evolution as compared to kin selection. Wilson (2012) gives a non-technical and wide-ranging account of this position. Kin selection or inclusive fitness was in turn defended against group selection by Abbot et al. (2011) in a paper that has 136 authors. Hence, the idea of group selection is still viewed with great suspicion by many evolutionary biologists. In the opinion pages of the *New York Times* on June 24, 2012, one of the main proponents of group selection, Edward O. Wilson, wrote:

But at no time have our mathematical and empirical arguments been refuted or even seriously challenged. Since that protest, the number of supporters of the multilevel selection approach has grown, to the extent that a similarly long list of signatories could be obtained. But such exercises are futile: science is not advanced by polling. If it were, we would still be releasing phlogiston to burn logs and navigating the sky with geocentric maps.

There is no consensus of views on these two opposing theories at this time.

14.9.3 Reciprocal altruism or direct reciprocity

The tit-for-tat strategy (see Section 14.6.1, above) is an exceedingly simple form of *reciprocal altruism*, sometimes referred to as *direct reciprocity* in the literature (Trivers, 1971). Following Bowles and Gintis (2011), consider the tit-for-tat strategy, T , for the infinitely repeated prisoner's dilemma game with the stage game given in Figure 14.12. We assume that individuals who use the tit-for-tat strategy, initially play the strategy A , and then in any subsequent period $t > 1$, copy the strategy of the opponent in period $t - 1$. This is sometimes known as the nice tit-for-tat because players initially play A .

The tit-for-tat strategy is a form of *conditional cooperation*, and we may refer to it as such. Suppose that the one-period discount factor is $\delta \in [0, 1]$ and players use exponential discounting. We are interested in checking if T is an ESS.

ESS is a subset of the set of Nash equilibria, and the two concepts coincide when the Nash equilibrium is strict. Thus, let us find the conditions for “all play T ” to be a strict Nash equilibrium. Conditional on all others playing their part of the Nash equilibrium, an individual prefers the strategy T over the strategy “defect” (i.e., play B every period) if²⁹

$$(b - c)[1 + \delta + \delta^2 + \dots] > b,$$

or $\delta > \frac{c}{b}$, which is similar to Hamilton’s inequality in (14.86) once the discount factor replaces the degree of relatedness, r .

Reciprocal altruism is, however, difficult to find in most animals, except close primate relatives because most animals have quite high discount rates, hence, they exhibit very low values of δ (Hammerstein, 2003). However, reciprocal altruism appears to play a role in human interaction. An example is the greater observed cooperation in the partner-treatment, as compared to the stranger-treatment in public goods games experiments (see Part 2 of the book). Indeed nothing in our derivation restricts such altruism to kin members only. In computer tournaments, Axelrod (1984) showed that the tit-for-tat was the winning strategy in the prisoner’s dilemma game shown in Figure 14.12.

Conditional cooperation of this sort can be an ESS under certain conditions, but not others. These conditions have to do with the size of groups, the number of interacting individuals, and behavioral errors. For instance, in larger groups, it will become more difficult to keep track of previous defectors, and for a variety of behavioral biases, individuals might not have perfect recall. A more detailed analysis of these issues can be found in Bowles and Gintis (2011) who also show that the empirical evidence for these sorts of models (e.g., reciprocal altruism) is not overwhelming. For these reasons, they advocate models of gene-culture coevolution as providing a more convincing explanation.

Suppose that there are behavioral errors, say, for whatever reason, players choose their strategies with some trembles. This increases the cost of playing T because one round of unintended defection by the opponent, induces endless defection under T , reducing the players’ payoffs; see, for instance, Selten and Hammerstein (1984).

This has led to a search for alternative strategies in repeated games that have been shown to perform better than T . These include: (i) the *generous tit-for-tat* in which an individual cooperates with some probability even if the opponent has defected in the previous period, and (ii) the *win-stay, lose-shift strategy* in which the previous period strategy is repeated if one is doing well (say, if both players have played A) and the previous period strategy is changed if one is not doing well (say, if the opponent has played B).³⁰

Colman et al. (2010) explore the possibility of learning under a noisy win-stay, lose-shift strategy when players have limited information on the strategic environment, as in models of reinforcement learning. They find that adaptive learning is very slow and players typically do not show awareness that they are participating in a strategic environment. Even relatively high incentives do not improve the speed of learning. Learning is slower in multiplayer, relative to dyadic, interactions, even when players are informed that they are engaged in strategic interaction.

Consider the one-period prisoner’s dilemma game shown in Figure 14.12. We wish to find how the payoff matrix is altered when we compare the strategy T against the alternative strategy that

²⁹ Payoffs are unaltered if one switches to A conditional on all others playing T .

³⁰ For a more detailed account of these strategies and their superiority to strategy T , see Fudenberg and Maskin (1990) and Nowak and Sigmund (1992, 1993).

plays B every period; call this the strategy, D , for defect. Suppose that the probability with which the same players meet in the next round is p . Thus, the expected number of rounds played between the two players is $1/(1-p)$. Thus, when one T player meets another T player, the expected payoff is $(b-c) + p(b-c) + p^2(b-c) + \dots = \frac{b-c}{1-p}$. When a T player meets a D player, then the current payoff is $-c$, followed by a payoff of zero in every future period. If a D player meets a T player, then he gets b in the current period, and zero thereafter, for a total intertemporal payoff of b . These payoffs are summarized in the payoff matrix in Figure 14.14.

The next proposition considers the evolutionary stability of strategy T against the strategy D ; we omit the proof and the interpretation and leave these as an exercise.

Proposition 14.15 (Nowak, 2006): Consider the strategic normal form game in Figure 14.14. The strategy T is an ESS if $p > \frac{c}{b}$ and it is risk dominant if $\frac{b}{c} > \frac{2-p}{p}$.

14.9.4 Indirect reciprocity

Direct reciprocity requires that individuals engage in repeated interactions with each other. In this case, individuals use *directly observed and experienced information* about past play to decide on the degree of cooperation. But we also do observe altruism and spite that is directed at complete strangers, where we have not had a chance to directly observe past play. Cooperative behavior with strangers and non-strangers is likely to be observed by others. Information on one's *reputation* and behavior, cooperative or non-cooperative, is then likely to spread among others through means such as *gossip* (Alexander, 1987; Nowak and Sigmund, 1998). The evolution of language must have played a critical role in this process. This gives rise to *indirect reciprocity*, i.e., conditioning one's current play on *indirectly observed past play of opponents*. Consistent with this view, evidence suggests that more helpful individuals are helped more in the future (Panchanathan and Boyd, 2004; Nowak and Sigmund, 2005). We may use indirect reciprocity not only to model the spread of altruism and cooperation, but also other social norms and even morality; for the implications for morality see Alexander (1987); and for social norms see Brandt and Sigmund (2004).

Let us consider indirect reciprocity when the stage game is the prisoner's dilemma game given in Figure 14.12. We need to specify two elements. The first element is an *action rule*, i.e., choose A or B depending on the *reputation* or *image score* of the other player. At the simplest level, the image score could be binary: 1 if the individual has a good reputation and 0 if the reputation is bad. The second element is an *assessment norm*, i.e., how does a third party assign image scores to others.

	C	D
C	$(b - c), (b - c)$	$-c(1 - q), b(1 - q)$
D	$b(1 - q), -c(1 - q)$	$0, 0$

Figure 14.15 Indirect reciprocity and the prisoner's dilemma game.

Source: From Nowak, M. A. (2006). "Five rules for the evolution of cooperation." *Science* 314(5805): 1560–3. Copyright © 2006, American Association for the Advancement of Science. Reprinted with permission from AAAS. Readers may view, browse, and/or download material for temporary copying purposes only, provided these uses are for noncommercial personal purposes. Except as provided by law, this material may not be further reproduced, distributed, transmitted, modified, adapted, performed, displayed, published, or sold in whole or in part, without prior written permission from the publisher.

In the context of the prisoner's dilemma game, consider two strategies. The temporal strategy, defect in every period, D , involves the play of B in the stage game, every period. The temporal strategy, C , denotes the cooperative strategy in which players play A unless they know that the reputation of the opponent is bad (corresponding to D). In the prisoner's dilemma game in Figure 14.12, players know the strategies of the opponents due to, say, observations on past reputations; and players are hardwired to play their strategies. Players who play C always cooperate when they meet other players who play C . However, when they meet a player with reputation to play D , they cooperate (i.e., confer a benefit b at a cost c) with probability $1 - q$, $q > 0$. These assumptions modify the original game to the one shown in Figure 14.15, which can now be considered to be a strategic normal form game.

The proof of the next proposition is left as an exercise for the reader. It shows that a form of Hamilton's rule is required to ensure the ESS of the cooperative strategy.

Proposition 14.16 (Nowak, 2006): Consider the strategic normal form game in Figure 14.15. The strategy C is (i) an ESS if $q > \frac{c}{b}$, and (ii) a risk dominant strategy if $\frac{q}{2-q} > \frac{c}{b}$.

14.9.5 Repeated games, cooperation, and classical game theory

Readers trained in classical game theory may believe that altruism can be explained using the theory of repeated games and self-regarding preferences. Gintis (2009b) and Bowles and Gintis (2011) strongly reject such an explanation and term Nash equilibria of repeated games as *evolutionary irrelevant equilibria*. We have already explored these arguments in Part 4 of the book. Here we simply note the salient problems with Nash equilibria in repeated games.

First, the folk theorem is an existence theorem that does not provide any satisfactory dynamic process for the adjustment to equilibrium. Second, repeated games typically involve public signals, i.e., all players receive the same signal, although the signal may be perfect or imperfect (e.g., defection of a particular player may be observed with some error). However, when players have private signals, the most relevant real-life case, then the existing results only apply to models where we have near-public signals. Third, there is no mechanism for coordinating on trigger strategies, particularly in large groups. Fourth, the equilibrium in repeated games, particularly with private signals, involves the play of mixed strategies. Since players are indifferent between the pure strategies in the support of the equilibrium mixed strategy, they have no incentive to play the pure strategies in the equilibrium proportions. This problem with mixed strategies is addressed in a simple class of games, through the purification agenda, but this class excludes repeated games.

14.9.6 The indirect evolutionary approach

In the *indirect evolutionary approach*, individuals are endowed with evolving preferences and they maximize their utility in each time period; see Güth and Yaari (1992) and Güth (1995). Over time, preferences evolve, depending on some underlying revision protocol, but conditional on the preferences, individuals continue to maximize their utility whenever they are called upon to make a choice.

THE BASIC CONCEPTS

Consider the following example that is taken from Robson and Samuelson (2011). The two-player strategic normal form game in Figure 14.16 has a unique Nash equilibrium (T, R) .

Suppose that there are two populations of players. The respective strategy sets in populations 1 and 2 are $S_1 = \{T, B\}$ and $S_2 = \{L, R\}$. In population 1, strategy T dominates strategy B . Players from the two populations are randomly matched to play the game in Figure 14.16. Players are hardwired with preferences for particular strategies. An important assumption is that players know the preferences of the opponent. The motivation is that humans possess subtle cues to recognize traits in others; often these traits are similar to their own, which is the *green-beard effect*. The material payoffs in Figure 14.16 are also the relevant fitness levels that determine reproductive success.

From the point of view of population 1, it is ideal if a player could pre-commit to playing the dominated strategy B . In standard game theory, this is ruled out because, in a static game, players cannot make such commitments. However, in the indirect evolutionary approach, credible commitments arise through hardwired strategies or preferences.

It might well be that some players in population 1 have the preference to play strategy T and others have the preference to play B . Since player 2 (from population 2) is assumed to observe these preferences, he will play R (respectively, L) when matched against an opponent who prefers to play T (respectively, B). Thus, in population 1, players who play B will get a higher material payoff, and achieve higher reproductive fitness, relative to players who play T . Thus, over time, as preferences evolve, players in population 1 who possess the preference to play B will overwhelm those who play T . In other words, B will eventually be an ESS, but T fails to be an ESS.

This framework has been used to provide a justification for the existence of departures from the findings of the standard textbook economic model. These departures include punishments in public goods games, altruism, and the endowment effect (Ostrum, 2000). However, there are several limitations of the indirect evolutionary approach. In the game in Figure 14.16, population 2 would likewise benefit by evolving a hardwired preference for playing R . Since such a preference will be observed by player 1, his best response is T , so that player 2 gets 4. It is not clear what outcome one would get by allowing a richer array of such preferences.

The assumption that the preferences of others can be observed is a strong one; however, this has been relaxed. When preferences are unobservable, then the steady state in the indirect evolutionary approach must be a Nash equilibrium (Ely and Yilankaya, 2001; Ok and Vega-Redondo, 2001). But then, in Figure 14.16, we are back to the outcome (T, R) under classical game theory. Güth (1995), however, shows that the indirect evolutionary approach can have important implications when players have some, but imperfect, information about the preferences of others that allows periodic observation of preferences.

Robson and Samuelson (2011) argue that the generation of cues that makes preferences recognizable to others, ought to be endogenous to an evolutionary process. But a weakness of the indirect evolutionary approach is that these cues are exogenous. They write: “In our view, the indirect evolutionary approach will remain incomplete until the evolution of preferences, the evolution of signals about preferences, and the evolution of reactions to these signals, are all analyzed within the model.” This requirement might be too challenging, not just for this theory, but for most of game theory.

THE EVOLUTION OF MORALITY

Alger and Weibull (2013) consider the *evolution of morality* within the indirect evolutionary approach. Aside from the intrinsic worth of these results, the framework allows us to define an ESS in the presence of asymmetric information (Definition 14.10 below), which allows readers to extend their knowledge of the basic concepts.

Suppose that we have a strategy set X that is shared by players from two different populations. Individuals are randomly matched across the populations to engage in bilateral interactions, but matching can be *assortative*. So, for instance, players who have identical types may have more than an even chance of being matched (perhaps on account of some underlying green-beard effect). The material payoff that is relevant for reproductive fitness when an individual plays a strategy $x \in X$ against an opponent who plays the strategy $y \in X$ is $\pi(x, y)$, so $\pi : X \times X \rightarrow \mathbb{R}$.

In each population, there are two types of preferences, θ and τ , in the proportions $1 - \epsilon$ and ϵ ; these types are drawn from the set of types Θ . Thus, a population state is summarized by $s = (\theta, \tau, \epsilon)$. For any state, $P(\tau | \theta, \epsilon)$ gives the conditional probability that an individual of type θ is matched with a type τ individual; $P(\theta | \tau, \epsilon)$ is defined analogously. Each of the types, θ, τ , pick strategies from the set X . The *types* of players are hardwired, but they simultaneously choose their *strategies* in order to maximize their expected utility.

For any $x, y \in X$, such that type θ plays x and type τ plays y , the expected payoff or fitness of the types θ and τ is given, respectively, by

$$\Pi_{\theta}(x, y, \epsilon) = P(\theta | \theta, \epsilon) \pi(x, x) + P(\tau | \theta, \epsilon) \pi(x, y), \quad (14.90)$$

$$\Pi_{\tau}(x, y, \epsilon) = P(\theta | \tau, \epsilon) \pi(y, x) + P(\tau | \tau, \epsilon) \pi(y, y). \quad (14.91)$$

In (14.90), with probability $P(\theta | \theta, \epsilon)$, a type θ player who plays x meets a type θ player from the other population who plays x , for a payoff of $\pi(x, x)$. With the complementary probability $P(\tau | \theta, \epsilon)$, the opponent is a type τ player from the other population who plays x , giving a payoff of $\pi(x, y)$. $\Pi_{\tau}(x, y, \epsilon)$ in (14.91) can be constructed analogously.

Strategy choices are made simultaneously and types are private information, so the relevant equilibrium concept in a static asymmetric information game is a Bayesian Nash equilibrium (BNE). Suppose that payoffs, π , and utilities, u , of players coincide; denote by u_{θ} and u_{τ} , respectively, the utilities of types θ and τ . Payoffs and utilities may or may not be identical; see Definition 14.12, below.

Definition 14.9 (*Bayesian Nash equilibrium*): Choose a particular state $s = (\theta, \tau, \epsilon)$. A pair of strategies $x^*, y^* \in X$ is a Bayesian Nash equilibrium if

$$\begin{cases} x^* \in \arg \max_{x \in X} P(\theta | \theta, \epsilon) u_\theta(x, x^*) + P(\tau | \theta, \epsilon) u_\theta(x, y^*), \\ y^* \in \arg \max_{y \in X} P(\theta | \tau, \epsilon) u_\tau(y, x^*) + P(\tau | \tau, \epsilon) u_\tau(y, y^*). \end{cases}$$

Restricting attention to the set of BNE, we can define an ESS under asymmetric information; this is a useful tool for the readers to add to their toolkit.

Definition 14.10 (*Evolutionary stability*): Suppose that $x^*, y^* \in X$ is a Bayesian Nash equilibrium. Type $\theta \in \Theta$ is evolutionarily stable against type $\tau \in \Theta$ if there exists an invasion barrier $\bar{\epsilon}$ such that, for all $0 < \epsilon < \bar{\epsilon}$, the following condition holds in all Bayesian Nash equilibria for all states $s = (\theta, \tau, \epsilon)$

$$\Pi_\theta(x^*, y^*, \epsilon) > \Pi_\tau(x^*, y^*, \epsilon).$$

Type θ is evolutionarily stable if it is evolutionarily stable against all $\tau \in \Theta$ such that $\tau \neq \theta$.

Random matching takes place through an assortative matching function, ϕ , as in Bergstrom (2003); ϕ is the difference in the conditional probability that type θ is matched with another type θ and the conditional probability that type τ is matched with type θ .

Definition 14.11 (*Assortment function and index of assortativity*): Define the assortment function $\phi : (0, 1) \rightarrow [-1, 1]$ such that

$$\phi(\epsilon) = P(\theta | \theta, \epsilon) - P(\theta | \tau, \epsilon).$$

We assume that ϕ is a continuous function and

$$\lim_{\epsilon \rightarrow 0} \phi(\epsilon) = \sigma, \quad (14.92)$$

where $\sigma \in [0, 1]$ is known as the “index of assortativity” of the matching process. Letting $\phi(0) = \sigma$ allows us to extend the domain of ϕ from $(0, 1)$ to $[0, 1]$. The special case of uniform random matching between players, irrespective of type, corresponds to $\phi(\epsilon) = 0$ for all $\epsilon \in (0, 1)$. In this case, the probability that a type θ or type τ player is matched with another type θ player is identical.

We now define the precise sense in which individuals possess moral virtues.

Definition 14.12 (*Homo-moralis*): An individual is said to be Homo-moralis if his utility function is given by the following convex combination of two different tendencies.

$$u(x, y; \kappa) = (1 - \kappa)\pi(x, y) + \kappa\pi(x, x), \quad (14.93)$$

where $\kappa \in (0, 1)$ is the degree of morality of the individual, $\pi(x, y)$ is the payoff from the strategy x , against an opponent who plays y , and $\pi(x, x)$ is the payoff against a hypothetical opponent who also plays x .

From Definition 14.12, a Homo-moralis individual cares about selfishness (first term in (14.93)) and morality (second term in (14.93)). Morality takes the *Kantian form*, i.e., choose a strategy such that if the same strategy is chosen by all players, it leads to the highest possible payoff, $\pi(x, x)$. Morality as defined above, is different from altruism, inequity aversion, or efficiency concerns. Two limiting cases of Definition 14.12 are stated next.

Definition 14.13 Consider the definition of utility function $u(x, y; \kappa)$ in Definition 14.12. An individual is *Homo oeconomicus* in the limiting case $u(x, y; 0)$ and *Homo kantiensis* in the limiting case $u(x, y; 1)$. Finally, using (14.92), the individual is termed as *Homo hamiltonensis* in the special case $u(x, y; \sigma)$.

From Definition 14.13, *Homo oeconomicus* is a textbook economic individual who is *amoral*. *Homo kantiensis*, at the other extreme, chooses his strategy $x \in X$ to maximize $\pi(x, x)$. *Homo hamiltonensis* turns out to be an evolutionary important type, as we shall see below. When the degree of relatedness among the individuals is given by σ , $u(x, y; \sigma)$ is the fitness of a mutant individual who plays x when the main population plays y .

Let the type of an individual $\theta \in \Theta$ be identical to the degree of morality κ of the individual, $\kappa \in [0, 1]$, so the utility function in (14.93) can be written as $u(x, y; \theta)$. For any type $\theta \in \Theta$, denote the best reply correspondence by β_θ , where

$$\beta_\theta(y) = \arg \max_{x \in X} u(x, y; \theta) \text{ for all } y \in X.$$

Denote the fixed points under β_θ by X_θ , where

$$X_\theta = \{x \in X : x \in \beta_\theta(x)\}.$$

For the case of *Homo hamiltonensis*, the best reply correspondence is given by β_σ and the set of fixed points under β_σ is given by X_σ .

For any state $s = (\theta, \tau, \epsilon)$, let $B^{NE}(s) \subseteq X \times X$ denote the set of Bayesian Nash equilibria (Definition 14.9). We now define our final construct. For any state $s = (\theta, \tau, \epsilon)$, let ϵ be vanishingly small. Then type θ is known as the resident population and type τ , the mutant population. For any resident type $\theta \in \Theta$ we wish to identify those types $\tau \in \Theta$ that are behaviorally indistinguishable from θ . This is achieved by defining the following set

$$\Theta_\theta = \{\tau \in \Theta : \exists x \in X_\theta \text{ such that } (x, x) \in B^{NE}(\theta, \tau, 0)\}.$$

An example of behaviorally indistinguishable types are those in which the utility function of one type is an affine transformation of another. We are now in a position to state the main result.

Proposition 14.17 (Alger and Weibull, 2013):

- (a) If $\beta_\theta(x)$ is a singleton for all $x \in X_\theta$, then *Homo hamiltonensis* is an evolutionary stable strategy (see Definition 14.10) against all types $\tau \notin \Theta_\theta$.
- (b) Suppose that we do not have assortative matching, i.e., $\sigma = 0$. Consider *Homo oeconomicus* $\kappa = 0 \in \Theta$. If $\beta_0(x)$ is a singleton for all $x \in X_0$, then *Homo oeconomicus* is an evolutionary stable strategy (see Definition 14.10) against all types $\tau \notin \Theta_0$.

The implications of Proposition 14.17 are profound. Assortativity appears to be quite important in humans for reasons of kinship, networks, and social groups. Indeed, if assortativity is present to any degree, then evolution ensures that *Homo oeconomicus* is not evolutionarily stable. Under these conditions, a form of *Homo-moralis*, the *Homo hamiltonensis* is evolutionarily stable if β_0 is unique. In related results, under assortative matching, Bergstrom (2009) established the

evolutionarily stability of a semi-Kantian type, which corresponds to $\kappa = 0.5$ in the model above. Proposition 14.17(b) is consistent with the results of Ok and Vega-Redondo (2001) and Dekel et al. (2007) who find that in the absence of any assortativity, *homo oeconomicus* is an evolutionary stable strategy.

Since these results are independent of payoffs, they lead to the remarkable conclusion that economic incentives cannot crowd out human morality, at least in an evolutionary sense. We have reviewed these issues in Part 2. For instance, the experimental results of Fischbacher and Föllmi-Heusi (2013) show that roughly 40% of the subjects are *completely honest* even when lying could have improved their payoffs. A significant fraction of the subjects tell *partial lies*, even when they could have lied more strongly (see also Gneezy et al., 2013). About 22% behave in a manner consistent with the *selfish black liars* assumed in neoclassical economics. The bottom line of this analysis is that economics needs to consider a blend of selfishness and morality, but a consideration of ‘selfishness only’ is simply not tenable. Readers who have read Part 2 of the book carefully might already have reached similar conclusions.

For a separate analysis of the evolutionary development of sibling altruism and the role of the harshness of the environment, in the presence of assortative matching, see Alger and Weibull (2010). They find that in the presence of uncertainty in the economic environment, altruism may be a double edged sword. On the one hand, altruism provides an insurance function between siblings, say, if the siblings experience very different economic outcomes. On the other hand, this insurance may lead to a reduction in the effort exerted by the siblings on account of moral hazard issues. As one might expect in this case, the beneficial effects of altruism, and its evolutionary stability, depend on the degree of uncertainty in the environment.

14.9.7 Other issues in evolutionary explanations of cooperation

Strong reciprocators are predisposed to cooperate, but they are willing to punish members of the group who do not adhere to the group norms, at a personal cost (see Part 2 of the book). In Part 2, in experimental public goods games, the nature of punishment is typically unilateral, as opposed to group punishment. This may reduce the average payoff of the group. Further, in experiments conducted in non-Western countries, we may also observe antisocial punishment of individuals who cooperate; prosocial punishments are correlated with the rule of law and other social institutions. Anthropological and ethnographic evidence, however, shows that individuals typically engage only in group punishment, e.g., social ostracization, and punishment raises the average group payoffs. Using these stylized facts, Boyd et al., (2010) show that strong reciprocity can evolve as an evolutionary equilibrium.

In this chapter, we have considered random bilateral interactions between players of the same, or different populations. However, in actual practice, people may interact disproportionately with others of their own type, i.e., matchings may be assortative. Thus, cooperators may survive in prisoner dilemma type games by interacting mostly with other cooperative people in their social clusters. This *network reciprocity* is a form of spatial reciprocity; for an explanation of cooperative behavior based on network reciprocity, see Durrett and Levin (1994) and Hauert and Doebeli (2004). Nowak (2006) shows that despite the complexities of this framework, a simple form of Hamilton’s rule applies to determine the success of the cooperative outcome under network reciprocity. This rule is $\frac{b}{c} > k$ where k is the average number of neighbors that a player has in the network.

	C	D
A	$\alpha + \beta, 0$	$0, 0$
B	$\alpha, 0$	$\alpha, 0$

Figure 14.17 A two-population, 2×2 strategic form game.

14.10 Social learning and replicator-like dynamics

We now consider some simple models of social learning in which players are not hardwired to play particular strategies. Yet, these models give rise to replicator-like dynamics in models of evolutionary game theory. We then consider the broader concept of *payoff monotonicity*, of which the replicator dynamics is a special case.

14.10.1 Social imitation and emulation dynamics

Consider the normal form game in Figure 14.17 that is played between two populations of players, population 1 (row players) and population 2 (column players); $\alpha, \beta > 0$.

Players in population 2 always get a payoff of 0. Using Fudenberg and Levine's (1998) terminology, we call this a dummy population. In population 1, the respective fractions of players playing A and B are $x_t(A) \geq 0$ and $x_t(B) = 1 - x_t(A)$. In population 2, the proportion of players who play strategies C and D are denoted, respectively, by the time-invariant fractions $y(C)$ and $y(D) = 1 - y(C)$.

Suppose that at the end of each time period, and in population 1 only, new players, the "children," replace their "parents." A fraction $1 - \lambda$ of the children inherit the strategy of the parent. However, the remaining fraction, $\lambda > 0$, get a revision opportunity. They randomly sample one more player, the "stranger," from their population and are able to observe his/her payoff from the latest period. They then use the following decision rule.

Decision Rule: Of the two observed strategies, the parent's strategy and the stranger's strategy, choose the one that has a higher payoff. If the payoffs from both strategies are identical, then choose the parent's strategy. Dynamics based on this decision rule are called *emulation dynamics* (Ellison and Fudenberg, 1993; Fudenberg and Levine, 1998).

The emulation dynamics favor those strategies that have a high median payoff rather than a high average payoff, as we shall see below. Given $x_t(A)$, we would like to determine this fraction in the following period, $x_{t+1}(A)$.

Consider the children of parents at time t who played the strategy A. There are two kinds of children.

1. A fraction $x_t(A)y(C)$ are children of parents whose payoff at time t was $\alpha + \beta$. A fraction $(1 - \lambda)x_t(A)y(C)$ does not get an opportunity to revise their strategy. The remaining fraction $\lambda x_t(A)y(C)$ gets a revision opportunity. Given the decision rule, they randomly sample the payoff of a stranger from their population and compare it to the payoff of their parent. Their parent always has the highest payoff, so they continue to choose their parent's strategy, A.
2. A fraction $x_t(A)y(D)$ are children of parents whose payoff at time t was 0. A fraction $(1 - \lambda)x_t(A)y(D)$ do not get a revision opportunity. The remaining fraction $\lambda x_t(A)y(D)$

that gets the revision opportunity switches the strategy to B with probability $x_t(B)$. Thus the total fraction that switches to B is $\lambda x_t(A)y(D)x_t(B)$ and the fraction that does not switch is $\lambda x_t^2(A)y(D)$.

Now consider the children of parents in population 1 who play B at time t , who comprise a fraction $x_t(B)$ of population 1. Of these, a fraction $\lambda x_t(B)$ get a chance to revise their strategy. When they randomly sample a stranger from their population, they find that a fraction $x_t(A)y(C)$ has a higher payoff ($\alpha + \beta > \alpha$). So a total fraction $\lambda x_t(B)x_t(A)y(C)$ of the children of B parents switch to the strategy A .

Putting this information together, and noting that $(1 - \lambda)x_t(A)y(C) + (1 - \lambda)x_t(A)y(D) = (1 - \lambda)x_t(A)$, the fraction of population 1 that plays strategy A at time $t + 1$ is

$$x_{t+1}(A) = (1 - \lambda)x_t(A) + \lambda x_t(A)y(C) + \lambda x_t^2(A)y(D) + \lambda x_t(B)x_t(A)y(C).$$

Alternatively, we can write the RHS in terms of those do not get a revision opportunity and those who do get the opportunity,

$$x_{t+1}(A) = (1 - \lambda)x_t(A) + \lambda [x_t^2(A) + 2x_t(A)x_t(B)y(C)]. \quad (14.94)$$

Using $x_t(B) = 1 - x_t(A)$ and rewriting (14.94) we get

$$x_{t+1}(A) - x_t(A) = cx_t(A)(1 - x_t(A)), \text{ where } c = \lambda(2y(C) - 1). \quad (14.95)$$

To find the continuous time analog of (14.95), let the time difference between successive periods be Δ , then (14.95) can be written as

$$x_{t+\Delta}(A) - x_t(A) = \Delta cx_t(A)(1 - x_t(A)). \quad (14.96)$$

Divide both sides of (14.96) by Δ and take the limit as $\Delta \rightarrow 0$ we get

$$\dot{x}_t(A) = f(x_t(A)) = cx_t(A)(1 - x_t(A)). \quad (14.97)$$

Setting $\dot{x}_t(A) = 0$, the steady states are given by $\bar{x}(A) = 0$ and $\bar{x}(A) = 1$. Since $f'(x) = c(1 - 2x)$, at the two steady states, we have $f'(0) = c$, $f'(1) = -c$. Stability requires that $f'(x) < 0$. Using (14.95)

$$c \begin{matrix} \geq \\ \leq \end{matrix} 0 \text{ as } y(C) \begin{matrix} \geq \\ \leq \end{matrix} \frac{1}{2}.$$

Hence, $\bar{x}(A) = 0$ is a stable steady state if $y(C) < \frac{1}{2}$, while $\bar{x}(A) = 1$ is a stable steady state if $y(C) > \frac{1}{2}$. Particularly disturbing is the stable steady state $\bar{x}(A) = 0$ when $y(C) < \frac{1}{2}$. In this case, social imitation leads everyone in population 1 to play the pure strategy B . What is wrong with this? The best response for a player in population 1 is to play A rather than B if $(\alpha + \beta)y(C) > \alpha$, or

$$y(C) > \hat{y} = \left(1 + \frac{\beta}{\alpha}\right)^{-1}.$$

As an example, consider $\frac{\beta}{\alpha} = 5$, so $\hat{y} = \frac{1}{6}$. When $\frac{1}{6} < y(C) < \frac{1}{2}$, the best response of a player from population 1 is to play A , while social imitation leads the whole population to play B instead. Ordering the payoffs of population 1 players in increasing order, we get $0, \alpha, \alpha, \alpha + \beta$, thus, the median payoff is α . Since $\bar{x}(A) = 0$ for $y(C) < \frac{1}{2}$, the payoff of population 1 players is the median payoff α , hence, such dynamics are sometimes called *median enhancing emulation dynamics*.

The model of emulation dynamics sets the stage for our microfoundations of the replicator dynamics in the next section.³¹

14.10.2 Some microfoundations of replicator dynamics: imitation learning

Suppose that there are two populations of players, $K = \{1, 2\}$ who are paired randomly. The respective pure strategy sets in the two populations are, $S_1 = (s_{11}, s_{12}, \dots, s_{1n_1})$ and $S_2 = (s_{21}, s_{22}, \dots, s_{2n_2})$. The payoff matrix of a representative player in population 1 is denoted by Π_1 and the p th row in Π_1 is given by

$$\Pi_{p1} = (a_{p1}, a_{p2}, \dots, a_{pn_2}),$$

where a_{pr} is the payoff to player 1 when he plays the pure strategy s_{1p} and player 2 plays the strategy s_{2r} . Similarly, we denote row p in the payoff matrix, Π_2 , of player 2 by

$$\Pi_{p2} = (b_{p1}, b_{p2}, \dots, b_{pn_1}),$$

where b_{pr} is the payoff to player 2 when he plays the pure strategy s_{2p} and player 1 plays the strategy s_{1r} .

A proportion x_{kj} of players in population $k \in K$ plays the pure strategy $s_{kj} \in S_k$. Let $x_k = (x_{kj})_{n_k \times 1}$ denote the column vector of these proportions in population k and denote the transpose by x_k^T . Thus, the expected payoff of player 1 from the pure strategy s_{1p} is given by $\Pi_{p1}x_2$. Likewise the expected payoff of player 2 from the pure strategy s_{2p} is given by $\Pi_{p2}x_1$.

Suppose that a fraction λ_{kj} of population $k \in K$ that is playing the pure strategy s_{kj} randomly gets an opportunity to revise its strategy. Denote by ρ_{kj}^i the proportion of these individuals who adopt the pure strategy s_{ki} , having abandoned the pure strategy s_{kj} . We now make assumptions about revision opportunities.

A1: The fraction λ_{kj} of individuals who play the pure strategy s_{kj} and get a revision opportunity, is a decreasing function of the expected payoff from the strategy, s_{kj} . Thus,

$$\begin{cases} \lambda_{1j} = \phi_1(\Pi_{j1}x_2); j = 1, 2, \dots, n_1 \\ \lambda_{2j} = \phi_2(\Pi_{j2}x_1); j = 1, 2, \dots, n_2 \end{cases}, \quad (14.98)$$

where for $k \in K$, $\phi_k : \mathbb{R} \rightarrow [0, 1]$, and $\phi'_k < 0$. There are two reasons why the revision opportunity depends negatively on the expected payoff from a strategy. First, there could be some fixed costs of switching strategies, so it is worth considering a switch only for strategies that are doing particularly poorly. Second, players might have aspiration levels,

³¹ Similar models are presented in Bjornerstedt (1995), Fudenberg and Levine (1998), and Vega-Redondo (2003).

and low payoff strategies may fall below aspirations, hence, motivating a greater need to switch. For pedagogical simplicity, let us specialize ϕ_1, ϕ_2 to be identical and linear, so

$$\phi_1 = \phi_2 = \phi \text{ and } \phi(y) = a - by. \quad (14.99)$$

A2: Whenever any player gets an opportunity to revise his strategy, he randomly picks a player from his own population and adopts his strategy (*imitation*). Given the frequencies with which various pure strategies are played in one's own population, the probability that a player who plays s_{kj} meets a player who plays s_{ki} is given by x_{ki} , hence, for all k, j, i

$$\rho_{kj}^i = x_{ki}. \quad (14.100)$$

Define the state of the system, x , as the fraction of players from each population who play each of the available pure strategies at any given time (we suppress time subscripts for now)

$$x = (x_1, x_2).$$

In any population $k \in K$, among the players who have a revision opportunity, the total inflow of players into strategy s_{ki} is given by

$$I_{ki} = \sum_{j=1}^{n_k} (\lambda_{kj} x_{kj}) \rho_{kj}^i; \forall k, j \neq i, \quad (14.101)$$

where $\lambda_{kj} x_{kj}$ is the fraction of individuals who play strategy s_{kj} and get an opportunity to revise their strategy. Of this, a fraction ρ_{kj}^i will switch to strategy s_{ki} . Summing across all strategies gives the total inflow into the strategy s_{ki} . The fraction $\lambda_{ki} x_{ki}$ of players in population $k \in K$ was using strategy s_{ki} and has been given an opportunity to revise their strategy. Given A1, A2, all of these players observe and imitate the strategy of another randomly picked player from their population who does not play s_{ki} . Hence, the total outflow O_{ki} from the set of players using strategy s_{ki} is given by

$$O_{ki} = \lambda_{ki} x_{ki}. \quad (14.102)$$

The evolution of the frequencies in each population that plays different pure strategies is given by the following equations of motion.

$$\dot{x}_t(s_{ki}) = I_{ki} - O_{ki}; \forall k, i = 1, \dots, n_i. \quad (14.103)$$

Substituting (14.98)–(14.102) in (14.103), and denoting by x_{-k} , the vector of frequencies for the other population:

$$\begin{aligned} \dot{x}_t(s_{ki}) &= \sum_{j=1}^{n_k} ((a - b \Pi_{jk} x_{-k}) x_{kj}) x_{ki} - (a - b \Pi_{ik} x_{-k}) x_{ki} \\ &= \left[\sum_{j=1}^{n_k} ((a - b \Pi_{jk} x_{-k}) x_{kj}) - (a - b \Pi_{ik} x_{-k}) \right] x_{ki} \\ &= \left[a \sum_{j=1}^{n_k} x_{kj} - b \sum_{j=1}^{n_k} x_{kj} \Pi_{jk} x_{-k} - a + b \Pi_{ik} x_{-k} \right] x_{ki}. \end{aligned} \quad (14.104)$$

Since the population frequencies sum upto 1, $\sum_{j=1}^{n_k} x_{kj} = 1$. By definition, $\Pi_{jk}x_{-k} = \pi(s_{kj}, x_{-k})$ is the expected payoff to a population k player from playing the pure strategy s_{kj} . Hence, we can rewrite (14.104) as:

$$\dot{x}_t(s_{ki}) = b [\pi(s_{ki}, x_{-k}) - \pi(x_k, x_{-k})] x_{ki}. \quad (14.105)$$

For $b = 1$, the resulting population dynamics, given by (14.105), are identical to the replicator dynamics for the case of two or more populations; see (14.35). However, this result is not necessarily robust to perturbations in the form of social learning.

Other microfoundations of replicator dynamics are also available. Bjornerstedt and Weibull (1993) consider a similar model to the one we describe above, except that players receive noisy statistical information about the payoff of others. In the special case when the noise has a uniform distribution, and the function ϕ has the linear form in (14.99), one obtains the replicator dynamics. Borgers and Sarin (1997) also recover replicator-like dynamics in a stimulus response model.

14.10.3 Social dynamics based on payoff monotonicity

Assumption A1 above, required that as the payoff from a pure strategy increases, players are less likely to wish to revise it. This appears to be a desirable feature of most models of learning. One way to formalize this idea is to use the concept of *payoff monotonicity*. Relying on payoff monotonicity alone, of which the replicator dynamics is a special case, we derive some interesting properties of an *evolutionary system* (defined below).

Definition 14.14 (*Evolutionary system*): Suppose that $K = \{1, 2, \dots, n\}$ is the set of competing populations. Players in population $k \in K$ have the pure strategy set $S_k = (s_{k1}, s_{k2}, \dots, s_{kn_k})$. A proportion x_{kj} of players in population $k \in K$ plays the pure strategy $s_{kj} \in S_k$. Let $x_k = (x_{kj})_{n_k \times 1}$ denote the column vector of these proportions in population k and x_k^T , the transpose of x_k . The state of the system is given by $x = (x_1, \dots, x_n)^T$. x_{-k} denotes the frequencies of play of all pure strategies in all populations other than the k th population. A social evolutionary system is a system of differential equations,

$$\dot{x}_t(s_{ki}) = g_{ki}(x), \forall k \in K \text{ and } \forall s_{ki} \in S_k. \quad (14.106)$$

We next define payoff monotonicity, which captures the idea that strategies that have a relatively higher payoff grow at a relatively faster rate.

Definition 14.15 (*Payoff monotonicity*): An evolutionary system is said to be *payoff monotonic* if for all x, k, j, i

$$\pi(s_{ki}, x_{-k}) \geq \pi(s_{kj}, x_{-k}) \Rightarrow \frac{\dot{x}_t(s_{ki})}{x_t(s_{ki})} \geq \frac{\dot{x}_t(s_{kj})}{x_t(s_{kj})}. \quad (14.107)$$

Definition 14.16 (*Regular evolutionary system*): The evolutionary system in Definition 14.14 is said to be *regular* if g_{ki} is a C^1 function for all k, i .³²

³² This condition can be weakened to Lipschitz continuity.

Regularity ensures that a unique solution exists to the problem. The analogues of Propositions 14.7, 14.8 for replicator dynamics can be shown to exist for *payoff monotone and regular dynamics* (PMR dynamics). The proofs are analogous to those in Propositions 14.7, 14.8, so we omit them.

Proposition 14.18 *Suppose that there exists some symmetric Nash equilibrium, $\sigma = (\sigma_1, \dots, \sigma_n)$, of the symmetric game $G(2, S, \pi)$. The interpretation is that σ_i is the probability with which the pure strategy s_i is played by both the populations. Consider the symmetric population state*

$$x_t(s) = \sigma \Leftrightarrow (x_t(s_1), x_t(s_2), \dots, x_t(s_n)) = (\sigma_1, \dots, \sigma_n),$$

where $x_t(s_i)$ is the population frequency with which strategy s_i is played. Then the population state $x_t(s)$ is a dynamic equilibrium (or steady state) of the PMR dynamics.

Proposition 14.19 *Consider the game $G(2, S, \pi)$. Suppose that there is some asymptotically stable state of the PMR dynamics given by*

$$\bar{x} = (\bar{x}(s_1), \bar{x}(s_2), \dots, \bar{x}(s_n)).$$

Now define a mixed strategy

$$\bar{\sigma} = \bar{x} : \bar{\sigma}_i = \bar{x}(s_i); i = 1, 2, \dots, n.$$

Then $(\bar{\sigma}, \bar{\sigma})$ is a symmetric Nash equilibrium of the game.

At least with respect to the two important results in Propositions 14.18, 14.19, replacing replicator dynamics by PMR dynamics is without loss in generality. However, these results rely on the existence of an asymptotically stable steady state, which might not exist in some cases. In this case, one may wish to ensure a weaker notion of rationality embodied in, say, the avoidance of dominated strategies.

Definition 14.17 *(Dominance in pure strategies): Consider a bilateral game with two populations, i.e., $K = \{1, 2\}$ and let $k = 1, 2$ index the two populations. A pure strategy $s_{ki} \in S_k$ is dominated in pure strategies if there exists some other pure strategy $s_{kj} \in S_k$ such that*

$$\pi_k(s_{kj}, x_{-k}) \geq \pi_k(s_{ki}, x_{-k}) \text{ for all } x_{-k}, \quad (14.108)$$

and at least one inequality is strict; x_{-k} is the vector of frequencies with which the other population plays its pure strategies.

We now give the main result for PMR dynamics. If some strategy is dominated in pure strategies, then PMR dynamics ensure that the dominated strategy disappears eventually.

Proposition 14.20 *(Samuelson and Zhang, 1992): Consider a bilateral game with $K = \{1, 2\}$. The pure strategy set of population $k \in K$ is given by $S_k = (s_{k1}, s_{k2}, \dots, s_{kn_k})$. The vector of frequencies with which these pure strategies are played is denoted by x_k . Suppose that the PMR dynamics induce a path $x(t) = (x_1(t), x_2(t))$ starting from some fully mixed initial point $x(0) = (x_1(0), x_2(0))$. If s_{ki} is dominated in pure strategies, then it follows that $\lim_{t \rightarrow \infty} x_t(s_{ki}) = 0$.*

Proof: Since s_{ki} is dominated in pure strategies, there exists some other pure strategy $s_{kj} \in S_k$ such that

$$\pi_k(s_{kj}, x_{-k}) - \pi_k(s_{ki}, x_{-k}) \geq \varepsilon \text{ for all } x_{-k} \text{ and some } \varepsilon > 0.$$

Then from continuity, and payoff monotonicity in (14.107) we get that for all $t \geq 0$,

$$\frac{\dot{x}_t(s_{kj})}{x_t(s_{kj})} - \frac{\dot{x}_t(s_{ki})}{x_t(s_{ki})} \geq \varepsilon_1 \text{ for some } \varepsilon_1 > 0. \quad (14.109)$$

Let

$$y_t = \frac{x_t(s_{kj})}{x_t(s_{ki})}, \quad (14.110)$$

then, using (14.109) we get

$$\frac{\dot{y}_t}{y_t} = \frac{\dot{x}_t(s_{kj})}{x_t(s_{kj})} - \frac{\dot{x}_t(s_{ki})}{x_t(s_{ki})} \geq \varepsilon_1.$$

It follows that $y_t \geq y_0 e^{\varepsilon_1 t}$. Since $\varepsilon_1 > 0$, $\lim_{t \rightarrow \infty} y_t = \infty$, so, from (14.110), it must be the case that $x_t(s_{ki}) \rightarrow 0$. ■

The result in Proposition 14.20 can be strengthened (see Proposition 3.4 in Fudenberg and Levine, 1998). It can be shown that if some pure strategy s_{ki} is eliminated by iterative deletion of dominated strategies, then along any path taken by the PMR dynamics, the share of the population that plays strategy s_{ki} goes to zero. However, as shown in Bjornerstedt (1995), pure strategies that are dominated by a mixed strategy need not be eliminated by payoff monotonic dynamics. Two approaches have been taken to rule out pure strategies that are dominated by a mixed strategy. Samuelson and Zhang (1992) specify an *aggregate monotonicity condition*, which requires that if a mixed strategy has a higher current payoff relative to another mixed strategy, then it also has a higher growth rate. Hofbauer and Weibull (1996) provide a weaker condition called *convex monotonicity*. This condition requires that if a mixed strategy has a higher current payoff relative to a pure strategy, then it also has a higher growth rate.

CHAPTER 15

Models of Learning

15.1 Introduction

Models of evolutionary game theory cannot explain the rapid rate of learning in experiments. By *learning*, we refer to any change in observed behavior as, *ceteris-paribus*, players accumulate experience. Models of learning may provide the foundations of equilibrium concepts, such as Nash equilibrium, that are not based on explicit learning dynamics. Or, we may find that existing equilibrium concepts do not organize very well the data from learning games. In this case, the emerging evidence can provide important clues for the development of new theories.

Section 15.2 considers a classical model of learning, the *reinforcement model of learning*, also known as *stimulus learning* or *rote learning* (Bush and Mostellar, 1951, 1955; Luce, 1959; Suppes and Atkinson, 1960). In this model, players have minimal rationality and limited information about the game being played. Players need not know the payoff matrix, or the strategies/types of other players. All that players need to know is the set of actions that they undertook in the past and the associated payoffs. Strategies that have given rise to higher payoffs in the past are more likely to be played in the present (*law of effect*), and there is no presumption that players should play best replies. This is formalized by associating with each strategy, a number called its *attraction* or *propensity*. Propensities are then reinforced with information about payoffs arising from the play of various strategies. The available strategies are then played probabilistically, in proportion to their relative propensities.

There are many variants of reinforcement learning. Section 15.2.1 considers the one-parameter reinforcement model, which requires a specification only of the initial propensities (Arthur, 1991, 1993). Section 15.2.2 considers the three-parameter model of reinforcement learning (Roth and Erev, 1995; Erev and Roth, 1998). This extends the one-parameter model to allow for (i) *experimentation*, by updating the propensities of strategies that are not played, but are similar to those that are played, and (ii) *recency*, by letting past experience attenuate and assigning greater weight to more recent experience. Section 15.2.3 briefly discusses other variants of reinforcement learning. These include the incorporation of payoff shocks (Sarin and Vahid, 1999, 2001), and learning from the payoff experience of others (Duffy and Feltovich, 1999).

Section 15.2.4 explores the optimality of reinforcement learning. Suppose that an individual plays a game against nature; nature chooses its strategies based on a stationary distribution. Then, under a form of reinforcement learning, called *cumulative proportional reinforcement learning*, the limiting play by the individual is optimal in the sense that the chosen strategy is a best response (Laslier et al., 2001). Indeed, such limiting choices can be shown to belong to asymptotically stable states of replicator dynamics (Hopkins and Posch, 2005).

Section 15.2.5 considers the empirical evidence for reinforcement learning. The main result is that while reinforcement learning is good at predicting the direction of change, the predicted speed of learning is too sluggish (Roth and Erev, 1995; McAllister, 1991). If the speed of adjustment is increased, then the model fails in other respects, e.g., players start to play dominated actions (Van Huyck et al., 2007). Furthermore, contrary to the predictions of reinforcement learning, information about other players, their payoffs, or even their strategies, affects choices (Mookerjee and Sopher, 1994; Rapoport and Erev, 1998). Hence, unless the underlying structure of the game is poorly understood by players, and they have relatively low information, reinforcement learning leaves out important determinants of human learning.

Section 15.3 considers models of *belief-based learning*. In these models, players compute the likely mixed strategy of the opponent, given observations on the past frequencies of play by the opponent. The strategies of the opponent are assigned some initial weights that are updated, depending on their observed strategies. The probability assigned to an opponent's pure strategy is the relative weight of that strategy. Conditional on the expected mixed strategy of the opponent, players then play a myopic best response. A prominent special case is Cournot dynamics (Cournot, [1838] 1927). The rationality and informational requirements in belief-based models are greater relative to models of reinforcement learning.

It can be shown that for 2×2 games (two players, and two pure strategies per player), the frequency of play under belief-based models has a limiting distribution that corresponds to a Nash equilibrium. These results were originally demonstrated for simple 2×2 games (Brown, 1951; Robinson, 1951), and then for more general 2×2 games (Miyasawa, 1961; Monderer and Shapley, 1996). Before the game even begins, players can compute the limiting frequency of play and when they actually have a chance to choose their strategies, they simply play their best response to the limiting frequency. The resulting best response of each player constitutes a Nash equilibrium. Hence, this kind of learning is also termed as *fictitious play*. However, these results hold only for the 2×2 case, and they may fail even for 3×3 games (Shapley, 1964).

One drawback of fictitious play is that the choice of strategies is too rigid and discontinuous. This leads to several well-known problems. For instance, players do not learn from systematic patterns of play. This problem is addressed by making the best response functions *smooth* (Fudenberg and Kreps, 1993). A popular solution is to introduce additive noise in payoffs and assume that the noise follows an extreme value distribution. In this case, the best response follows the smooth logistic function.

Section 15.3.1 reviews some of the empirical evidence on fictitious learning. *Weighted fictitious play* nests ordinary fictitious play and Cournot play as two polar extremes. Using such a model, some studies find that the majority of observations are closer to the Cournot extreme (Cheung and Friedman, 1997). Others find that play is closer to the predictions of ordinary fictitious play and there is divergence between stated beliefs and the beliefs fitted to a model of fictitious play (Nyarko and Schotter, 2002). Interestingly, the actual play is consistent with players who play a best response to stated beliefs, not fitted beliefs, even though the latter converge quickly, while the former are very volatile.

There is a departure from myopic best reply dynamics when one varies the information that is available to players (Huck et al., 1999). In this case, results are sensitive to whether players have information about the market (cost/demand conditions), or information about others (quantity/profits of others). A variety of other learning mechanisms, such as *imitate the best*, *learning direction theory*, and *trial and error learning* explain well the results in several treatments. These results have been extended (Bosch-Domènech and Vriend, 2003). In summary, fictitious play, by itself, is too simple to explain all relevant aspects of human learning.

Section 15.3.2 looks at the empirical performance of fictitious learning, relative to reinforcement learning. Results tend to depend on the type of the game, the particular version of each learning model used, and the treatments allowed for. For these reasons, general conclusions are hard to draw out. Playing dominated strategies is consistent with reinforcement learning, but not with fictitious play because, in the latter, players always play best replies. There is evidence that in repeated rounds of experiments, players sometimes play dominated strategies early on, but are less likely to do so in later rounds (Mookerjee and Sopher, 1997). Reinforcement learning appears to fit better in games with relatively low dimensional strategy spaces that have a mixed strategy equilibrium. However, belief-based models appear to make relatively better predictions in coordination games.

The *optimization premium* (forgone payoff from playing a non-best response) substantially alters the dynamics of play, even when there is no change in the Nash equilibrium of the game (Battalio et al., 2001). Furthermore, the optimization premium plays an important role in understanding the long-run choice between payoff-dominant and risk dominant equilibria. These results reinforce the message that it is not sufficient to focus on best response dynamics.

Camerer and Ho (1999) proposed the five-parameter *experience weighted attraction* (EWA) model. In this model, in any round, players update propensities of strategies that are not played in that round by taking account of the forgone payoffs. They also allow for depreciation of past experience on account of limited memory, or forgetfulness. We explain the EWA model in Section 15.4. Reinforcement learning, belief-based learning models and EWA models are sometimes also known as *adaptive learning models* because, at any instant in time, players adapt their current strategies to the past choice of strategies and/or to the past observations of payoffs.¹

On the face of it, reinforcement learning and fictitious play would appear to be two distinct models. In reinforcement learning, players completely ignore the strategies/payoffs of others, concentrating only on their own history of payoffs and strategies. Since strategies that have given higher payoffs in the past are more likely to be played now, such players play a *better response*, but not a *best response*. In fictitious play, players focus on the historical record of strategies played by the opponents in order to form inferences about their likely current choice of strategies and then play a best response to these expectations. However, we show in Sections 15.4.1 and 15.4.2, that these two models are simply special cases of the EWA model for different parameter configurations. For other parameter values, EWA specializes to a range of other known models such as the Cournot model, cumulative reinforcement model, weighted fictitious play, and the average reinforcement model.

Empirical evidence on the EWA model is considered in Section 15.4.3 (Camerer and Ho, 1999; Camerer et al., 2001; Camerer and Ho, 2014). One possible objection to the EWA model is that its performance is unsurprisingly better than other models, simply because it has a larger number of free parameters. There are two ways of addressing this concern. (i) One can compare the relative performance of the alternative models by using the parameters estimated from in-sample observations to fit out-of-sample observations. There is no guarantee that a model with more free parameters performs better out-of-sample, although it probably would perform better in-sample. (ii) One can use statistical tests such as the Akaike and Bayesian information criteria that trade off better explanatory power against a larger number of parameters. On both criteria, EWA does better relative to reinforcement learning and fictitious play.

¹ It is very plausible to suppose that players have a sudden eureka moment and figure out the structure of the underlying game and/or the strategies of the opponent. Recent experimental evidence supports this form of learning and it will clearly play a more important part in learning models of the future; see, for instance, Dufwenberg et al. (2010) and Gneezy et al. (2010) for experimental evidence.

A more parsimonious alternative to the EWA model is the one-parameter *functional* EWA model or fEWA or *EWA-lite* (Ho et al., 2002); we consider this in Section 15.4.4. The parameters in this model are *self-tuning* in the sense that they respond to changes in the environment. For instance, when the environment is changing rapidly, then less weight is given to past experience. The single parameter of the model is the parameter in the logit function that is used to convert attractions to probabilities. When this model is fitted to the data, it performs better, relative to reinforcement learning and fictitious play. In a comprehensive horse race between the alternative models, tested on seven different games, EWA and fEWA outperform other models such as reinforcement learning, weighted fictitious play, and quantal response equilibrium (Ho et al. 2002; Camerer and Ho, 2014).

Adaptive players in the EWA model ignore information on the payoffs of others, even when doing so would allow them to outguess others and improve their payoffs. *Sophisticated players* are likely to do the opposite. When sophisticated players are matched with adaptive players, they may attempt to teach them, when it improves their future payoffs, even at the cost of short-run payoffs. Formal models of this phenomenon are sometimes known as models of *anticipatory learning*. Furthermore, in games like the p-beauty contest, relatively experienced players are known to converge relatively faster to the Nash equilibrium outcome. The *EWA model with sophistication* takes account of these considerations (Camerer et al., 2002; Camerer et al., 2003). We consider this model in Section 15.4.5. It is able to explain the difference in behavior among experienced and inexperienced subjects in 10 period p-beauty contest games. Experienced players are also less likely to be overconfident about the relative proportion of adaptive players in the population (Camerer et al., 2002).

In Section 15.5, we consider two alternative points of view about the nature of learning models and their generalizability that one may associate with the names of Colin Camerer and Amnon Rapoport. Colin's approach, in common with the general approach in economic modeling, is to strive to build general models that apply to all players/contexts/frames and use statistical criteria, such as AIC and BIC, that trade off greater generality of models against increased explanatory power, particularly in out-of-sample predictions. Amnon rejects this approach and argues for learning models that are tailored for different contexts and games, as well as take greater account of individual heterogeneity and the forward-looking behavior of individuals.

In Section 15.6, we consider the class of *learning direction theories*. The basic model of *learning direction theory* (Selten and Stöcker, 1986) is considered in Section 15.6.1. The essential idea can be explained by the analogy of an archer whose objective is to hit a target (his best response), but he discovers that he has hit a spot to the left of the target. In the next period, he adjusts by aiming between the previous hit and the target. The expectation is that by these successive adjustments, the archer moves qualitatively in the direction of the target.

The aim of learning direction theory is qualitative, i.e., to predict the direction of change, rather than the quantitative aim of specifying the probabilities with which players play their strategies. The theory predicts well the high degree of observed cooperation in repeated prisoner's dilemma game experiments (Selten and Stöcker, 1986). It also predicts well the direction of bid changes in Samuelson and Bazerman's takeover game (Selten et al., 2005).

In Section 15.6.2, we consider extensions of learning direction theory to enable quantitative predictions about the probabilities with which players play their strategies. These extensions have been applied mostly to 2×2 games, although the principle should apply more generally. Two of these extensions are *impulse matching learning* (Selten and Chmura, 2008; Chmura et al., 2012) and *impulse balance equilibrium* (Selten et al., 2005 and Selten and Chmura, 2008). In these theories, payoffs that are higher or lower than some aspiration level lead, respectively, to gains and losses.

One may then transform any normal form game into a game where the payoffs reflect loss-aversion if they are below the aspiration level. In each period, the strategy that could have received a higher payoff if played, receives an *impulse* from the other strategy. These impulses are then cumulated and transformed into probabilities with which various pure strategies are played. We also consider two variants of theories in this class: *action-sample learning* and *payoff-sampling learning* (Selten and Chmura, 2008). As the names indicate, these theories require sampling of past actions or payoffs to determine the current probabilities of play.

These extensions to learning direction theory allow for a direct comparison of this class of models with other models of learning. An earlier empirical attempt (Selten and Chmura, 2008) that found the class of learning direction theories to perform better than the mainstream alternatives was shown to have computation errors (Brunner et al., 2011). This was followed by a comprehensive horse-race between the main theories (Chmura et al., 2012), which ranked them in the following order from best to worse: impulse matching learning, action-sample learning, self-tuning EWA, and reinforcement learning. Importantly, it was also shown that the superior ranking of the class of learning direction theories is not an artifact of the inclusion of loss aversion.

The experimental results from *order statistic games* that we examined in detail in Part 4 of the book, pose an intriguing puzzle (Van Huyck et al., 1990, 1991). These experiments revealed that when the order statistic is the median, the initial choices are dispersed, and there is a strong history-dependence of outcomes. The final outcome, when subjects make a choice among the first seven positive integers is typically about 4 or 5. By contrast, in minimum action games, play quickly converges to the lowest integer choice available to players. Many learning models would struggle to explain the results from order statistic games. Section 15.6.3 considers the explanation offered by Crawford (1991, 1995), which shares some features that make it close, in spirit, to the class of learning direction models.

In the learning models considered so far, players try to learn aspects of the environment and update their propensities about their own, or the opponent's strategies. However, they continue to adopt the same learning rule throughout, e.g., reinforcement learning, belief-based learning, or EWA. Section 15.7 relaxes this assumption, and allows for the possibility that, given a set of rules, players also learn which rules might perform better than others (Stahl, 1999, 2000, 2001; Stahl and Haruvy, 2002). Hence, in each stage, players choose probabilistically among rules, choosing those rules that have done better, as in reinforcement learning. Each rule then prescribes a probabilistic play of pure strategies.

Even if the population is homogeneous, players draw from among the set of rules by using independently and identically distributed densities. This will typically generate heterogeneity in the choice of rules among the population. We consider choice from a plausible set of rules. An important family of such rules are *evidence based rules* in which players weight the evidence for and against the rule.

The empirical evidence supports rule-based learning relative to no rule learning. The predictions of the model, when we allow for choice from a set of evidence based rules, outperform other kinds of learning in which subjects simply play Nash with or without noise (Stahl, 2000). Further, there is strong evidence for a form of simple cooperation rule in which players play the payoff dominant action, and have an initial propensity to cooperate. These experiments do not find evidence for aspiration based learning, or the tit-for-tat rule (Stahl and Haruvy, 2002).

So far, the learning environment has typically involved single-game situations. However, it is possible that individuals might be asked to learn in situations in which nature probabilistically draws a game from a set of games. Furthermore, in different treatments, the set of games may be small or large, and information to players on payoffs and the past strategies of the opponents

may also vary. We may term these factors as reflecting the underlying *complexity* of playing in a particular treatment. How likely is it that subjects learn to play the Nash equilibrium, as the degree of complexity is varied across treatments? These issues are considered in Section 15.8 (Grimm and Mengel, 2012).

The basic hypothesis is that, as complexity increases, players with scarce cognitive resources respond by categorizing games in a convenient manner. Such categorization may be endogenous (Samuelson, 2001; Fryer and Jackson, 2008; Mengel, 2012), but we consider exogenous categorization only. Once players have categorized the games in some cognitively convenient manner, they may choose a range of simplifying heuristics that economize on scarce cognitive resources. For instance, for any category in a partition of a set of games, they may act as if they faced the average payoffs, or have the average beliefs for the category. This leads to the definition of a range of useful concepts such as *payoff bundling* and *belief bundling*.

The empirical results show that greater complexity (larger set of games and lower information) reduces the probability of playing a Nash equilibrium. Although the degree of complexity in even the most complex situation in the experiments is typically low, and the number of rounds at 100 is very large, the results are sobering for classical Nash equilibrium play. Framing effects and learning spillovers across games are observed; play in strategically equivalent games is similar; transparency of information on payoffs rather than past play of the opponent is more conducive to the Nash equilibrium being played; subjects with higher cognitive ability are more likely to play a Nash equilibrium, and action, or best-response bundling explains the data better than belief bundling.

Section 15.9 briefly illustrates two polar positions on learning.² The first position takes the view that under fairly strong restrictions, Bayesian learning, coupled with a technical condition, the absolute continuity condition, ensures that the limiting play converges to a Nash equilibrium (Kalai and Lehrer, 1993). Others may feel that this framework imposes excessive rationality requirements that are unlikely to be supported by the empirical evidence. Indeed, the evidence in this chapter points in this direction. The second position denies the possibility of such learning (Foster and Young, 2001); this can be shown, for instance, in cases where there is enough ex-ante uncertainty about the payoffs of others.

We have considered a range of models above that incorporate the idea of regret from forgone payoffs, for instance, EWA and impulse matching. The idea is that the regret arising from a strategy is the average payoff forgone from playing other strategies. One may then play pure strategies with probabilities that reflect their relative regret; this is known as *regret matching*. It can be shown that in limiting time, regret matching leads to behavioral strategies that have no associated regret, and the empirical frequency of play converges to the set of coarse correlated equilibria (Hart and Mas-Colell, 2000). This set of equilibria is typically much larger than the set of Nash equilibria, although in very special cases, the two concepts make identical predictions.

15.2 Reinforcement learning

Reinforcement learning, sometimes known as *stimulus response learning* or *rote learning*, is based on the following idea. Strategies that have resulted in a greater payoff in the past are more likely to be played in the future. This form of learning imposes very limited rationality and information

² For a more detailed account of these issues, see Young (2004).

requirements on the parts of players. For instance, players do not require information about the identities and strategies of other players, or even knowledge of the nature of strategic interaction between themselves and other players. Thus, players do not experience regret in these models because they do not have knowledge of the underlying game.

Models of reinforcement learning first appeared in the mathematical psychology literature (Bush and Mostellar, 1951; Suppes and Atkinson 1960). Arthur (1991, 1993) gives an early application of these models to problems in economics. Roth and Erev (1995) and Erev and Roth (1998) modified the basic model to better explain the evidence arising from a range of experimental games. Reinforcement learning appears to fit well human and non-human subjects in very simple games, particularly when players do not know the structure of the game. However, in games where the structure is better known to the players, reinforcement learning does not fit very well. Furthermore, the predicted speed of learning under reinforcement learning is quite sluggish relative to the speed of learning that is observed in experiments.

The basic features of the model that were emphasized in the original papers by Bush and Mostellar (1955), Luce (1959), and Suppes and Atkinson (1960) are as follows.

1. *Law of effect*: If a strategy results in a higher payoff (*stimulus*), then it is more likely to be played in the future (*response*), an idea that goes back to Thorndike (1911). Hence, the basic models in this literature are sometimes termed as *stimulus–response learning*.
2. *Choice is probabilistic*: At each point in time, players play their pure strategies in a probabilistic manner. More successful strategies that have resulted in a higher payoff in the past are more likely to be played in the present (*law of effect*).
3. *Power law of practice*: Players' learning curves are steep initially, but then gradually flatten out. However, the evidence on this is not conclusive.

15.2.1 The one-parameter reinforcement learning model

The one-parameter reinforcement learning model was used extensively until the mid 1990s (Bush and Mostellar, 1955; Arthur, 1991, 1993). Suppose that the set of players is given by $N = \{1, 2, \dots, n\}$. The pure strategy set of player i is given by $S_i = (s_{i1}, s_{i2}, \dots, s_{in_i})$. Players only play pure strategies. Time $t = 1, 2, \dots$ is discrete. Each player has certain *propensities*, sometimes also termed as *attractions*, to play each of the available pure strategies. For player i , the propensity to play strategy $s_{ij} \in S_i$ at time t is given by $q_t(s_{ij})$. We assume that the initial propensity to play any pure strategy is identical, i.e., for any $s_{ij}, s_{ik} \in S_i$ we have $q_1(s_{ij}) = q_1(s_{ik})$.

Players are not required to know the structure of the game they are playing, or even if they are playing a game against an opponent. Hence, unlike classical game theory, payoffs are not defined as mappings from the Cartesian products of strategy sets of players to the set of real numbers. For player i , the payoff function is simply $\pi_i : S_i \rightarrow \mathbb{R}$.

For any player i , we define a *reinforcement function*, $R : \mathbb{R} \rightarrow \mathbb{R}$,

$$R(\pi_i(s_{ij})) = \pi_i(s_{ij}) - \bar{\pi}, s_{ij} \in S_i, \quad (15.1)$$

where $\bar{\pi}$ is the minimum payoff.

Propensities are updated over time as follows. For $t = 1, 2, \dots$

$$q_{t+1}(s_{ij}) = \begin{cases} q_t(s_{ij}) + R(\pi_i(s_{ij})) & \text{if } s_{ij} \text{ is played at time } t \\ q_t(s_{ij}) & \text{otherwise} \end{cases}. \quad (15.2)$$

The choice of $\bar{\pi}$ as the minimum payoff ensures that propensities never become negative. The final step is the translation of propensities into probabilities of playing the various pure strategies. Let $p_t(s_{ij})$ be the probability that, at time t , player i plays strategy $s_{ij} \in S_i$. Then the probabilistic choice rule is given by

$$p_t(s_{ij}) = \frac{q_t(s_{ij})}{Q_{it}}, \text{ where } Q_{it} = \sum_{k=1}^{n_i} q_t(s_{ik}). \quad (15.3)$$

Thus, the probability with which a strategy is played equals its propensity, relative to the aggregate propensity, Q_{it} . Even if $Q_{it} \neq 1$, we have a well-defined probability measure because $\sum_{j=1}^{n_i} p_t(s_{ij}) = 1$. In applied work, sometimes the following one-parameter exponential rule for computing probabilities is used (see Appendix B)

$$p_t(s_{ij}) = \frac{e^{\lambda q_t(s_{ij})}}{\sum_{k=1}^{n_i} e^{\lambda q_t(s_{ik})}}, \quad (15.4)$$

where the single parameter λ reflects the sensitivity of probabilities to reinforcements. For instance, when $n_i = 2$ we can write (15.4) as

$$p_t(s_{i1}) = \frac{1}{1 + e^{\lambda[q_t(s_{i2}) - q_t(s_{i1})]}}. \quad (15.5)$$

Thus, if $q_t(s_{i2}) - q_t(s_{i1}) > 0$, then a higher λ reduces $p_t(s_{i1})$. If $q_t(s_{i2}) - q_t(s_{i1}) < 0$, then a higher λ increases $p_t(s_{i1})$. Thus, a higher λ magnifies the probabilities of strategies whose propensities are also higher.

From (15.2), (15.3), we have $\frac{d}{dt}(Q_{it}) > 0$. Also, from (15.2), if strategy s_{ij} is played at time t , we can write

$$Q_{it+1} = Q_{it} + R(\pi_i(s_{ij})), t = 1, 2 \dots \quad (15.6)$$

One interpretation of the probabilistic choice rule in (15.4) is that players continually experiment. The actual choice of player i in any period, which is to play one of the pure strategies in S_i , is made by using some randomizing device that reflects the choice probabilities in (15.3). We need to fix the initial value of aggregate propensity, Q_{i1} , for each player, in order to determine the initial probabilities of play in (15.3). We assume that it is identical for all players, i.e.,

$$Q_{i1} = \bar{Q}, \forall i \in N. \quad (15.7)$$

$\bar{Q}$ is the only parameter of the model. For this reason, we call this version the *one-parameter reinforcement learning model*.

We can check that the one-parameter model satisfies all the features, 1–3, of the reinforcement learning model. From (15.2), positive reinforcement is given at time t to the action that is played in that time period. From (15.1), the magnitude of reinforcement is directly proportional to the payoff associated with a strategy (law of effect). From (15.3), this directly affects the probability of playing that strategy (choice is probabilistic). To demonstrate the third feature, the power law of practice, suppose that s_{ij} is the action played at time t . Then substituting (15.2) in (15.3), we get that

$$\frac{dp_t(s_{ij})}{d(R(\pi_i(s_{ij})))} = \frac{1}{Q_{it}} > 0; \frac{d}{dt} \left(\frac{dp_t(s_{ij})}{R(\pi_i(s_{ij}))} \right) = \frac{-1}{Q_{it}^2} \frac{d}{dt}(Q_{it}) < 0. \quad (15.8)$$

Thus, the impact of a given reinforcement on the probability of playing s_{ij} is positive, but diminishes with time. So, the learning curve gets flatter with the passage of time, as required by the power law of practice.

15.2.2 The three-parameter model of reinforcement learning

Motivated by psychological evidence,³ Roth and Erev (1995) and Erev and Roth (1998) propose a *three-parameter reinforcement learning model*. They essentially add two psychological features to the one-parameter model.

1. *Experimentation*: The probabilistic nature of choice in the one-parameter model already ensures that individuals are not locked-into choices they make at any time. Experimentation ensures that players experiment with choices “similar” to those that were successful in the past.
2. *Recency*: Recent events and experiences influence behavior to a greater extent than those in the more distant past.

These two features, *experimentation* and *recency*, are incorporated by modifying the updating of propensities in (15.2), as follows. Suppose that given any strategy, s_{ij} , we can order the remaining strategies in the set S_i in a linear order such that the most adjacent strategies to s_{ij} are most “similar” to s_{ij} .⁴ This ensures that s_{ij-1} and s_{ij+1} are more similar to s_{ij} than s_{ij-2} and s_{ij+2} , and so on. Suppose that strategy s_{ij} is played at time t . Then player i updates his propensities in the following manner.

$$q_{t+1}(s_{ik}) = \begin{cases} (1 - \phi) q_t(s_{ik}) + (1 - \varepsilon) R(\pi_i(s_{ij})) & k = j \\ (1 - \phi) q_t(s_{ik}) + \frac{\varepsilon}{2} R(\pi_i(s_{ij})) & k = j - 1, j + 1 \\ (1 - \phi) q_t(s_{ik}) & \text{for } k \neq j \text{ and } k \neq j - 1, j + 1 \end{cases}, \quad (15.9)$$

where $R(\pi_i(s_{ij}))$ is defined in (15.1), and $\varepsilon > 0$ is a small number. $\phi > 0$ is a “forgetting parameter” which gradually reduces the influence of more distant experiences in the past. The first row in (15.9) shows that the strategy s_{ij} , which is most recently played, is reinforced in a manner similar to (15.2). However, reinforcement is reduced by the experimentation parameter ε . The second row shows that “similar” strategies in the immediate neighborhood of s_{ij} are also reinforced, although not to the same extent as s_{ij} . Finally, all other strategies are not reinforced at all (third row). Hence, the model has three parameters, $\phi, \varepsilon, \bar{Q}$ (where $\bar{Q}$ is defined in (15.7)).

When strategies cannot be ordered by similarity, then the three-parameter model imposes the following reinforcement of propensities following a play of s_{ij} at time t (recall that player i has n_i pure strategies).

$$q_{t+1}(s_{ik}) = \begin{cases} (1 - \phi) q_t(s_{ik}) + (1 - \varepsilon) R(\pi_i(s_{ij})) & k = j \\ (1 - \phi) q_t(s_{ik}) + \frac{\varepsilon}{(n_i - 1)} R(\pi_i(s_{ij})) & k \neq j \end{cases}. \quad (15.10)$$

³ See, for instance, Guttman and Kalish (1956) and Brown et al. (1958).

⁴ Similarity is not defined in the paper; rather, it appears to be a matter of judgment about the various strategies, exercised by the player. For instance, a bunch of strategies may be similar because they could be recognized as cooperative strategies, or relying on a some common notion of justice or fairness.

15.2.3 Some other variants of reinforcement learning

Sarin and Vahid (1999, 2001) propose the injection of greater rationality within the reinforcement learning framework. When choosing their strategies, players face some uncertainty about the future states of the world. Let Ψ be the set of possible states of the world, which may be thought of as some compact subset of $\mathbb{R}$. Payoffs are random and given by the payoff function $\pi : S_i \times \Psi \rightarrow \mathbb{R}$. Suppose that strategy s_{ij} is played at time t and $s_{ik} \in S_i$. Then, in Sarin and Vahid (1999), for $\omega \in \Psi$ the player assigns an assessment that the payoff from the strategy s_{ik} at time $t + 1$ is given by

$$u_{t+1}(s_{ik}) = \begin{cases} (1 - \lambda) u_t(s_{ik}) + \lambda \pi(s_{ik}, \omega) & k = j \\ u q_t(s_{ik}) & k \neq j \end{cases} \quad (15.11)$$

where $\lambda \in (0, 1)$, the time-invariant learning parameter is the only parameter in the model in addition to the initial assessments. The higher is λ , the greater is the responsiveness of assessments to observed payoffs. Sarin and Vahid (1999) dispense with the construction of probabilities. They directly assume that the player optimizes and chooses an action $s_i^* \in S_i$ that maximizes the assessment at time t . Sarin and Vahid (2001) find that when the results are averaged across subjects in games that have a unique mixed strategy Nash equilibrium, their model fits better overall as compared to the three-parameter Roth and Erev (1998) model.

Duffy and Feltovich (1999) consider the possibility that players learn not just from their own experiences, but also from the experiences of others. Suppose that there are only two players, A and B , with identical pure strategy sets. They respectively play strategies s_{Aj} and s_{Bl} in period t . Player A updates his propensities in the following manner that modifies the one-parameter reinforcement learning model to take account of the experience of player B .

$$q_{t+1}(s_{Ak}) = \begin{cases} q_t(s_{Ak}) + R(\pi_A(s_{Aj})) & \text{if } k = j \\ q_t(s_{Ak}) + \beta R(\pi_B(s_{Bl})) & \text{if } k = l \\ q_t(s_{Ak}) & \text{otherwise} \end{cases}, \beta \geq 0. \quad (15.12)$$

Players update strategies based on their own experience (first row) and the experience of the other player (second row). Using $\beta = 0.5$, Duffy and Feltovich (1999) find that their model gives a good fit to the data for the best shot and the ultimatum games used in Roth and Erev (1995).

The reinforcement model is also used in models of *aspiration adaptation*. Essentially, players have aspiration levels, as envisaged in Herbert Simon's notion of satisficing. Denote the aspiration level of player i at time t by a_{it} , where the initial level of aspiration a_{i0} is given for each player. Subsequent to the play of a strategy $s_{ik} \in S_i$, the aspiration levels are updated gradually in the following manner,

$$a_{it+1} = \gamma a_{it} + (1 - \gamma) \pi(s_{ik}), \gamma \in (0, 1).$$

Hence, at time $t + 1$, aspirations are a convex combination of current aspirations and the payoff received at time t from playing s_{ik} . In *aspiration-based reinforcement learning*, the following condition is imposed on propensities.

$$\text{If } \pi(s_{ik}) \geq a_{it}, \text{ then } q_{t+1}(s_{ik}) \geq q_t(s_{ik}) \text{ and } p_{t+1}(s_{ik}) \geq p_t(s_{ik}). \quad (15.13)$$

Thus, (15.13) requires that if at time t , the payoff from some strategy is greater than the current aspiration level, then the propensity and the probability of playing that strategy increases. A variety of functional forms can be used to implement (15.13).⁵ The propensities are then converted into probabilities of playing various strategies as in, say, (15.3). For evidence in support of aspiration-based learning models, see Bereby-Meyer and Erev (1998) and Huck et al. (2007).

15.2.4 Optimality of reinforcement learning in a stationary environment

Consider a single player who plays a game against nature in a stationary environment. The pure strategy set of the player is given by the finite set $A = (a_1, a_2, \dots, a_{n_A})$. Mixed strategies over this set are denoted by ΔA . Nature has the finite strategy set $B = (b_1, b_2, \dots, b_{n_B})$. Let mixed strategies over B be given by ΔB . The payoff function of the player is given by $\pi : A \times B \rightarrow \mathbb{R}$.

Consider the following updating rule for propensities

$$q_{t+1}(a_i) = \begin{cases} q_t(a_i) + \pi(a_i, b_j) & \text{if } a_i \text{ is played at time } t \\ q_t(a_i) & \text{otherwise} \end{cases}, \quad (15.14)$$

where $a_i \in A$ is the action chosen by the player and $b_j \in B$ is the action chosen by nature in period t . This updating rule is known as the *cumulative payoff matching rule* (CPM), or sometimes also as the *cumulative proportional reinforcement rule*. At time t , denote the tuple of strategies played by the player and by nature, by (a^t, b^t) . Let $t = 1$ be the initial period. Then, the history of play at the end of time period t , is given by

$$h^t = [(a^1, b^1), (a^2, b^2), \dots, (a^t, b^t)]. \quad (15.15)$$

Under reinforcement learning, players use (15.14), (15.15) as inputs into the determination of probabilities with which they play their various pure strategies, given in (15.3).

Suppose that in every period, nature plays according to some time-invariant probability distribution $p^b = (p^b(b_1), \dots, p^b(b_{n_B})) \in \Delta B$. The best response of the player to p^b , $BR(p^b)$, can be found as follows

$$BR(p^b) \in \arg \max_{a_i \in A} \sum_{j=1}^{n_B} p^b(b_j) \pi(a_i, b_j). \quad (15.16)$$

Definition 15.18 (*Optimal behavioral strategy*) A behavioral strategy of the player at time t , $s_A^t : p^b \rightarrow A$ is optimal against the stationary distribution p^b if the probability with which a_i is played under s_A^t goes to zero (almost surely) for all $a_i \notin BR(p^b)$.

The following result has been either conjectured, or shown to be true in several contributions.⁶

Proposition 15.21 (Laslier et al., 2001): For finite action sets, A, B , if players use reinforcement learning and update their propensities using cumulative payoff matching, then, in the limit, such a behavioral strategy is optimal (belongs to the set of strict best responses) against a stationary distribution of play by nature.

⁵ See for instance, Karandikar et al. (1998), Borghers and Sarin (2000), and Bendor et al. (2001).

⁶ See for instance, Arthur (1993), Rustichini (1999), Laslier et al. (2001), and Hopkins and Posch (2005).

In addition, Hopkins and Posch (2005) showed that the limiting points in Proposition 15.21 do not converge to fixed points that are not asymptotically stable under replicator dynamics. Players who use reinforcement learning behave as automata. They mechanically convert inputs, from history and their propensities, into outputs, i.e., probability distributions over their actions. However, when they use cumulative payoff matching, then in a stationary environment, reinforcement learning converges to a best response.

15.2.5 *Empirical evidence on reinforcement learning*

Reinforcement learning often correctly predicts the direction of learning; this is not surprising because it reinforces propensities of more successful strategies, relatively more. However, the predicted speed of learning is too slow relative to experimental results from a variety of games, such as the ultimatum game and the public goods game; see, Roth and Erev (1995).

McAllister (1991) used the reinforcement learning model to test the predictions of the *weak link game* of Van Huyck et al. (1990) (see Part 4 of the book). They find that speed of learning predicted by the reinforcement model is too slow relative to actual learning. If the reinforcement model is modified to include reinforcements for forgone payoffs (see this modification in the discussion of the EWA model below), then the predicted speed of learning is higher and more in conformity with the evidence.

Figure 15.1 shows the results of fitting the data from 5 simple classes of 2×2 games in Erev and Roth (1998); a total of 12 games are fitted to the data. The games are shown along the left margin. The strategies of the row player are A1 and B1, and the strategies of the column player are A2 and B2. The alphabets for each game (e.g., S & A2, M & L) are acronyms for the names of authors who originated the corresponding games. Four of the five classes of games had a unique mixed strategy Nash equilibrium that is shown in the first column in Figure 15.1. For instance, the mixed strategy equilibrium for the game in the first row (S & A2) is for the row player to play A1 with probability $1/3$ and for the column player to play A2 with probability $5/6$. However, subjects did not see the game. They pressed keys and the probability of a correct answer is determined by the payoff matrix in a manner that we do not go into here; this accounts for the variation in the mixed strategy predictions across the rounds.

Columns 2 and 3 in Figure 15.1 show the predictions of the one parameter (Roth and Erev, 1995) and the three parameter (Erev and Roth, 1998) models of reinforcement learning. The final column shows the predictions of a model of fictitious play (see Section 15.3 below). The accuracy of predictions is judged by calculating the mean square deviations (MSD) of the predictions from the actual data. The predictions are derived by populating the models with imaginary agents, and endowing them with the model parameters. Furthermore, the parameters are chosen using a grid search method to minimize MSD. The MSD were calculated for each block of data, and then averaged across the blocks. Among any two models, the one with the smaller value of MSD is to be preferred.

The results are shown in Table 15.1. Columns 2–13 correspond to one of 12 games and each row corresponds to a particular model of learning. The numbers in each results column are the values of $\text{MSD} \times 100$ for the corresponding game and the last column reports $\text{MSD} \times 100$ aggregated across all 12 games for each learning model. Other than random choice and equilibrium choice, the remaining learning models are presented in terms of the best fit across all games and the best fit in each game. Across all games, the equilibrium predictions (corresponding to mixed strategy Nash) have an MSD of 3.87, which is worse than random choice (1.87). When compared across individual games, random does better than equilibrium in five games and ties in one game.

Figure 15.1 Results of fitting the data from 5 simple classes of 2×2 games.

Overall, the basic one-parameter model of reinforcement learning does better than equilibrium (MSD of 1 as compared to 3.57). However, it does not explain the late movement in many games towards equilibrium. The one-parameter model shows a greater sluggishness in response to the play of the opponent relative to the actual data. The three-parameter model that best fits the data across all games gives the following values of the parameters: $Q(1) = 9$, $\phi = 0.1$ and $\varepsilon = 0.2$. This model outperforms all the other models used. The authors argue that this is not due to the addition of extra parameters alone, but rather that the three-parameter model captures something fundamental about the nature of human learning. The three-parameter model, for instance, outperforms the one-parameter model even when the one-parameter model uses game-specific 12 parameters.

Choi et al. (2009) provide evidence from 401(k) savings plans in the US to show that investors appear to follow *naïve reinforcement learning*, hence confirming experimental findings. Investors who observe a higher than average return, or a relatively low variance return increase their savings rate in this investment vehicle relatively more. This finding cannot be explained by investor fixed effects, or time-varying investor-level heterogeneity.

Van Huyck et al. (2007) consider an *order statistic game* with five players; see Part 4 for the details. The strategy of each player is a choice of number $x_i \in [0, 1]$. Denote the strategy choice of players other than i by the vector x_{-i} , and the strategy profile by $x = (x_i, x_{-i})$. Let the median strategy choice be x_m . Then, the payoff of the i th player is given by

$$\pi_i(x_i, x_{-i}) = 0.5 - |x_i - \lambda x_m(1 - x_m)|, \lambda > 0. \quad (15.17)$$

By inspection, the optimal choice of the i th player is $x_i^* = \lambda x_m(1 - x_m)$. In one of the games considered by the authors, $\lambda = 2.44$. For this game, the symmetric Nash equilibrium is given by the solution to $x^N = 2.44x^N(1 - x^N)$ for all i . There are two symmetric Nash equilibria, $x^N = 0$ and $x^N = 0.59$. In one treatment, each experimental subject was informed that there were four other players and the game would be repeated over 75 periods. In particular, the payoff functions of the other players were not revealed. Play settles down to the interior Nash equilibrium in a zig-zag pattern after about 20 periods.

Van Huyck et al. (2007) then ask if this is in accord with the predictions of reinforcement learning. However, the learning dynamics induced by reinforcement learning are too slow. If the parameters in the model are altered to speed up learning, then it gives rise to other undesirable side-effects such as the play of dominated strategies.

The information requirements in models of reinforcement learning are limited. Players only need information about their own past payoffs. However, Mookerjee and Sopher (1994) found that the experimental results depend on extra information, in addition to the data on players' own past payoffs. A similar result is found in Rapoport and Erev (1998) and Battalio et al. (2001); the latter found that the provision of extra information can speed up the learning process substantially.

15.3 Belief-based models of learning

How do players form beliefs about others and about the environment around them, and how do these beliefs evolve over time? In the literature, the general class of models that address this question is known as *belief-based models of learning*. In models of reinforcement learning, players are not required to be informed of the underlying game and they only play a *better response*, but not a *best response*. By contrast, in belief-based models, there is a greater degree of rationality.

Players in belief-based models know the game that they are playing, and conditional on their beliefs about the opponent, they play a *best response*. However, they have limited rationality in the sense that they do not realize that their opponents are also engaged in a similar exercise. Beliefs are typically formed by observing the past strategies of the opponent. For instance, in the Cournot model, players play a best response to the previous period's output of the opponent, believing that the opponent will choose the same output this period. However, the general class of belief-based models allows for a sophisticated weighting of past actions of the opponent in order to form the relevant beliefs.

An important subclass of belief-based models is the model of *fictitious play*. Most results in the literature on fictitious play are available only for two-player simultaneous move games, so we restrict our analysis to such games. In models of fictitious play, each of the two players observes the past frequency of play of different actions by the opponent. This data is then used to compute the probabilities with which the opponent is expected to play various pure strategies; opponents are assumed to draw their strategies from a stationary distribution. Once such probabilities are

computed, each player behaves in a myopic manner and maximizes the current payoff. Thus, players take into account the entire history of play (unlimited memory), but assume a stationary environment.

An interesting question is whether the computed frequencies of play of the opponent under fictitious play converge to some limiting distribution. Also, does the play converge to a Nash equilibrium, conditional on this limiting distribution? The answer to both questions is in the affirmative for two-player games. Indeed, the original motivation to study fictitious play (Brown, 1951; Robinson, 1951) was to find an alternative method of computing a Nash equilibrium.

If the strategy profile in the game converges to a Nash equilibrium (as we shall see below), then one could envisage that players engage in a mental exercise prior to the game. As part of this mental exercise, each player goes through the steps of computing a limiting distribution of play of the opponent's actions. Subsequently, when each player is given a chance to play the game, they can straightaway play the Nash equilibrium, using the limiting distribution as the initial expectation over the opponent's actions. Hence, the name, *fictitious play*.

Denote the two-player simultaneous move game by $G(2, S_1, S_2, \pi_1, \pi_2)$, where π_1, π_2 are von Neumann–Morgenstern utility functions. The set of players is $N = \{1, 2\}$, the pure strategy sets of players 1 and 2 are, respectively, given by $S_1 = (s_{11}, s_{12}, \dots, s_{1n_1})$, $S_2 = (s_{21}, s_{22}, \dots, s_{2n_2})$ and the payoffs by $\pi_i : S_1 \times S_2 \rightarrow \mathbb{R}$. Time is discrete, $t = 0, 1, 2, \dots$. Each player $i \in N$ associates, at time t , a weight $w_t^i(s_{jk})$ to the pure strategy s_{jk} of the opponent $j \in N$, where $j \neq i$ and $s_{jk} \in S_j$. Denote the vector of these weights by

$$w_t^i = (w_t^i(s_{j1}), \dots, w_t^i(s_{jn_j})).$$

There is an initial set of non-negative weights w_0^i , $i \in N$ that is taken as given and $\sum_{k=1}^{n_j} w_t^i(s_{jk}) > 0$, $j \neq i$. Over time, the weights are adjusted as follows.

$$w_{t+1}^i(s_{jk}) = \begin{cases} w_t^i(s_{jk}) + 1 & \text{if } s_{jk} \text{ is played at time } t \\ w_t^i(s_{jk}) & \text{otherwise} \end{cases}; \quad i, j \in N, j \neq i \text{ and } s_{jk} \in S_j. \quad (15.18)$$

Hence, if a pure strategy is played by the opponent, then its weight is augmented by 1 unit in the next period, but the weight on all other pure strategies is unchanged.

Each player uses the weights, constructed as in (15.18), to assign probabilities to the opponent's pure strategies. Define

$$\bar{w}_t^i = \sum_{k=1}^{n_j} w_t^i(s_{jk}). \quad (15.19)$$

Denote by $x_t^i(s_{jk})$, the probability with which player i expects player j ($j \neq i$) to play the pure strategy $s_{jk} \in S_j$. Then, under fictitious play

$$x_t^i(s_{jk}) = \frac{w_t^i(s_{jk})}{\bar{w}_t^i} \geq 0. \quad (15.20)$$

From (15.20), we have $\sum_{k=1}^{n_j} x_t^i(s_{jk}) = 1$. Denote the vector of probabilities with which player i expects player j to play all pure strategies in the set S_j by

$$x_t^i = (x_t^i(s_{j1}), x_t^i(s_{j2}), \dots, x_t^i(s_{jn_j})); \quad i, j \in N, j \neq i \text{ and } s_{jk} \in S_j. \quad (15.21)$$

Finally, fictitious play requires that each player chooses a pure strategy $s_{ik}^* \in S_i$, such that it is a best response to beliefs, x_t^i . Thus,

$$s_{ik}^* \in BR(x_t^i) \equiv \{s_i \in S_i : \pi(s_i, x_t^i) \geq \pi(\hat{s}_i, x_t^i), \forall \hat{s}_i \in S_i\}, i = 1, 2. \quad (15.22)$$

Under fictitious play, players do not try to influence the opponent's action, nor do they take into account the strategic effect of their actions on others. One feature of belief-based models is that the best reply functions of players may be non-differentiable. An example is the battle-of-sexes game. In order to smooth the best response functions, one can extend belief-based models to noisy play in many ways. In Boylan and El-Gamal (1993), with probability ϵ , players randomly choose one of their actions and with probability $1 - \epsilon$, they play their best response, as described above.

Let us now consider a version of fictitious play known as *smooth fictitious play* by introducing a small additive shock to the payoff of players, so the payoff of player i becomes

$$\pi_i(s_i, \sigma_{-i}) + \eta_i, \quad (15.23)$$

where η_i is a random shock. Suppose that the cumulative distribution of the shock is given by

$$\ln \Pr(\eta_i < y) = -e^{-\lambda_i y}, \quad (15.24)$$

where λ_i is an individual specific parameter. Then it can be shown that the best response of the player is given by the *logistic* or *quantal response function* (see Appendix B). Suppose that the probability that player i plays strategy s_{ik} when the other players are expected to play a mixed strategy σ_{-i} is given by $p_t^i(s_{ik} | \sigma_{-i})$. Then, under (15.23), (15.24), the best response of player i is given by the quantal response function

$$p_t^i(s_{ik} | \sigma_{-i}) = \frac{e^{-\lambda_i \pi_i(s_{ik}, \sigma_{-i})}}{\sum_{j=1}^{n_i} e^{-\lambda_i \pi_i(s_{ij}, \sigma_{-i})}}, \quad (15.25)$$

which is completely smooth.

In Section 15.2.4, we showed that in special circumstances, reinforcement learning is consistent with fully rational behavior. It can also be shown that fictitious play is consistent with fully rational optimizing behavior under the following two conditions (Fudenberg and Levine, 1998). (1) The initial beliefs of a player about an opponent's actions are given by the Dirichlet distribution (which is a generalization of the beta distribution). (2) Each player believes that in each subsequent period, the opponent's play is a sequence of iid multinomial random variables.

Example 15.7 In 2×2 games, if the probabilities of the play of others are given in (15.20) and a strict Nash equilibrium is played, then Fudenberg and Kreps (1990) showed that under fictitious play, this Nash equilibrium is played for all time periods. To illustrate this result, consider the symmetric 2×2 coordination stage-game, shown in Figure 15.2, that is played in every period.

This game has two strict Nash equilibria: (s_1, s_1) and (s_2, s_2) . Denote the row and the column players by players 1 and 2 respectively. Suppose that player 2 plays action s_1 with probability q and s_2 with probability $1 - q$. Then player 1's best response is to play action s_2 if $9q \leq 7q + 8(1 - q)$ or $q \leq 0.8$.

	s_1	s_2
s_1	9, 9	0, 7
s_2	7, 0	8, 8

Figure 15.2 A symmetric 2×2 coordination game.

Suppose that initial weights are identical and given by the ordered pair $w_0^1 = w_0^2 = (6, 4)$. Using (15.20), the probabilities assigned by each player to the actions (s_1, s_2) played by the other player are symmetrically given by the ordered pair $x_0^1 = x_0^2 = (0.6, 0.4)$. Since $0.6 < 0.8$, the best response of each player is to play s_2 . Using (15.18), the weights in period 1 are $w_1^1 = w_1^2 = (6, 5)$. From (15.20) the opponent is expected to play each of the pure strategies with probabilities $x_1^1 = x_1^2 = (0.545, 0.455)$. Since $0.545 < 0.8$, the best response by each player is again to play s_2 . The calculations for the next two periods, each eliciting a best response of s_2 from each player are: $w_2^1 = w_2^2 = (6, 6)$, $x_2^1 = x_2^2 = (0.5, 0.5)$ and $w_3^1 = w_3^2 = (6, 7)$, $x_3^1 = x_3^2 = (0.46, 0.54)$. This is a strictly decreasing sequence, ensuring that s_2 is played in every period.

Do the probabilities given in (15.21) converge? Robinson (1951) showed that they converge for the case of zero-sum games. Miyasawa (1961) and Monderer and Shapley (1996) show that convergence takes place for generic 2×2 games. We state this result without proof.

Proposition 15.22 Consider the game $G(2, S_1, S_2, \pi_1, \pi_2)$. Suppose that $n_1 = n_2 = 2$, initial weights are w_0^i , $i = 1, 2$, and the sequence $(x_t^1, x_t^2)_0^\infty$ is induced by (15.18)–(15.22). Then $\lim_{t \rightarrow \infty} x_t^i = x^{i*} = (a, b) \in [0, 1] \times [0, 1]$, $i = 1, 2$.

For Example 15.7, the vector of probabilities converges to the tuple $x^{1*} = x^{2*} = (0, 1)$. The best response of each player is to play s_2 , so the limiting outcome is the Nash equilibrium (s_2, s_2) . The next proposition shows that this is not a coincidence.

Proposition 15.23 Consider the game $G(2, S_1, S_2, \pi_1, \pi_2)$. Suppose that $n_1 = n_2 = 2$ and initial weights are given by w_0^i , $i = 1, 2$. Let the sequence $(x_t^1, x_t^2)_0^\infty$ be induced by (15.18)–(15.22). Suppose that $\lim_{t \rightarrow \infty} x_t^i = x^{i*} = (a, b) \in [0, 1] \times [0, 1]$. Now define a mixed strategy for each player as follows:

$$\sigma_i^* = x^{i*}; i = 1, 2.$$

Then (σ_1^*, σ_2^*) is a Nash equilibrium of $G(2; S_1, S_2; \pi_1, \pi_2)$.

Proof: Suppose by way of contradiction that (σ_1^*, σ_2^*) is not a Nash equilibrium. Let there be some $s_1^* \in S_1$ in the support of σ_1^* and another $\hat{s} \in S_1$ that is not in the support of σ_1^* . Then we have

$$\pi(s_1^*, \sigma_2^*) < \pi(\hat{s}, \sigma_2^*). \quad (15.26)$$

Since the sequence $\{x_t^1, x_t^2\}$ converges to (σ_1^*, σ_2^*) and π is continuous, along the path of play, there is a neighborhood of σ_1^* such that (15.26) holds for all σ_1 in that neighborhood. Alternatively, there exists some integer value τ such that for all $t \geq \tau$, the condition (15.26) holds. Thus, s_1^* is

never played by player 1 subsequent to time period τ . Hence, using (15.18), its decision weight is never updated, so

$$w_t^2(s_1^*) = w_\tau^2(s_1^*), \forall t \geq \tau. \quad (15.27)$$

From (15.19) we get that

$$\bar{w}_t^2 = \bar{w}_\tau^2 + (t - \tau), \forall t \geq \tau. \quad (15.28)$$

Using, (15.20) we expect that player 2 assigns a decreasing sequence of probabilities to player 1 playing s_1^* ever again. Indeed in the limit, such a probability may vanish as we now see. Since $x_t^2(s_1^*) = \frac{w_t^2(s_1^*)}{\bar{w}_t^2}$ and using (15.27), (15.28) we have that

$$\sigma_1^*(s_1^*) = \lim_{t \rightarrow \infty} x_t^2(s_1^*) = \lim_{t \rightarrow \infty} \frac{w_\tau^2(s_1^*)}{\bar{w}_\tau^2 + (t - \tau)} = 0.$$

But if $\sigma_1^*(s_1^*) = 0$, then it contradicts the condition that s_1^* belongs to the support of σ_1^* . An analogous proof applies if, in this symmetric game, we had started off with player 2 instead. ■

Propositions 15.22, 15.23 apply to special classes of 2×2 games. Shapley (1964) showed that for 3×3 games, the sequence $\{x_t^1, x_t^2\}$ induced by (15.18)–(15.22) might not converge. Consider, for instance the symmetric two-player game shown in Figure 15.3, originally due to Shapley (1964).

Suppose that the initial weights are such that the equilibrium induced by (15.18)–(15.22) is (s_1, s_2) . Any set of initial weights in which the row player assigns the highest initial weight to the column player's choice of s_2 and the column player assigns the highest initial weight to the row player's choice of s_2 will do. One can then check that the play induced by (15.18)–(15.22) in the following periods is similar to the Cournot dynamics, i.e., each player plays a best response to the previous period's play by the opponent. Thus, play in the subsequent periods is (s_1, s_3) , (s_2, s_3) , (s_2, s_1) , (s_3, s_1) , (s_3, s_2) , (s_1, s_2) , $\dots$. Along the path that we have sketched out, play begins at (s_1, s_2) and returns to (s_1, s_2) . Thus, the entire process keeps cycling repeatedly and the empirical frequencies of play never converge.

Consider another example due to Fudenberg and Kreps (1993). Suppose that we have the symmetric two-player game shown in Figure 15.4. There are two pure strategy Nash equilibria in this game, (s_1, s_2) and (s_2, s_1) . There is also a mixed strategy Nash equilibrium in which each player randomizes between his two pure strategies. Now consider fictitious play. Suppose that

	s_1	s_2	s_3
s_1	0, 0	1, 0	0, 1
s_2	0, 1	0, 0	1, 0
s_3	1, 0	0, 1	0, 0

the initial weights for each player on the strategies of the opponent, (s_1, s_2) , are identical and given by $w_0^1 = w_0^2 = (1, \sqrt{2})$. Thus, the probabilities of play of the opponent are given by $x_0^1 = x_0^2 = (0.41, 0.59)$. Each player's best response is to choose s_1 . The weights in period 1 are $w_1^1 = w_1^2 = (2, \sqrt{2})$, and the probability vectors are $x_1^1 = x_1^2 = (0.58, 0.42)$. So the best response of each player is s_2 . The weights in period 2 are $w_2^1 = w_2^2 = (2, 2.41)$, the probability vectors are $x_2^1 = x_2^2 = (0.45, 0.55)$, hence, the best response of each player shifts back to s_1 . It can be shown, using an induction argument, that the sequence of play oscillates as follows: (s_1, s_1) , (s_2, s_2) , (s_1, s_1) , (s_2, s_2) , $\dots$

Since the game in Figure 15.4 is a 2×2 game, Proposition 15.22 applies. Hence, there is a unique limiting distribution of the probabilities with which the opponents are expected to play each of their pure strategies. In this case, the unique distribution (from Proposition 15.23) coincides with the mixed strategy Nash equilibrium of the game, i.e., $x^{1*} = x^{2*} = (0.5, 0.5)$. While the marginal distribution of the player's strategies converges to $(0.5, 0.5)$, the joint distribution of play oscillates repeatedly between the two worse outcomes.

A striking aspect of this equilibrium is that each player gets a payoff of 0 in each period, when the expected payoff under the mixed strategy Nash equilibrium is 0.5. Since play incessantly cycles, if one of the players departs from fictitious play, while the other does not, then he can improve his payoff to 1. Hence, behavior in fictitious play is too rigid and players do not seem to learn from systematic patterns of play.

Another variant of fictitious play called *weighted fictitious play* was proposed by Cheung and Friedman (1997). Suppose that there are two players. Pick any player i and refer to the other player $j \neq i$ as his opponent. The strategy played at time t by player i is denoted by $s_i(t) \in S_i$, where $S_i = \{s_{i1}, s_{i2}, \dots, s_{in_i}\}$.⁷ The opponent plays the strategy $s_j(t) \in S_j$ at time t , where $S_j = \{s_{j1}, s_{j2}, \dots, s_{jn_j}\}$. Define an indicator function I over pairs of the opponent's strategies as follows

$$I(s_{jk}, s_j(t)) = \begin{cases} 1 & \text{if } s_{jk} = s_j(t) \\ 0 & \text{if } s_{jk} \neq s_j(t) \end{cases}, s_{jk}, s_j(t) \in S_j.$$

Under *weighted fictitious play*, the beliefs of player i about the strategy of the opponent (the analog of (15.20)) are given by

$$x_{t+1}^i(s_{jk}) = \frac{I(s_{jk}, s_j(t)) + \sum_{\tau=1}^{t-1} \phi_i^\tau I(s_{jk}, s_j(t-\tau))}{1 + \sum_{\tau=1}^{t-1} \phi_i^\tau} \in [0, 1]; k = 1, 2, \dots, n_j, \quad (15.29)$$

⁷ Recall that under fictitious play, all pure strategies have some probability of being played. However, players actually play only one pure strategy.

where ϕ , the weighting parameter, allows this framework to nest a range of models. Once players form beliefs as in (15.29), they play a best response; so player i chooses $s_i \in S_i$ to maximize expected payoff $\pi_i(s_i, \sigma_{-i})$, where σ_{-i} is the vector of mixed strategies of the opponent, computed in accordance with (15.29). The *Cournot adjustment dynamics* correspond to the case $\phi = 0$, so $x_{t+1}^i(s_{jk}) = I(s_{jk}, s_j(t))$, i.e., players believe that the last period choice of the opponent will be played again and they play a best response to it. When $\phi = 1$, weighted fictitious play corresponds to ordinary fictitious play.

15.3.1 Empirical evidence on some belief-based models

Cheung and Friedman (1997) test for the predictions of weighted fictitious play in four games: a hawk–dove game, a coordination game (which is a stag-hunt game⁸), a buyer–seller game, and the battle of the sexes game. They estimate the parameter ϕ separately for the individuals in their experiment. The median values of ϕ lie between 0.25 to 0.50, which is closer to the Cournot extreme rather than the other extreme of ordinary fictitious play. For instance, in the battle of the sexes game, 51 individuals behaved in a Cournot manner, 18 in the manner of ordinary fictitious play (i.e., $\phi = 1$), 6 were adaptive ($0 < \phi < 1$), and 4 were fickle ($\phi < 0$). The type distribution is similar across the four games.

A more direct approach to testing for fictitious play is to test if the measured beliefs in actual games correspond to fictitious play. Nyarko and Schotter (2002) elicited beliefs in repeated play of the 2×2 game in Figure 15.5, which has a unique mixed strategy equilibrium.

Subjects in experiments played 60 rounds of the game in four sessions. Actual frequencies of play were intermediate between the unique mixed strategy equilibrium and uniform randomization. Since beliefs were directly measured, they could be fitted to a model of fictitious play. The results are as follows. (i) The parameter ϕ in (15.29) is close to 1, which corresponds to ordinary fictitious play. (ii) There is divergence between stated and fitted beliefs. (iii) Fitted beliefs converge rapidly, while stated beliefs vary substantially from one period to another and do not converge; see Figure 15.6. (iv) The actions of players seem to be consistent with the play of best response, given stated beliefs, but not, given the fitted beliefs; this holds in 75% of the cases. One implication is that using fictitious play as a model of stated beliefs is inappropriate; perhaps players are using information and a level of sophistication that exceeds what is required for fictitious play.

Cheung and Friedman (1998) compare the relative performance of replicator dynamics and weighted fictitious play using two games: a hawk–dove game, and a buyer–seller game. The

⁸ In a stag-hunt game, there are two pure strategy Nash equilibria, one is payoff-dominant, while the other is risk-dominant. Examples are considered below.

Table 15.2 Summary of the treatments in Huck et al. (1999).

Treatment	Cost/demand information given?	Information on q_{ti} , p_t revealed at the end of each period?
<i>BEST</i>	Yes	No
<i>FULL</i>	Yes	Yes
<i>NOIN</i>	No	No
<i>IMIT</i>	No	Yes
<i>IMIT+</i>	Partial	Yes

learning model performs slightly better than the replicator model for the one population hawk–dove game, but substantially better in the two-population buyer–seller model.

Huck et al. (1999) test a range of belief-based theories. They consider a model of four symmetric firms with linear demand and unit marginal costs. At time t , the demand curve is given by

$$p_t = \max \{100 - Q_t, 0\},$$

where p_t is the market price, q_{ti} is the quantity chosen by the i th firm and $Q_t = \sum_{i=1}^4 q_{ti}$ is the total market quantity at time t . The four firms played this game for 40 time periods. Inertia is built into the model by allowing each firm to revise its strategy, every period, with probability equal to $2/3$; the probabilities of revision are independent across firms. The cost function of firm i is $C(q_{ti}) = q_{ti}$ and the profit function is $\pi_{ti} = q_{ti}(p_t - 1)$. The five treatments are summarized in Table 15.2.

The “partial information” in the treatment *IMIT+* provided to the subjects is the following statement: “as more is sold on the market, the lower is the price per unit that one obtains.” A simple

calculation shows that the symmetric Cournot–Nash outcome is given by $q_{ti}^N = 19.8$, $Q_t^N = 79.2$, $p_t^N = 20.6$. The Walrasian outcome (price equals marginal cost for each firm) is given by $q_{ti}^W = 24.75$, $Q_t^W = 99$, $p_t^W = 1$. The symmetric collusive outcome, which maximizes joint profits of all four firms, is given by $q_{ti}^C = 12.375$, $Q_t^C = 49.5$, $p_t^C = 50.5$.

The following main theories are tested.

- A. Under *myopic best reply dynamics*, each individual plays a best response in quantity, given the other players' choice of quantity in the previous period. This requires information on the cost and demand conditions. Both these pieces of information are given in the BEST and FULL treatment cases (see Table 15.2). The myopic best response dynamics are predicted to converge in finite time to the Cournot–Nash equilibrium.
- B. Under *imitation dynamics*, when a firm gets an opportunity to revise its strategy, then with probability $1 - \varepsilon$ (for some small $\varepsilon > 0$) it imitates the best choice by any of the firms' last period. This learning rule is also sometimes called *imitate the best*.⁹ But with probability ε , it chooses one of its feasible strategies (i.e., quantity) randomly. It was shown by Vega-Redondo (1997) that such imitation dynamics converge to the Walrasian outcome as $\varepsilon \rightarrow 0$.¹⁰ The intuition is simple. Since all firms face the same price, and have identical costs, thus the firm which produces the higher quantity makes the highest profits.

Suppose that in period $t - 1$, price exceeds marginal cost (i.e., $p_t > 1$). Consider a firm that in period t , gets an opportunity to choose its quantity, q_{ti} . Then, it will imitate the firm that produced the highest quantity in period $t - 1$. So its quantity chosen will increase over the previous period. This process continues until in some future period, price is equated to marginal cost. The converse process takes place, if at time $t - 1$, price falls below marginal cost, i.e., $p_t < 1$. In this case, the highest profits are made by the firm that produced the least. Hence, imitation dynamics dictate a reduction in quantity. This process continues until parity between price and marginal cost is restored. The information requirement for imitation dynamics is the quantity levels and profit levels of all firms in the last period. In particular, cost and demand conditions need not be known. The treatments FULL and IMIT contain this information (see Table 15.2).

- C. *Other models: Learning direction theory* associated most closely with Reinhard Selten, predicts that, over time, subjects should move in the direction of the best reply; see Section 15.6. Since players are always moving in the direction of their best reply, this dynamics naturally converges to the Cournot–Nash equilibrium.

In *trial and error learning*, subjects do not repeat their mistakes. So, for instance, if by reducing quantity, a firm finds that its profits have reduced, then it does not reduce quantity again. Huck et al. (2004) show that trial and error learning leads to the collusive outcome, which maximizes joint profits.

The results are as follows.

1. In all five treatments, on average, the total output produced exceeded the Cournot level. In treatment IMIT+, the actual outcome is very close to the competitive outcome, $Q_t^W = 99$. The collusive outcome was not observed in any treatment. The collusive price of $p_t^C = 50.5$ was exceeded in only 12 out of 1200 observations.

⁹ Another possible learning rule is *imitate the average* of the other firms rather than *imitate the best*. This can be motivated on grounds of caution.

¹⁰ Apesteguia et al. (2010) show that this result is not theoretically robust to asymmetric costs. However, in their experiments with asymmetric costs, they find that the outcomes still converge to a Walrasian equilibrium. They propose an alternative learning model to explain their results.

2. Greater *information about the market*, i.e., the cost/demand conditions, results in a *less* competitive outcome. To test for the role of information on market conditions, the treatments *BEST* and *NOIN* are compared as are the treatments *IMIT* and *IMIT+*. In each case, the mean quantity was lower in the treatment with the higher information about the market (i.e., information about cost/demand conditions). By contrast, more *information about the behavior of others*, i.e., quantities, profits of other firms, results in a *more* competitive outcome. This is seen by a comparison of the conditions *BEST* versus *FULL* and *NOIN* vs *IMIT*; in each of these comparisons, more information about others results in a higher mean quantity produced.
3. Firms produce higher output levels in the treatment *FULL* relative to the treatment *BEST*; in the latter treatment, the quantity converges fairly quickly to the Cournot–Nash solution. Insofar as only treatment *FULL* reveals the quantity/profit choices of others, imitation of others appears to play some role.
4. When subjects have the information necessary to play best replies, then most play a best reply. Similarly, when information on the quantity/profits in the previous period is available, then at least a few firms become pure imitators.
5. Learning direction theory does better in the treatment *BEST* relative to the treatment *FULL*. Furthermore, it predicts correctly in more than 70% of the cases and performs better when an upward, rather than a downward adjustment is required. However, trial and error learning does better than learning direction theory and “imitate the average” learning.

The role of imitation learning is also tested by Bosch-Domènech and Vriend (2003) in their duopoly and tripoly experiments. They consider a generic demand curve $p_t(Q_t) = a + bQ_t$, where $Q_t = \sum_i q_{ti}$ and the exact values of a, b vary over the treatments. Players compete over 22 rounds of play. The cost curve is given by $C(q_{ti}) = kq_{ti} + F$, where F is the fixed cost and $k > 0$. The profit of the i th firm is $\pi_{ti} = q_{ti}p_t(Q_t) - C(q_{ti})$.

Three different treatments are considered: Easy, hard, and hardest. The underlying market conditions and the information provided is identical in each of three treatments. However, the treatments differ in two dimensions. First, the time allowed to make a decision decreases as we move from the easy to the hardest treatment. In the easy treatment, there is no time pressure, while in the hardest treatment, subjects must make their output choices in one minute. Second, the framing of information is most transparent in the easy condition, most opaque in the hardest treatment, and intermediate in the hard treatment. Hence, one would expect that subjects are more likely to play their best response in the easy treatment. On the other hand, in the other two treatments, cognitive bounds are more likely to lead players away from best response to something like imitation learning. The latter should lead to the Walrasian outcome as $\varepsilon \rightarrow 0$ (see discussion of the previous model).

As one moves from the easy to the hardest treatments, we get the following results. (i) There is greater variability in output choices. (ii) Average output increases, but falls short of the Walrasian output levels. (iii) There is no trend movement in output towards the Walrasian level. (iv) There is no increase in the level of imitation. Thus, there is only weak support for the theoretical predictions.

15.3.2 Reinforcement learning versus fictitious play: empirical evidence

Mookerjee and Sopher (1997) test various models of learning, including reinforcement learning and fictitious play. They conduct their experiments using two zero-sum games, a 4×4 game,

and a 6×6 game. Each strategy for player i , $s_{ij} \in S_i$, is given a *score*. The score given to strategy s_{ij} is

$$\phi_{ij} = \sum_{k=1}^{n_i} \alpha_{jk} A_{t-1}(s_{ik}),$$

where $\alpha_{jk} \in \mathbb{R}$, and $A_{t-1}(s_{ik})$ is the previous period's *attraction/propensity*, or *weight* to play strategy s_{ik} . Using scores, and a logit rule, players compute the probability of playing any strategy s_{ij} as

$$p_{ij} = \frac{e^{\phi_{ij}}}{\sum_{k=1}^{n_i} e^{\phi_{ik}}}. \quad (15.30)$$

The logit rule used in (15.30) is very general; it allows the attractions of one strategy to affect the probabilities of playing other strategies. In this sense, Mookerjee and Sopher (1997) also generalize the insights obtained from the quantal response equilibrium of McKelvey and Palfrey (1995). Indeed, the author's preferred name for their learning mechanism is *quantal response learning*.

The results are as follows. Players learn from experience. The bulk of the evidence points to reinforcement learning. Fictitious play does not fit their data as well. The estimated parameters of the learning model fluctuate from game to game and vary between the early and later stages of play. The cross-attraction effects are generally insignificant. The Nash equilibrium for constant-sum games implies minimax play (i.e., minimize the maximum loss). However, substantial deviations from minimax play are found. The initial play influences the path of play in subsequent periods in important ways (history dependence). Dominated strategies are also sometimes played, but early rather than later during the 40 rounds of play.

Playing dominated strategies is consistent with reinforcement learning, but not deterministic fictitious play because in the latter, players play a best response given their beliefs about the other player. Dominated strategies can be accommodated within fictitious play only when players make mistakes, or there are some random shocks to the payoff function. This is not the case in the games studied here. However, the early play of dominated strategies is more consistent with reinforcement learning because players make mistakes early on and then learn not to play their dominated actions.

Battalio et al. (2001) consider three *stag-hunt* games. In a stag-hunt game, there are two pure strategy Nash equilibria, one is payoff-dominant, while the other is risk-dominant. The focus of these experiments is to see which of the two Nash equilibria is played. The three games are labeled as 2R, R, and 0.6R, and are shown in Figure 15.7. The payoffs shown in each cell are the actual number of cents received by each player. Subjects in experiments have complete information

Game 2R				Game R				Game 0.6R			
		X	Y			X	Y			X	Y
X	45, 45	0, 35		X	45, 45	0, 40		X	45, 45	0, 42	
Y	35, 0	40, 40		Y	40, 0	20, 20		Y	42, 0	12, 12

Source: Battalio et al. (2001) with permission of The Econometric Society.

about their own payoffs and the payoff of others. There is no preplay communication. In each of the three games, the payoff Nash equilibrium is (X, X) and the risk-dominant Nash equilibrium is (Y, Y) .

For all three games, suppose that the probability with which a player plays X is given by q . The essential difference between each game is the incentive/penalty attached to not playing one's best response. To see this, denote in game $j = 2R, R, 0.6R$, the payoff to a player from playing strategy $s = X, Y$ when the opponent is expected to play X with probability q by $\pi_j(s, q)$; this payoff is symmetric. The benefit from playing a best response, relative to playing a non-best response is termed as the *optimization premium*. Let $q^* = 4/5$. For any of the games, the best response is X if $q > q^*$, and Y if $q < q^*$. If $q = q^*$, then the player is indifferent between X and Y . Let

$$\Delta\pi_j = \pi_j(X, q) - \pi_j(Y, q); j = 2R, R, 0.6R.$$

For game $j = 2R, R, 0.6R$, and for beliefs about the opponent's play of X given by q , we denote the optimization premium as $r_j(q)$. A simple calculation gives

$$\begin{aligned} r_{2R}(q) &= \Delta\pi_{2R} = 45q - [35q + 40(1 - q)] = 50q - 40 = 50(q - q^*) = \delta_{2R}(q - q^*), \\ r_R(q) &= \Delta\pi_R = 45q - [40q + 20(1 - q)] = 25q - 20 = 25(q - q^*) = \delta_R(q - q^*), \\ r_{0.6R}(q) &= \Delta\pi_{0.6R} = 45q - [42q + 12(1 - q)] = 15q - 12 = 15(q - q^*) = \delta_{0.6R}(q - q^*), \end{aligned}$$

where δ_j is called the *optimization premium parameter*. Suppose that $p_j(q; \lambda)$ is the probability that “ X is chosen” for game j , where λ is a parameter of the probability density function, and q is the probability with which the opponent is expected to play X . The logistic response function that is used is given by

$$p_j(q; \lambda) = \frac{e^{\lambda\delta_j(q-q^*)}}{1 + e^{\lambda\delta_j(q-q^*)}}. \quad (15.31)$$

If $\lambda = 0$, then $p_j(q; \lambda) = 0.5$, so each player plays both strategies with equal probability. On the other hand, as λ increases, one approaches best response behavior.

Definition 15.19 (McKelvey and Palfrey, 1995): For a given value of λ , a *logit* (or a *quantal response*) *equilibrium* is a fixed point of the two players' logit response functions, i.e., $q^* = p_j(q^*; \lambda)$.

The Nash equilibrium is invariant to the optimization premium. However, holding λ fixed, $\frac{\partial p_j}{\partial \delta_j} > 0$, hence we get the first hypothesis under a quantal response equilibrium:

H1: Actual behavior of subjects is more responsive to beliefs if the optimization premium parameter is higher.

The second hypothesis follows by using the single population continuous-time logistic-response dynamic. This dynamic is given by $\dot{q} = p_j(q; \lambda) - q$, where q is now interpreted as the frequency of X choices in the population; see for instance Fudenberg and Levine (1998).

H2: The convergence to an equilibrium is faster if the optimization premium is higher.

To get a feel for the final hypothesis, consider the following intuition. Suppose that learning is noisy. For instance, with some probability players choose their best response, but with a complementary probability, they make a tremble and randomize equally between their strategies.

In this case, for a smaller optimization premium, the likelihood of entering the basin of attraction of the payoff dominant equilibrium increases. This can be shown by using the aspiration adaptation model of Binmore and Samuelson (1997), but the explanation relies on tools that we develop in Chapter 16.

Whenever the payoffs are below the aspiration level, players are more likely to experiment by trying other strategies, so learning is relatively noisier. In the games shown in Figure 15.7, the payoffs in the risk dominant equilibrium (Y, Y) fall as the optimization premium falls, but the payoffs in the payoff dominant equilibrium are unchanged. Hence, as the optimization premium falls, the greater experimentation of players with alternative strategies in the risk dominant equilibrium makes it relatively less costly to escape its basin of attraction. The cost of escaping from the basin of attraction of the payoff dominant equilibrium is unchanged. Hence, as the optimization premium falls, the payoff dominant equilibrium is more likely to be *stochastically stable*; See Appendix C and Chapter 16. This leads to a prediction that is not made by best-response, logistic-response, or replicator dynamics.

H3: There is a greater likelihood of the behavior converging to the payoff dominant equilibrium if the optimization premium is lower.

All three hypotheses are confirmed by the experimental data. Individuals are more sensitive to the past play of the opponent, the greater the optimization premium. Play converges faster to an equilibrium, if the optimization premium is larger. Thus, the fastest convergence is in game 2R, followed by games R and 0.6R. The payoff dominant equilibrium is more likely to emerge, the smaller the optimization premium and this effect is more pronounced in later periods of play. The main message of this paper is that it is not sufficient to focus on the best response dynamics—other factors such as the optimization premium matter too.

Individual behavior is studied, using a modified version of (15.31), which is written as

$$p_{it}(q_{it}; \lambda) = \frac{e^{\alpha_i + \lambda \delta_j(q_{it} - q^*)}}{1 + e^{\alpha_i + \lambda \delta_j(q_{it} - q^*)}}; i = 1, 2, j = 2R, R, 0.6R \quad (15.32)$$

where $i = 1, 2$ is an index for players, p_{it} is the probability that player i plays X at time t , q_{it} is the probability with which the opponent is believed to be playing X at time t , and α_i is a player-specific drift parameter. They also consider the case where $\delta_j(q_{it} - q^*)$ is the average of all play up to that point in time. This corresponds to the *average-payoff reinforcement model*. The two main findings are that the belief-based model fits the data better than the average-payoff reinforcement model, and a combination of the belief-based and the reinforcement model does even better.

Feltovich (1999, 2000) argues that the existing experiments use games that are too simple. He introduces complexity through the channel of asymmetric information. Nature chooses one of the two games in Figure 15.8, Left or Right. The row player (player 1) is the informed player and knows nature's choice of the game. The column player (player 2) is the uninformed player and his prior belief that the game is Left is given by p . Denote this game by $G(p)$. In each game, player 1 has a weakly dominated strategy (B in Left and A in Right). Once nature chooses one of these games, it is played over two stages. The total payoffs for each player equal the sum of the payoffs over the two stages. The payoffs in the first stage are not revealed to player 2, but the actions of both players are publicly revealed at the end of the first stage.

If player 1 uses the strategy “play A if chosen game is Left and play B if the chosen game is Right,” then these actions fully reveal the type of game to player 2. These are the stage dominant actions of player 1 that are completely revealing of his type. In this case, player 2's optimal second

Left matrix			Right matrix		
	A	B		A	B
A	1, 0	0, 1	A	0, 1	0, 1
B	0, 1	0, 1	B	0, 1	1, 0

Figure 15.8 Introducing complexity through the channel of asymmetric information.

Source: Feltovich (2000) with permission of The Econometric Society.

period strategy is to play B if player 1 plays A in the first period and play A if player 1 plays B in the first period. In each of these cases, player 1 gets a payoff of zero in the second period. Hence, player 1 might do better by playing a mixed strategy in the first period that does not reveal the game to player 2. We focus only on the first stage play of player 1, contingent on the choice by nature of either the Left or the Right payoff matrix.

For the game $G(0.5)$, the following is an equilibrium (Feltovich, 2000). Player 1 randomizes equally between his two first period strategies irrespective of the payoff matrix chosen by nature. Suppose that Player 2 observes a choice of A by player 1, then he plays his best response in a completely revealing equilibrium with probability $\beta \in [0.5, 1]$. If player 2 observes a choice of B, then he plays his best response in a completely revealing equilibrium with probability $1.5 - \beta$. This describes the Nash equilibrium of the game. This equilibrium is not unique because it depends on the parameter β . In a second game, $G(0.34)$, the equilibrium is unique. Here, in the Left matrix, player 1 plays his stage dominant action A with probability 0.97 and in the Right matrix, he randomizes equally between the two actions. The authors then pit this equilibrium model against the reinforcement and the belief-based learning models.

The results are as follows. In both games, play starts and ends (over several rounds) substantially away from the Nash equilibrium outcome. Averaged across 40 rounds of learning, the results are shown in Table 15.3. There is little support for the Nash predictions in the behavior of either of the two players. These results, and many other reviewed in this chapter and elsewhere in the book, should caution us against assuming that given sufficiently many periods of learning, the outcome is a Nash equilibrium.

Examining the time pattern of play in Figure 15.9, both learning models, reinforcement and belief-based learning, are able to explain the qualitative features of actual play. Whilst the

belief-based model is better at predicting aggregate behavior (shown in Figure 15.9), the reinforcement model does better at explaining individual behavior.¹¹

Overall, based on the evidence reviewed above, it is difficult to declare a clear winner in the comparison between these two alternative models of learning. Confounding reasons include: (i) The papers differ very much in the sorts of games that are analyzed. (ii) Differences in the way that the experiments are implemented. (iii) Differences in the versions of the two learning models used. Reinforcement learning appears to fit better than belief-based models in games with mixed strategy equilibrium that have relatively low dimensional strategy spaces (Erev and Roth, 1998; Mookerjee and Sopher, 1994). However, belief-based models make relatively better predictions in coordination games (Battalio et al., 2001; Ho and Wiegelt, 1996).

15.4 The experience weighted attraction model of learning

Models of reinforcement learning and fictitious play are sometimes seen as two entirely separate models of learning. Under reinforcement learning, players are not required to know the structure of the game. They do not use the historical information on the strategies of the opponent, nor are they required to be aware of any such information. Their objective is to play those strategies that, in their experience, have done well in the past. More successful strategies are then used more often. Under fictitious play, players know the structure of the game. They are not interested in their own historically successful strategies. Rather, they are interested in the history of play of their opponents, and use it to predict their current choices; and they play a best response to these

¹¹ The reinforcement learning model is also found to fit better as compared to the belief-based model in Blume et al. (2001) (for a sender-receiver game) and by Nagel and Tang (1998) (for the centipede game).

predictions. Camerer and Ho (1999) show that both these models are actually special cases of an overarching model which they call *experience weighted attraction* model of learning (EWA).¹²

Suppose that each player $i = 1, 2, \dots, n$ has a set $S_i = \{s_{i1}, s_{i2}, \dots, s_{in_i}\}$ of *pure strategies*; denote a typical element of S_i by s_i . In any period, the profile of strategies that is played is $s = \{s_1, s_2, \dots, s_n\} \in S = S_1 \times S_2 \times \dots \times S_n$. Denote the pure strategy profile of all opponents of player i by s_{-i} . The players have *payoff functions* $\pi_i : S \rightarrow \mathbb{R}$. Time is discrete, $t = 0, 1, 2, \dots$

The EWA model has two main components.

1. At any time t , the experience weight N_t encapsulates the experience of the players. It is also known as the *observation-equivalents of past experience*.
2. The second component is similar to *propensities* under reinforcement learning. It is denoted by $A_t^i(s_{ij})$, $\forall i, j$ and is referred to as the *attraction* that player i has at time t for his j th pure strategy, s_{ij} .

The initial values of $N_t, A_t^i(s_{ij})$, denoted respectively by $N_0, A_0^i(s_{ij})$, reflect pre-game experience of the players, say, from having played similar games in the past. The updating rules for $N_t, A_t^i(s_{ij})$ are as follows.

1. The updating rule for experience, N_t , is given by

$$N_t = (1 - \kappa)\phi N_{t-1} + 1, t \geq 1, \quad (15.33)$$

where $(1 - \kappa)\phi \in [0, 1]$. The parameter ϕ allows for the depreciation of past experience, on account of (i) forgetting, or limited memory, or (ii) a rapidly changing environment. In most empirical work, N_0 is set equal to 1.

2. Although *attractions* under EWA are similar to *propensities* under reinforcement learning, there is an important difference. Under reinforcement learning, only the strategies that are actually played get reinforced (*law of effect*). Players do not, however, take account of the forgone payoff that could have resulted from playing other strategies.

EWA alters this assumption by proposing, instead, a *law of simulated effect*. This does not dispute the law of effect, but, in addition, also updates the attractions of unchosen strategies by taking account of forgone payoffs from having not played these strategies.

Suppose that player i plays $s_i(t) \in S_i$ at time t , while the opponents play $s_{-i}(t) \in S_{-i}$. Then EWA specifies attractions as follows.

$$A_t^i(s_{ij}) = \frac{1}{N_t} [\phi N_{t-1} A_{t-1}^i(s_{ij}) + [\delta + (1 - \delta) I(s_{ij}, s_i(t))] \pi_i(s_{ij}, s_{-i}(t))], \forall s_{ij} \in S_i. \quad (15.34)$$

The constant $\phi \in [0, 1]$ enables previous levels of experience weighted attractions, $N_{t-1} A_{t-1}^i(s_{ij})$, to decay. The second term in (15.34) allows for the laws of actual and simulated effects to work out. $\delta \in [0, 1]$ is a parameter that gives the weight placed on forgone payoffs; one may interpret it as a form of *regret* over forgone payoffs. $I(s_{ij}, s_i(t))$ is an indicator function that is defined as

$$I(s_{ij}, s_i(t)) = \begin{cases} 1 & \text{if } s_{ij} = s_i(t) \\ 0 & \text{if } s_{ij} \neq s_i(t) \end{cases},$$

¹² Hopkins (2002) showed that the expected dynamics under stochastic fictitious play and reinforcement learning with experimentation can be shown to be a perturbed form of replicator dynamics. It is possible that this result may also hold for the EWA model.

where $s_{ij} \in S_i$ is any pure strategy of player i , and $s_i(t) \in S_i$ is the strategy that is actually played at time t . $\pi_i(s_{ij}, s_{-i}(t))$ is the payoff at time t of player i from playing s_{ij} against the “actual” strategies of the opponents, $s_{-i}(t) \in S_{-i}$. When $s_{ij} = s_i(t)$, the law of effect operates and when $s_{ij} \neq s_i(t)$, the law of simulated effect operates. Thus,

$$A_t^i(s_{ij}) = \begin{cases} \frac{1}{N_t} [\phi N_{t-1} A_{t-1}^i(s_{ij}) + \pi_i(s_{ij}, s_{-i}(t))] & \text{if } s_{ij} = s_i(t) \\ \frac{1}{N_t} [\phi N_{t-1} A_{t-1}^i(s_{ij}) + \delta \pi_i(s_{ij}, s_{-i}(t))] & \text{if } s_{ij} \neq s_i(t) \end{cases} \quad (15.35)$$

The parameter κ in (15.33) determines the growth rate of attractions; it is also referred to as the *lock-in parameter*. When $\kappa = 0$, attractions are weighted averages of past payoffs and lagged attractions. When $\kappa = 1$, attractions cumulate and can exceed the stage game payoffs.

The final step in the model is similar to the conversion of propensities into probabilities in the reinforcement learning model. In EWA, we convert attractions into probabilities with which players play their strategies. These probabilities of play can take several forms, logit, exponential, power, probit, or normal. Camerer and Ho (1999) prefer the logit form. Let $p_t^i(s_{ik})$ be the probability with which player i plays pure strategy s_{ik} at time t , then, the logit form dictates that

$$p_{t+1}^i(s_{ik}) = e^{\lambda A_t^i(s_{ik})} / \sum_{j=1}^{n_i} e^{\lambda A_t^i(s_{ij})}. \quad (15.36)$$

The parameter λ measures the sensitivity of probabilities to attractions, as in the reinforcement model. If payoffs are negative, i.e., $\pi_i(s_{ij}, s_{-i}(t)) < 0$, then the corresponding attractions can also be negative. However, this is not a problem if one uses the logit form, because it is invariant to adding a constant to all attractions (this can be directly checked from (15.36)). One could also use the *power form*, which is given by

$$p_{t+1}^i(s_{ik}) = (A_t^i(s_{ik}))^\lambda / \sum_{j=1}^{n_i} (A_t^i(s_{ij}))^\lambda. \quad (15.37)$$

It is easy to check that the power form is invariant to multiplying all attractions by a constant. It is not established, yet, which of these forms, logit, or power, fits better. Erev and Roth (1998) and Chen and Tang (1998) are unable to conclude that any of these forms is superior to the other, while Camerer and Ho (1997) find that the logit form fits relatively better.

We now show that reinforcement learning and belief-based learning are special cases of this model.

15.4.1 Special case: reinforcement learning

Section 15.2 considered a variety of reinforcement learning models. Consider the one-parameter model in (15.2), but allow for past levels of reinforcements to decay at the rate $\phi \in [0, 1]$, and specialize the reinforcement function to $R(\pi_i) = \pi_i$. Hence, (15.2) can be written as:

$$q_{t+1}(s_{ij}) = \begin{cases} \phi q_t(s_{ij}) + \pi_i(s_{ij}, s_{-i}(t)) & \text{if } s_{ij} \text{ is played at time } t \\ \phi q_t(s_{ij}) & \text{otherwise} \end{cases} \quad (15.38)$$

In the EWA model, suppose that $\delta = 0$, $N_0 = 1$, and $\kappa = 1$, so $(1 - \kappa)\phi = 0$. Using (15.33), this implies that $N_t = 1$ for all t . (15.35) implies that

$$A_{t+1}(s_{ij}) = \begin{cases} \phi A_t(s_{ij}) + \pi_i(s_{ij}, s_{-i}(t)) & \text{if } s_{ij} \text{ is played at time } t \\ \phi A_t(s_{ij}) & \text{otherwise} \end{cases}. \quad (15.39)$$

Interpreting attractions as propensities, (15.38), (15.39) are identical.

When $\delta = 0, \kappa = 0$, and $N_0 = \frac{1}{1-\phi}$, we get that

$$A_{t+1}(s_{ij}) = \begin{cases} \phi A_t(s_{ij}) + (1 - \phi) \pi_i(s_{ij}, s_{-i}(t)) & \text{if } s_{ij} \text{ is played at time } t \\ \phi A_t(s_{ij}) & \text{otherwise} \end{cases} \quad (15.40)$$

which takes the form of *average choice reinforcement*, as in Mookerjee and Sopher (1997) and Sarin and Vahid (2001).

15.4.2 Special case: belief-based learning

Section 15.3 considered a simple model of fictitious play. Here we consider a more general version of the model of fictitious play. Denote the initial beliefs of player i about the frequencies of choices of other players by $N_0(s_{-i}) > 0, s_{-i} \in S_{-i}$; these are the initial weights w_0^i in Section 15.3. For all $s_{-i} \in S_{-i}$, define $N_t^i = \sum_{s_{-i} \in S_{-i}} N_t(s_{-i})$, $t = 0, 1, 2, \dots$. Then, the prior belief of player i that the other players will play the strategy profile $s_{-i}^k \in S_{-i}$ is given by

$$B_0^i(s_{-i}^k) = \frac{N_0(s_{-i}^k)}{N_0^i}. \quad (15.41)$$

Notice that we model beliefs over strategy profiles of opponents here, rather than beliefs over each individual pure strategy. Beliefs about the strategy profiles of others, for the next period, are then constructed recursively, as follows

$$B_t^i(s_{-i}^k) = \frac{\rho N_{t-1}(s_{-i}^k) + I(s_{-i}^k, s_{-i}(t))}{\sum_{j=1}^M \rho N_{t-1}(s_{-i}^j) + I(s_{-i}^j, s_{-i}(t))}, \quad (15.42)$$

where M is the cardinality of the set S_{-i} , $\rho = (1 - \kappa)\phi$ is a decay parameter. $I(s_{-i}^k, s_{-i}(t))$ is an indicator function such that

$$I(s_{-i}^k, s_{-i}(t)) = \begin{cases} 1 & \text{if } s_{-i}^k = s_{-i}(t) \\ 0 & \text{if } s_{-i}^k \neq s_{-i}(t) \end{cases}, \quad (15.43)$$

where $s_{-i}(t)$ is the actual strategy profile played by players others than i at time t . Using (15.41), we can rewrite (15.42) in terms of the beliefs in the previous period, as

$$B_t^i(s_{-i}^k) = \frac{\rho N_{t-1}^i B_{t-1}^i(s_{-i}^k) + I(s_{-i}^k, s_{-i}(t))}{\rho N_{t-1}^i + 1}. \quad (15.44)$$

By definition, the expected payoff of player i from playing some strategy s_{ij} is defined by

$$\Pi_t^i(s_{ij}) = \sum_{k=1}^M B_t^i(s_{-i}^k) \pi(s_{ij}, s_{-i}^k). \quad (15.45)$$

Figure 15.10 The EWA cube.

Source: Reprinted from *Handbook of Game Theory with Economic Applications*, Young, P. and Zamir, S. (eds.), "Behavioral game theory experiments and modeling," Camerer, C. and Ho, T.-H. Volume 4, pages 517–73. Copyright © 2015, with permission from Elsevier.

Substituting (15.44) into (15.45) we can express the period t expected payoffs in terms of the period $t - 1$ expected payoffs as follows:

$$\Pi_t^i(s_{ij}) = \frac{\rho N_{t-1}^i \Pi_{t-1}^i(s_{ij}) + \pi(s_{ij}, s_{-i}^k)}{\rho N_{t-1}^i + 1}. \quad (15.46)$$

Consider the attractions given in (15.34). Let $\delta = 1, \kappa = 0$, and let initial attractions equal the expected payoffs $(A_0^i(s_{ij}) = \Pi_0^i(s_{ij}) = \sum_{k=1}^M B_0^i(s_{-i}^k) \pi(s_{ij}, s_{-i}^k))$. Then the attractions in (15.34) are identical to (15.46), so the weighted belief model is a special case of EWA. Not all learning models can, however, be subsumed within the EWA model.¹³

The various special cases of the EWA model are shown in (κ, ϕ, δ) space in the cube in Figure 15.10. Cournot best-response dynamics is shown by the triple $(\kappa, \phi, \delta) = (0, 0, 1)$, standard fictitious play by $(\kappa, \phi, \delta) = (0, 1, 1)$, and weighted fictitious play by the line $(\kappa, \phi, \delta) = (0, \phi, 1)$. Various forms of reinforcement learning correspond to $\delta = 0$ and different values of κ .

¹³ These include, for instance, certain kinds of belief learning models (Crawford, 1997; Broseta et al., 2000) and rule learning models (Stahl, 2000, 2001).

15.4.3 Empirical evidence for the EWA

The EWA model has been tested in a range of games such as the centipede game, signaling games, and patent race games.¹⁴ From these studies, Camerer et al. (2001) conclude the following. When there are no mixed strategy equilibria in a game, then the value of δ lies between 0.5 and 1. In games with mixed strategy equilibria, δ is close to 0. ϕ lies close to a value of 0.9.¹⁵ However, Wilcox (2006) shows that if parameter heterogeneity across players is not considered, then one obtains biased estimates that favor reinforcement learning over belief-based learning.

One potential criticism of the EWA model is that it has a greater number of free parameters than most models, so it is expected to fit better. In response, Camerer et al. (2001) first fit the model to the data and then they use the estimated parameters of the model in order to check for the success of out-of-sample predictions. A model with a greater number of parameters need not predict better out-of-sample. The EWA does better (often modestly) than the reinforcement learning model in 11 out-of-sample comparisons. And in 9 out of 11 out-of-sample cases, it does better (often dramatically) than belief-based learning. Using statistical tests such as the Akaike and the Bayesian criteria, which penalize more complex models, EWA does better than belief-based learning in all in-sample comparisons and better than reinforcement learning in 16 out of 20 comparisons.

In Figure 15.10, each of the dotted lines with a hollow circle at the top represents a three-parameter estimate of ϕ, δ, κ in the cube in 20 different datasets, each from a different game. The results from various studies are summarized by Camerer et al. (2001) as follows.

1. The points generally lie away from the edges or corners that represent an extreme case. The only cluster of points is toward the region where $\phi \cong 1, \delta = \kappa = 0$ (this is the average reinforcement model). This data typically arises from games with a mixed strategy equilibrium.
2. The estimated triples are dispersed throughout the cube, which suggests that no single special case of EWA describes well the data from diverse games.
3. One particular vertex of the cube $\delta = \kappa = 1$ corresponds to no known learning theory. However, estimates from three order-statistic games and the p-beauty contest¹⁶ lie in this region. This justifies the extra flexibility incorporated in the EWA model.

15.4.4 Functional EWA (fEWA)

In response to the criticism of “too many parameters” in the EWA model, Ho et al. (2007) propose a one-parameter family of learning models that they call *functional EWA* or fEWA. In fEWA models, for any player i , the three parameters ϕ, δ, κ in EWA are replaced by deterministic functions of experience, $\phi_i(t), \delta_i(t)$. These functions are player and time dependent, hence, this model is also sometimes known as self-tuning EWA. The parameter κ is set to 0 because it does not appear to have a significant effect on the fit of the model (Ho et al., 2008).

This leaves only two more parameters to be determined relative to EWA. These are the initial attractions and the parameter λ in (15.36) that enables the conversion of attractions to probabilities. The initial attractions are estimated from first period data. Hence, λ is the single parameter

¹⁴ See, for instance, Camerer and Ho (1999), Camerer et al. (1999), Andersen and Camerer (2001), Morgan and Sefton (1999), Rapoport and Amaldoss (2000), and Stahl (2001).

¹⁵ See Camerer et al. (2001) for a summary of these values over many different empirical studies.

¹⁶ These games are discussed in Part 4.

in fEWA models that is estimated using maximum likelihood methods. For this reason, relative to the EWA model, this model is also sometimes known as EWA-lite.

In the EWA model, the parameter ϕ is termed as the forgetting parameter. By contrast, fEWA unpacks this parameter and replaces it by the function $\phi_i(t)$ that is designed to detect the speed with which the environment is changing. $\phi_i(t)$ is called the *change-detecting function*. The function ϕ_i is self-tuning in the sense that if player i detects at time t that the environment is changing rapidly, then $\phi_i(t)$ falls, so that the weight placed on past experience is reduced.

It is important to distinguish real change and change that simply results from noise. In fEWA this is accomplished through a *surprise index* that detects the difference between the historical frequency of strategies of other players relative to their current choices. Denote by $h_i(t)$, the *cumulative history vector*, such that an element of this vector is given by

$$h_i^k(t) = \frac{1}{t} \sum_{\tau=1}^t I(s_{-i}^k, s_{-i}(\tau)), \quad (15.47)$$

where $I(s_{-i}^k, s_{-i}(\tau))$ is defined in (15.43). Thus, (15.47) gives the fraction of times that player i observes strategy s_{-i}^k to be played in the last t time periods. In contrast, the immediate history vector, $g_i(t)$, records the current choices of opponents. All elements of $g_i(t)$ are either zero or one. If $s_{-i}^k = s_{-i}(t)$, then the k th element in the vector $g_i(t)$ takes a value 1, and 0 otherwise, so $g_i^k(t) = I(s_{-i}^k, s_{-i}(t))$.

The *surprise index* for player i at time t is defined as the sum of squared deviations of the current strategy from the historical observations, as follows.

$$S_i(t) = \sum_{\tau=1}^t (h_i^k(\tau) - g_i^k(\tau))^2 \in [0, 2). \quad (15.48)$$

Suppose that the strategy of the opponents is identical in the last t periods, say, $s_{-i}^k = s_{-i}(\tau)$, $\tau = 1, \dots, t$, then $S_i(t) = 0$. This is a stationary environment, so there is no surprise. At the other extreme, suppose that for the first $t-1$ periods, the opponents played the strategy s_{-i}^k , but in period t they switch to another strategy $s_{-i}^r \neq s_{-i}^k$, then (15.48) can be written as

$$S_i(t) = \left(\frac{t-1}{t} \right)^2 + (-1)^2. \quad (15.49)$$

For the case depicted in (15.49) we have $\lim_{t \rightarrow \infty} S_i(t) = 2$, which gives the upper limit of $S_i(t)$ in (15.48). This is the most turbulent environment faced by the individual. The *change-detecting function* is then given by

$$\phi_i(t) = 1 - \frac{1}{2} S_i(t) \in (0, 1]. \quad (15.50)$$

The bounds in (15.50) follow from the bounds on $S_i(t)$ in (15.48). For the case depicted in (15.49) we have $\phi_i(t) = \frac{2t-1}{2t^2}$. For values of $t = 2, 3, \dots$ the value of $\phi_i(t)$ can be seen to be declining. Thus, the value of ϕ_i is lower and past experience is discounted more, the longer the environment is stationary followed by an abrupt change in strategy.

In the EWA model, δ allowed the player to take account of forgone payoffs (see (15.34)). However, δ may also be linked to the attention that subjects pay to the game. More inattentive players

will experience more ex-post regret from discovering that they have forgone higher payoffs. In order to take account of these concerns, define the *attention function*

$$\delta_{ij}(t) = \begin{cases} 1 & \text{if } \pi_i(s_i^j, s_{-i}(t)) \geq \pi_i(t) \\ 0 & \text{otherwise} \end{cases}, \quad (15.51)$$

where $\pi_i(t)$ is the actual payoff of player i at time t and $\pi_i(s_i^j, s_{-i}(t))$ is the payoff of player i at time t if he chooses s_i^j , when the strategy profile of others is $s_{-i}(t)$. Thus, all strategies that give a weakly higher payoff relative to the realized payoff are reinforced, and all remaining strategies receive zero reinforcement. If players play a best response, then $\delta_{ij}(t) = 0$ for all strategies that were not chosen. At the other extreme, if subjects choose their worse strategy, then $\delta_{ij}(t) = 1$ for all their strategies. The attention function in (15.51) describes a position in between these two extremes that captures limited attention. This is consistent with learning direction theory in which players gradually move in the direction of their ex-post best responses; see Section 15.6.

In the early stages of a game, the choices of players are quite variable, and because they may have limited experience and limited attention, they may make lots of mistakes. Thus, initially $\phi_i(t)$ is low and $\delta_{ij}(t)$ is high, so past experience is relatively highly discounted and players pay relatively low attention. In many experimental games, the behavior stabilizes over time, so $\phi_i(t)$ rises and $\delta_{ij}(t)$ falls. Thus, as the game proceeds, the weight on experience goes up and the forgone strategies are reinforced less.

Once these functions feed into the determination of attractions, the attractions are converted to probabilities of play, using (15.36). Ho et al. (2007) examine the empirical properties of fEWA using seven games, most of which were discussed in detail in Part 4 of the book. These games are listed in the first column of Table 15.4 that is an updated table of results from Camerer and Ho (2014). The labels of these games and the source is as follows. (i) The Cont'l divide game is the continental divide game (Van Huyck et al., 1997). (2) The Median action game (Van Huyck et al., 1991). (3) p-bc is the p-beauty contest game (Ho et al., 1998). (4) Price matching game, or the traveller's dilemma (Capra et al., 1999). (5) Mixed games are games with a unique mixed strategy Nash equilibrium (Mookerjee and Sopher, 1997). (6) Patent race games (Rapoport and Amaldoss, 2000). (7) Pot games are a form of market entry games (Amaldoss et al., 2005).

The subject pool is divided into two parts. First, data from 70% of the subjects is used to estimate the value of λ (see (15.36)), using maximum likelihood methods in an fEWA model that is described above. Second, the estimated model is used to form predictions for the behavior of the remaining 30% subjects, and the out-of-sample predictions are then compared to actual data. Two measures are used to evaluate the success of out-of-sample predictions. These are: the hit rate (fraction of the highest probability choices using (15.36) that are actually chosen by the 30% of subjects) and the log likelihood (denoted by LL). Ho et al. (2007) also report results for the Bayesian information criterion (BIC) for the estimates, based on 70% of the data. This criterion trades off the larger number of parameters in a model against better explanatory power.

In Table 15.4, for any game, the highest hit rates and the best fits are shown in bold. When two hit rates or two values of LL are not statistically different then they are both shown in bold. From left to right in Table 15.4, the theories tested are the following. (1) Thinking+fEWA is fEWA in which the initial attractions are computed from a cognitive hierarchy model (1 parameter). (2) fEWA (1 parameter). (3) EWA (5 parameters). (4) Weighted fictitious play, which is a belief-based model (2 parameters). (5) Reinforcement learning with payoff variability as in Roth and Erev (1995) and Erev and Roth (1998). (6) QRE, which is short for quantal response equilibrium

Source: Camerer and Ho (2014). The sample sizes for the games in the first column are as follows: 315, 160, 580, 160, 960, 1760, 739, 4674 (pooled), 80.

(see Part 4 of the book for a discussion). Based on the hit rates, the three best theories are EWA, Thinking+fEWA and fEWA (highest in 6 out of 7). Reinforcement learning just follows behind these models (highest in 4 out of 7), followed by weighted fictitious play (highest in 3 out of 7), while QRE is the worst (highest in 1 out of 7). Based on the LL, EWA is best (highest in 4 out of 7) followed by reinforcement learning (highest in 2 out of 7). QRE is the worse in this respect too.

When the data is pooled across all games and parameters are estimated based on pooled data (except for value of λ that is estimated for individual games), then Thinking+fEWA gets the highest hit rate and fEWA the highest LL. Thus on both criteria, fEWA outperforms other models for pooled out-of-sample data. Below the row labeled pooled data in Table 15.4, the authors also report results from an analysis of the p-beauty contest game from Kocher and Sutter (2005); fEWA again performs better than the other models.

15.4.5 Sophisticated EWA learning and strategic teaching

The EWA model contradicts observed behavior in several respects.

1. It is based on players who use *adaptive learning*. Thus, they do not use knowledge of the payoffs of others, even if such knowledge is available, in order to outguess them. Experimental evidence indicates that players use information on the payoffs of others (Cachon and Camerer, 1996; Mookherjee and Sopher, 1997). When players have the option of using or ignoring the payoff information about others, they often opt to use it. This is implemented in some experiments by checking if players opt to open boxes containing payoffs of others (Camerer et al., 1993; Costa-Gomes et al., 2001).
2. Consider the *p-beauty contest*. A group of players are asked to guess a number between 0 and 100. The winner chooses a number closest to $p > 0$ times the average. When $p \in$

(0, 1], the Nash equilibrium is for each player to choose 0 (see Part 4 of the book). In p-beauty contests, it is found that experienced players converge to the Nash equilibrium faster than inexperienced players (Ho et al., 1998). Camerer et al. (2002) take this as suggestive evidence that players learned about how others were learning.

In order to account for these stylized facts, Camerer et al. (2002) propose the *EWA learning with sophistication* model. A proportion α of the players are sophisticated, and the rest, $1 - \alpha$, are adaptive, as in the fEWA model. The adaptive players use the fEWA model, while the sophisticated players form an estimate of the fraction of the adaptive players, $1 - \alpha'$ and take this information into account when forming their attractions. Sophisticated players may be overconfident and overestimate the proportion of adaptive players, $\alpha > \alpha'$, or they might be cautious, and underestimate this fraction, $\alpha < \alpha'$. Sophisticated players believe that other sophisticated players also believe that the proportion of adaptive players is $1 - \alpha'$.

Denote the type of the players by $\theta = s, a$ for, respectively, sophisticated and adaptive. The relation between probabilities and attractions for player i of type θ is given by

$$p_{t+1}^i(s_{ik}; \theta) = \frac{e^{\lambda A_t^i(s_{ik}; \theta)}}{\sum_{j=1}^{n_i} e^{\lambda A_t^i(s_{ij}; \theta)}}, \theta = s, a \text{ and } i \in N. \quad (15.52)$$

where $A_t^i(s_{ik}; \theta)$ is the attraction of strategy s_{ik} for player i of type θ at time t . Sophisticated players form attractions as follows

$$A_t^i(s_{ij}; \theta) = \sum_{k=1}^{n_{-i}} \left[\alpha' p_{t+1}^{-i}(s_{-i}^k; s) + (1 - \alpha') p_{t+1}^{-i}(s_{-i}^k; a) \right] \pi_i(s_{ij}, s_{-i}^k). \quad (15.53)$$

In (15.53), $s_{-i}^k \in S_{-i}$ is the k th strategy profile of others and there is a total of n_{-i} such strategies; $p_{t+1}^{-i}(s_{-i}^k; s)$ and $p_{t+1}^{-i}(s_{-i}^k; a)$ are, respectively, the probabilities of play of sophisticated and adaptive players, other than player i , at time $t+1$, which are determined by an expression analogous to (15.52). Given the interdependence between (15.52) and (15.53), the model is solved recursively. It can be shown that a Nash equilibrium and a quantal response equilibrium (QRE) are special cases of this model when $\alpha = \alpha' = 1$ (Camerer et al., 2002).

The model is applied to a ten period p-beauty contest game using data from Ho et al. (1998). Two values of p are considered in the experiments, $p = 0.7$ and $p = 0.9$. *Inexperienced subjects* first play a game with one value of p . They then play the second game with a different value of p ; in the second game they are referred to as *experienced subjects*. The results are shown in Table 15.5, drawing on Camerer and Ho (2014); Table 2 on p. 156 in Camerer et al. (2002) gives additional results on the QRE.

The results are as follows. When subjects are inexperienced, the adaptive EWA model generates estimates that are consistent with Cournot beliefs ($\delta = 0.9, \phi = 0$). The estimated value of ϕ is larger in the sophisticated EWA for both experienced and inexperienced subjects. Sophistication also improves the log-likelihood value for in-sample and out-of-sample observations for experienced and inexperienced subjects. Among inexperienced subjects, about 24% of the players are estimated to be sophisticated and for these players, $\alpha' = 0$, so they are overconfident. The estimated fraction of sophisticated subjects among experienced players is larger at 77% and these players are less overconfident; for these players $\alpha' = 0.41$. Hence, for experienced subjects, adaptive EWA fits much worse than sophisticated EWA. Hence, learning appears to occur in the

Table 15.5 Estimates for the parameters of the sophisticated and adaptive EWA models. Standard errors in parentheses.

	Inexperienced subjects		Experienced subjects	
	Sophisticated EWA	Adaptive EWA	Sophisticated EWA	Adaptive EWA

expected direction, however, the repeated p-beauty contest may be particularly amenable to these results, which need to be checked for other classes of games.

The matching protocol used in experiments, e.g., random matching in each round, or repeated matching with the same opponent is known to affect the outcome (Andreoni and Miller, 1993; Clark and Sefton, 1999). This is not predicted by the EWA model. When *sophisticated players* are matched with *adaptive players* (all players are adaptive in the standard EWA model) in a repeated game setting, the former usually have an incentive to teach the latter in a strategic manner. Such *strategic teaching* can take the form of deliberately playing strategies that could have a lower short-run payoff, but which alters the behavior of the adaptive player in a manner which is to the long-run benefit of the sophisticated player. This often leads to repeated game equilibria and behavior that is consistent with reputation formation.¹⁷

Camerer et al. (2002) discuss an application of a model of strategic teaching to a finitely repeated trust game. In 3×3 games played over 20 rounds, Hyndman et al. (2012) give empirical evidence to show that certain players emerge as “teachers.” These players repeatedly play the Nash outcome when it is not in their best short-term interests. However, by their actions, they are able to shepherd learning in the direction of a Nash equilibrium. In conditions where such teaching is more difficult, there is less frequent convergence to Nash behavior.

Unlike adaptive models (e.g., reinforcement learning, belief-based learning, and EWA) that are backward looking, models of strategic teaching are forward looking. For this reason, they are sometimes referred to as models of *anticipatory learning*. Other models in this class include models of rule-based learning that we consider in Section 15.7.

¹⁷ See for instance, Fudenberg and Levine (1989), Watson (1993).

15.5 Learning models: two points of view

We complete this discussion by giving two opposing points of view on the class of EWA models, which includes reinforcement learning and belief-based models as special cases. The first point of view is already implicit in our discussion above; we may call this the Colin Camerer view. The idea is to construct ever improving models in the EWA class. If this improvement comes about by adding extra parameters (a counter example is the fEWA), then we use statistical criteria such as the AIC and the Bayesian information criteria to trade off the extra explanatory power against the larger number of parameters. Furthermore, we may use estimated parameters based on in-sample estimation to test the model based on out-of-sample data.

A second point of view may be associated with the work of the eminent mathematical psychologist, Amnon Rapoport.¹⁸ This view has two components.

1. Individuals exhibit *heterogeneity in learning*, and there are important context dependent features in learning. Heterogeneity in learning among individuals reflects differences in the learning models used and differences in their cognitive processes. These effects cannot be captured by simply allowing for a distribution of parameters in a common learning model, such as the EWA model. Amnon Rapoport argues that:¹⁹ “any attempt to account for the complex adaptive learning process over iterations of the stage game is doomed to fail. It is like attempting to place multiple individuals of different height into a Procrustean bed.”
2. The class of EWA models, except models of strategic teaching, is backward looking. It ignores the forward-looking aspects of human learning and the ingenuity of human learning. For instance, the end effects in a prisoner’s dilemma game are not captured by purely backward-looking models. In other cases, individuals may sacrifice short-term gains to credibly signal an intention to shift the group behavior in a direction that is mutually beneficial to the players. Indeed, sophisticated EWA learning and strategic teaching that we consider in Section 15.4.5 already considers this possibility in a formal manner. So there are already attempts underway to address this concern.

In the Amnon Rapoport view, statistical tests such as the AIC and the Bayesian information criteria are not very useful if the class of models that is being considered is mis-specified. In this view, a mis-specified model omits heterogeneity in learning/cognitive processes. The alternative is to write context-dependent learning models. Examples include: variations of the reinforcement model, augmented for context and individual variations in learning, to apply to market entry games (Rapoport et al., 2000, 2002), two-player bargaining games (Rapoport et al., 1998), common pool resource problems (Botelho et al., 2014), route choice in congestible networks (Mak et al., 2014), and a three-player centipede game (Rapoport et al., 2003). In each case, these augmented models are successful in explaining the particular features of the experimental results.

As an example, consider the market entry games in Rapoport et al. (2000, 2002). In this model, players simultaneously decide to enter two different markets. Players use a simple cutoff rule to make their entry decision, based on the combined capacity in both markets. Conditional on entry, players probabilistically decide to enter each market; these probabilities, in turn, are based on propensities to enter each market. In the manner of reinforcement learning, the actual observations are used, in each round, to update the cutoff rules to determine entry as well as the propensities to enter the markets. In line with earlier experiments on single market entry games, the

¹⁸ I am grateful to Amnon Rapoport for discussing and clarifying his position on these issues.

¹⁹ The source for this quote is personal communication.

authors find a high degree of implicit coordination on entry that conforms well with equilibrium predictions. The proposed learning model also conforms well with actual data.

The Rapoport et al. (2003) experiments extend the standard two-player centipede games (see Part 4 of the book) to three players, more rounds of learning (from 10 rounds to 60 rounds), higher stake payoffs,²⁰ and terminal payoffs of zero. With these changes, the authors find that, in their four sessions, the equilibrium prediction (play down at the first node) holds in 46.3%, 39.3%, 30.3%, and 40.7% of the cases.

They then propose a reinforcement learning model to explain their results. In this model, players begin with some initial probabilities of playing “down” at each of the nodes in the centipede game. They then update the probabilities at the end of each round, based on the observed play of “down” in that round. The model is fairly parsimonious. It requires a specification of the initial probabilities and the single parameter of the reinforcement learning model. The predicted conditional probability of moving down at the first node increases over successive rounds of learning, as does the observed probability.

One disadvantage of this approach may be that we could have a plethora of learning models that are designed for each situation; something that most economists would find unattractive, given their approach to model building. However, against this criticism is the maintained hypothesis in this view that it is impossible to construct general models anyway. At a minimum, these results highlight the importance of considering individual differences in learning and cognition, and the necessity of incorporating forward-looking elements into existing learning models.

15.6 The class of learning direction theories

In this section, we consider learning models that are either inspired by *learning direction theory*, or are close relatives.

15.6.1 *Learning direction theory*

There has been growing recent interest in *learning direction theory*. A popular analogy used to describe the theory is the problem faced by an archer (Selten and Stöcker, 1986). The best response of an archer is to hit the absolute middle of the target. Suppose instead that the archer hits to the left of the target. In the next step, the archer realizes that he needs to aim a little bit to the right. Thus, in each period, the player appears to best respond to last period’s play, as under Cournot dynamics—a form of *ex-post rationality*. An attractive feature of this theory is the low informational requirement on account of the limited objective to predict only the direction of change.

Selten et al. (2005, p. 6) write “Learning direction theory is not meant to be a complete explanation of adaptive behavior. Therefore, it does not propose the hypothesis that ex-post rationality prevails in all cases. Sometimes other influences might move the decision in the opposite direction. However, it is assumed that ex-post rationality is the strongest influence.” The theory is qualitative. It does not specify the magnitude of adjustment from one period of learning to another—the interest lies only in the direction of change.

²⁰ In the four move centipede game, the maximum payoff was 200 times higher relative to the McKelvey and Palfrey (1992) two-player centipede experiments considered in Part 4; the corresponding figure for the six move game (see also Part 4) was 50.

In successive steps of learning, players may converge to the target, so, for instance, the archer may eventually hit the bulls eye. The objective of *impulse balance theory*, outlined in Selten et al. (2005) is to describe the long-run consequences of such directional learning. The idea in this theory is to find an *impulse balance point* at which, on average, one is equally likely to move to the left or to the right. We defer a discussion of these issues to Section 15.6.2.

Suppose that player $i \in N = \{1, 2, \dots, n\}$ chooses strategy $s_i(t)$ at time t , while others choose the strategy profile $s_{-i}(t)$. Let the pure strategy set of player i be given by S_i . The *ex-post best response* of player i is

$$b_i(t) \in \arg \max_{s_i \in S_i} \pi_i(s_i, s_{-i}(t)).$$

Then, under learning direction theory, and as indicated in the example of the archer above, the strategy chosen by player i in period $t + 1$, $s_i(t + 1)$, lies between $s_i(t)$ and $b_i(t)$. In relation to other learning models, two comments are in order. First, the notion of moving in the direction of improving payoffs is a feature of many other learning models, such as belief-based models, aspiration adaptation theory, or the EWA model. Second, and as noted by Camerer (2003), suppose that the current action is not the best response and that there are several “intermediate actions” between the current action and the best action. It is quite conceivable that some of these intermediate actions might have a very low payoff. Learning direction theory does not predict which, if any, of these intermediate low payoff actions will be played. However, belief-based, or EWA learning models are able to make such predictions, giving, in some cases, a sharper predictive alternative to learning direction theory.

The comparison of learning direction theory with some of the other models that we have considered is as follows. Unlike reinforcement learning, the central issue for players who use learning direction theory is not the payoff in the previous period. Instead, they ask if they could they have achieved a higher payoff if they had followed another action? This consideration of *forgone hypothetical payoffs* is similar to some belief-based models and EWA. However, unlike the adaptive learning models that we have considered, learning direction theory does not predict the probabilities with which players play their strategies.

In order to test the predictions of learning direction theory, Selten and Stöcker (1986) had six groups of subjects in experiments play 25 supergames. Each supergame was a ten period repeated prisoner’s dilemma game. They were interested in examining the variations in the defection strategy on account of learning, as players play successive supergames. The neoclassical prediction is that players must defect in the first round.

Cooperative behavior in these experiments is defined as the play of the cooperative strategy for at least four periods, followed by a defection from at least one player, which, in turn, is followed by mutual defection from both players until the tenth period. On this definition, most players, particularly experienced players (those who had played several supergames) choose to cooperate.

Let $k \in \{1, 2, \dots, 10\}$ be the earliest period that a player wishes to play the strategy defect. This can be revealed through an actual defection, or if a defection is not observed, through a written response from the player at the end of the supergame. For each of the six groups, k fell as the players successively played the supergames. Table 15.6 shows the average value of k for six groups of experienced subjects for supergames 13–19 and 20–25.

Classical game theory predicts $k = 1$. However, from Table 15.6, for experienced subjects, $k > 4$, hence, players play the cooperative outcome (this also holds when one looks at data that is disaggregated by supergames). There is variability across groups. For instance, on average, in supergames 13–19, there is almost perfect cooperation in groups V and VI. Even in group I where

Table 15.6 Average defection period, $k=1, 2, \dots, 10$, for experienced subjects.

Supergames	I	II	III	IV	V	VI	Average
13–19	7.1	8.6	9.9	7.3	9.6	10.0	8.8
20–25	5.9	7.8	9.6	6.4	8.8	8.7	7.8

Source: Selten and Stöcker (1986).

the average cooperation is the lowest, on average, no player defects until round 7 of the ten round supergame. There is a reduction in k , typically by about one round on average, across the two sets of average figures, across the supergames reported in Table 15.6.

The authors propose a model based on learning direction theory to organize the data. Suppose that players begin with some intended period of deviation, k . If they find that their opponent defected before them, then in the next supergame, they reduce k by one unit with probability α . In the case of simultaneous defection, players reduce k by one unit with probability β . Finally, if they find that they defected first, then in the next supergame they increase k by one unit with probability γ . The estimated values are $(\alpha, \beta, \gamma) = (0.50, 0.14, 0.23)$; these might be taken to be the estimates of learning direction theory for the finitely repeated prisoner's dilemma game.

Selten et al. (2005) show that learning direction theory can explain the data arising from the *takeover game*, due to Samuelson and Bazerman (1985), that we describe in detail in Part 4 of the book. In these experiments, subjects repeatedly place bids in auctions, over 100 periods. At the end of each period, they learn about the valuation of the firm that they were bidding for. Learning direction theory prescribes that if the bid turns out to be greater (lower) than the valuation, then it should be reduced (increased) in the next period. The results show that the majority of the changes are in the direction predicted by learning direction theory.

15.6.2 Impulse matching theories

In this section we are interested in two-player normal form games in which each player has two actions (2×2 games). The *impulse balance equilibrium* was introduced by Selten et al. (2005) and Selten and Chmura (2008). However, we first outline *impulse matching learning*, which is a closely related concept (Selten and Chmura, 2008; Chmura et al., 2012). Unlike traditional learning direction theories, that could only predict the direction of change, these newer concepts are able to predict the probabilities with which players play their strategies. Thus, they allow the predictions of learning direction theory to be directly compared with other theories that predict probabilities of play.

IMPULSE MATCHING LEARNING

The basic idea is that if in any round, a player were to choose an alternative strategy that could have given him a higher payoff, then in the next round, he receives an *impulse* to play the alternative strategy. Consider, for instance, the 2×2 game shown in Figure 15.11, which is game 3 from Selten and Chmura (2008). Suppose that in some round, the column player plays L and the row player plays D. However, the row player's best response would have been U, thus, in the next round, the row player receives an impulse to play U. One could calculate impulses based on the forgone payoff, as in theories that incorporate regret. However, Chmura et al. (2012) incorporate a form of loss aversion by first defining an *aspiration level* that is taken to be the *maximin payoff*.

	L	R		L	R
U	8, 6	0, 14		U	7.5, 6
D	7, 7	10, 4	→	D	7, 6.5
					8.5, 4

Figure 15.11 Original game (left) and transformed game (right) based on an aspiration level of 7 for the row player and 6 for the column player.

Source: Reprinted from *Games and Economic Behavior* 76(1): 44–73. Chmura, T., Goerg, S., and Selten, R. “Learning in experimental 2×2 games.” Copyright © 2012, with permission from Elsevier.

In the original game in the left panel in Figure 15.11, the maximin payoffs for the row and the column players are, respectively, 7 and 6. Payoffs that exceed the aspiration levels are termed as gains and those that fall below are termed as losses. Taking a value of the loss aversion parameter to be 2, gains above the aspiration level are cut by half. Consider, for instance, the payoff of 8 of the row player from (U, L). Relative to the aspiration level of the row player, 7, this is a gain of 1, which is cut by half. Thus, in the transformed matrix in Figure 15.11, the payoff of the row player is $7 + \frac{8-7}{2} = 7.5$. Applying this transformation to each payoff in the original matrix on the left gives the transformed matrix in the right panel in Figure 15.11. The payoffs used below shall all refer to the payoffs in the transformed matrix.

Suppose that the row and column players are labeled 1 and 2, respectively, and their respective strategy sets are $S_1 = \{s_{11}, s_{12}\}$ and $S_2 = \{s_{21}, s_{22}\}$. At any time $t = 1, 2, \dots$, suppose that the action of the opponent is s . Fixing s , let the payoff of player $j = 1, 2$ from his two actions s_{j1}, s_{j2} be $\pi_{j1} = \pi_j(s_{j1}, s)$ and $\pi_{j2} = \pi_j(s_{j2}, s)$. Then, the impulse from action s_{j2} to action s_{j1} for player $j = 1, 2$ is given by

$$r_{j1}(t) = \max \{0, \pi_{j1} - \pi_{j2}\}, j = 1, 2. \quad (15.54)$$

Similarly, the impulse from action s_{j1} to action s_{j2} is $r_{j2}(t) = \max \{0, \pi_{j2} - \pi_{j1}\}, j = 1, 2$. The impulses in any time period contribute to the *cumulative impulses*. The cumulative impulse for strategy i of player j , denoted by R_{ji} , is calculated as follows. Initial values of the cumulative impulses are $R_{ji}(1) = 0, i, j = 1, 2$. For any $t > 1$, the cumulative value of the impulse for strategy i of player j is

$$R_{ji}(t+1) = R_{ji}(t) + r_{ji}(t), j = 1, 2 \text{ and } i = 1, 2.$$

Player j plays the two pure strategies in $S_j = \{s_{j1}, s_{j2}\}$ with the following probabilities

$$p_{ji} = \begin{cases} \frac{R_{ji}}{R_{j1} + R_{j2}} & \text{if } R_{j1} > 0 \text{ and } R_{j2} > 0 \\ 0.5 & \text{otherwise} \end{cases}, j = 1, 2 \text{ and } i = 1, 2.$$

IMPULSE BALANCE EQUILIBRIUM

The idea of an *impulse balance equilibrium* is similar to impulse matching learning except for the calculation of impulses in (15.54). In this case, the analog of (15.54) is

$$r_{j1}(t) = \begin{cases} \max \{0, \pi_{j1} - \pi_{j2}\} & \text{if the chosen action is } s_{j2} \in S_j \\ 0 & \text{otherwise} \end{cases}, j = 1, 2,$$

where π_{ji} is the payoff to player j from the strategy s_{ji} , as given in the transformed matrix in Figure 15.11.²¹ Thus, there is an impulse from strategy s_{j2} to s_{j1} if the payoff would have been higher from playing s_{j1} instead of s_{j2} . A potential impulse in the other direction, $r_{j2}(t)$, can be explained in an analogous manner,

ACTION-SAMPLE LEARNING

In *action-sample learning*, players take a sample of past observations of the opponent's strategies and optimize with respect to the average (Selten and Chmura, 2008). More formally, let $A_t = \{a_1, \dots, a_m\}$ be a sample of size m of the past actions of the opponent, taken without replacement at time t . Let $\pi_{jk}(a_i)$ be the payoff of player $j = 1, 2$ from his action $s_{jk} \in S_j = \{s_{j1}, s_{j2}\}$ against the opponent's sampled action $a_i \in A_t$. Let $P_{jk}(t) = \sum_{i=1}^m \pi_{jk}(a_i)$ be the cumulative payoffs of the player when he uses the strategy s_{jk} , against the set of opponent's sampled actions, A_t . Then the probabilities of the two actions of player j , s_{jk} and s_{jl} , are given by

$$p_{jk}(t) = \begin{cases} 1 & \text{if } P_{jk}(t) > P_{jl}(t) \\ \frac{1}{2} & \text{if } P_{jk}(t) = P_{jl}(t), k, l = 1, 2, k \neq l. \\ 0 & \text{if } P_{jk}(t) < P_{jl}(t) \end{cases}$$

The initial probabilities of the two actions of player j are set at $p_{j1}(1) = p_{j2}(1) = 0.5$ until the opponent plays both of his possible actions at least once.

PAYOFF-SAMPLING LEARNING

The final learning model that we consider in this section is *payoff-sampling learning* (Selten and Chmura, 2008). In this model, players take two samples of equal size from observed past play. Any player, $j = 1, 2$, takes one sample of m observations in which he played his strategy s_{j1} in the past and another sample of m observations when he played the strategy s_{j2} . Denote by $T_{jk}(t) = \sum_{i=1}^m \pi_{jk}(a_i)$, $k = 1, 2$ the total payoff of player j from his strategy s_{jk} when he uses the sample relevant to s_{jk} . Then, the probabilities of the two actions of player j are given by

$$p_{jk}(t) = \begin{cases} 1 & \text{if } T_{jk}(t) > T_{jl}(t) \\ \frac{1}{2} & \text{if } T_{jk}(t) = T_{jl}(t), k, l = 1, 2, k \neq l. \\ 0 & \text{if } T_{jk}(t) < T_{jl}(t) \end{cases}$$

EMPIRICAL EVIDENCE ON LEARNING DIRECTION MODELS

Selten and Chmura (2008) pit various models of learning against each other by using 12 games, of which 6 were constant sum, and 6 were non-constant-sum games. There were 12 subject groups of 4 members each, for each constant-sum game and 6 subject groups for the non-constant-sum games. For each game, members of each subject group were randomly matched to play the game for 200 rounds. Based on their results, the authors ranked the various learning models from best to worse, as follows: impulse balance equilibrium, payoff-sampling equilibrium, action-sampling equilibrium, quantal response equilibrium, and Nash equilibrium. However, Brunner et al. (2011) reanalyzed the data and found computation errors. They undertook two revisions of the results. First, they augmented the other learning models also with loss aversion; impulse balance equilibrium, payoff-sampling equilibrium, and action-sampling equilibrium already incorporate loss

²¹ Ockenfels and Selten (2014) apply impulse balance equilibrium to the newsvendor problem that we considered in Part 1 of the book. Ockenfels and Selten (2005) apply this concept to explaining experimental results in private value auctions with feedback on losing bids.

aversion, as shown, for instance, in Figure 15.11. Results showed that the other learning models performed as well as impulse balance equilibrium. Second, in 2×2 matching pennies games where loss aversion plays no role, they find that quantal response equilibrium performs as well as impulse balance equilibrium. In their reply, Selten et al. (2011) contest both these claims, although they admit the computation errors.

It is against this backdrop that the paper by Chmura et al. (2012) runs a comprehensive horse-race between several competing one-parameter learning models, including the ones introduced in this section. They use the same 12 games, and a similar experimental structure to that in Selten and Chmura (2008) described above. One of the games is shown in Figure 15.11; the row player's strategies are U and D, while the column player's strategies are L and R. They run 500 simulations with computer agents to derive the predictions of the following models: impulse balance equilibrium, payoff-sampling equilibrium, action-sampling equilibrium, reinforcement learning, one-parameter self-tuning model, and Nash equilibrium.

Using their simulations and the data from the experiments, they propose the *mean quadratic distance*, Q , to rank the various models; Q is defined as follows

$$Q = \frac{1}{12} \sum_{i=1}^{12} \left(\frac{1}{500} \sum_{k=1}^{500} (\phi_{ik}^L - f_i^L)^2 + (\phi_{ik}^U - f_i^U)^2 \right),$$

where 12 is the total number of games, 500 is the number of simulations, f_i^L and f_i^U are the experimentally observed frequencies of play of L (by the column player) and U (by the row player). ϕ_{ik}^L and ϕ_{ik}^U are, respectively, the frequencies of play of L and U in game i and simulation k . Q lies between 0 and 1. A smaller value of Q shows a better fit with the data. The parameters of each model are chosen so as to minimize the corresponding value of Q for that model. For instance, for

Figure 15.12 Q values for various learning models. Stationary concepts are depicted in dark bars and learning models are depicted in light bars.

action-sample learning, a value of $m = 12$ (sample size) minimizes Q and for the one-parameter EWA model, a value of $\lambda = 0.2775$ (parameter used to compute probabilities, based on attractions) minimizes Q .

Figure 15.12 shows the value of Q for the various learning models considered. This allows a clear ranking of models from best to worse: impulse matching learning, action-sample learning, self-tuning EWA, reinforcement learning. The last two are barely distinguishable, however, reinforcement learning does better than EWA in constant-sum games, but the converse is true for non-constant-sum games. The Q value for EWA is 18 times that of impulse matching learning. Reinforcement learning and EWA are outperformed by the three stationary models (Nash, impulse-balance, action-sampling).

Is the superior performance of impulse matching due to loss aversion? Figure 15.13 gives a comparison of Q values when loss aversion is incorporated in the other models as well (by using the transformed matrix, as in the right panel of Figure 15.11). Impulse matching and reinforcement learning benefit by the incorporation of loss aversion, but it does not alter the ranking of models. Hence, in these results, the superior performance of impulse learning is not an artifact of loss aversion. The ranking is stable over time. The overall ranking is same for rounds 1–100, 101–200, and 1–200.

15.6.3 An explanation of the data from order statistic games

In this section we consider the work of Crawford (1991, 1995) and Crawford and Broseta (1998); their work is typically not included in this category, yet in important ways it is a close relative of learning direction theory. Recall from Part 4 of the book, the experimental results on *order*

statistic games from Van Huyck et al. (1990, 1991). In these games, a set of $N = \{1, 2, \dots, n\}$ players simultaneously choose a strategy (a positive integer) $s_i \in \{1, 2, \dots, \bar{s}\}$, where $\bar{s}$ is the maximum number that can be chosen. The payoff of player i is given by

$$\pi(s_i, M) = aM - b(M - s_i)^2 + c; \quad a > 0, b > 0. \quad (15.55)$$

In (15.55), M is an order statistic, which could be a *median*, or *minimum value*. There are multiple symmetric Nash equilibria that can be Pareto ranked. In the Pareto optimal action, all players should choose $\bar{s}$. In general, the payoff is increasing in one's own choice, but decreasing in the deviation of that choice from the order statistic.

When M is the median, two interesting results are that initial choices are quite dispersed and there is a strong effect of history—the period 10 median is always the same as the median in the first period of play. When $\bar{s} = 7$, the typical choice is 4 or 5. When M is the minimum, initial choices are again dispersed, suggesting the lack of a common prior among the players. The equilibrium typically converges to a play of 1 by each player by round 10 and convergence is often fairly quick.

An initial explanation of these results was given in Crawford (1991) using an evolutionary explanation, while taking particular care to distinguish between the results from small and large groups. We now briefly focus on Crawford (1995). The underlying model is a belief-based learning model that explains the data from the games in Van Huyck et al. Players ignore the effect of their choice on the order statistic. Suppose that the choice of a strategy by player i at time t is given by s_{it} and the period t order statistic is M_t . The order statistic may be written as

$$M_t = f(s_{1t}, s_{2t}, \dots, s_{nt}), \quad t = 1, 2, \dots \quad (15.56)$$

The function f satisfies

$$f(c + ds_{1t}, c + ds_{2t}, \dots, c + ds_{nt}) = c + df(s_{1t}, s_{2t}, \dots, s_{nt}), \quad (15.57)$$

which is satisfied by the median and the minimum. Suppose that the initial choices of strategies are given by

$$s_{i0} = \alpha_0 + \varsigma_{i0}, \quad (15.58)$$

and the strategy choices in any period, $t \geq 1$, are given by

$$s_{it} = \alpha_t + \beta_t M_{t-1} + (1 - \beta_t) s_{it-1} + \varsigma_{it}, \quad \beta_t \in (0, 1] \text{ and } \lim_{t \rightarrow \infty} \alpha_t = 0. \quad (15.59)$$

In (15.58) and (15.59), α_t is a individual-invariant, but time-specific drift parameter. The variable ς_{it} is random with mean zero and variance $\sigma_{\varsigma_t}^2$ and represents individual-specific shocks to beliefs. A high value of β_t captures a greater responsiveness to experience (in this case, the observation of the order statistic in the previous period). It can be shown that (15.59) allows for fictitious play and Cournot best response dynamics. *Deterministic dynamics* allow for an initial dispersion of beliefs by $\sigma_{\varsigma_0}^2 > 0$, but no subsequent belief differences among players, so $\alpha_t = \varsigma_{it} = 0$ and $\sigma_{\varsigma_t}^2 = 0$ for $t = 1, 2, \dots$

We now show that even in the absence of any noise and absence of the drift parameter (deterministic evolutionary dynamics) the equilibrium is history-dependent, which is one of the central findings in the median action game.

Proposition 15.24 (*Deterministic evolutionary dynamics; Crawford, 1995*) Suppose that there exists some time $\tau \geq 1$ such that $\alpha_t = \varsigma_{it} = 0$ and $\sigma_{\varsigma_t}^2 = 0$ for $t = \tau, \tau + 1, \dots$.²² Then s_{it} approaches $M_{\tau-1}$ monotonically and $M_t = M_\tau$ for $t = \tau, \tau + 1, \dots$. This result is independent of the number of players, n , and the functional form of f , provided (15.57) holds.

The intuition behind Proposition 15.24 is that players do not have idiosyncratic beliefs and using (15.59) we have

$$s_{it} - M_{t-1} = (1 - \beta_t)(s_{it-1} - M_{t-1}). \quad (15.60)$$

From (15.60), the signs of $s_{it} - M_{t-1}$ and $s_{it-1} - M_{t-1}$ are identical, but $|s_{it} - M_{t-1}| < |s_{it-1} - M_{t-1}|$. Hence, over time, $s_{it} \rightarrow M_{\tau-1}$, which occurs independently of n and f . However, under deterministic dynamics one can determine which of many possible steady states will occur by invoking the role of history, e.g., by invoking differences in the value of M_τ in Proposition 15.24.

An alternative approach is to examine stochastic dynamics in which the strategies of players are subject to random mutations. Under the assumptions that $\alpha_t = 0$, $\beta_t = \beta$, and $\sigma_{\varsigma_t}^2 = \varepsilon > 0$ in (15.59) for $t = 1, 2, \dots$ the stochastic dynamics are ergodic and initial history does not play a role; however, the most recent history plays a role. When the probability of mutations approaches zero, the long-run equilibrium of the ergodic distribution approaches one of the steady states (that arise in the absence of mutations) with probability one. The long-run steady state depends on the difficulty of moving from various steady states to the basin of attraction of other steady states; the stochastically stable steady state is the one whose basin of attraction is the hardest to escape from. This is essentially the framework that we consider in Chapter 16. The next proposition summarizes the results for alternative order statistics in relation to the median for the games in Van Huyck et al. (1990, 1991).

Proposition 15.25 (*Crawford, 1995*) Suppose that $\alpha_t = 0$, $\beta_t = \beta$, and $\sigma_{\varsigma_t}^2 = \varepsilon > 0$ for $t = 1, 2, \dots$. Consider the games in Van Huyck et al. (1990, 1991) and an order statistic that satisfies (15.56) and (15.57).

- (i) If the order statistic is below (above) the median, the long-run equilibrium assigns probability 1 to the lowest (highest) possible strategy choice.
- (ii) If the order statistic equals the median, then the long-run equilibrium assigns positive probability to all every equilibrium.

Recall that when the order statistic is the minimum, then the equilibrium is a symmetric strategy choice of the lowest possible number, 1. This is consistent with the results in Proposition 15.25. However, the result in Proposition 15.25 is history independent, while the empirical results demonstrate the strong effect of history.

In order to incorporate history dependence, let us consider adaptive dynamics in the sense that $\lim_{t \rightarrow \infty} \sigma_{\varsigma_t}^2 = 0$. In contrast, under stochastic evolutionary dynamics, the variance in beliefs is constant. However, the assumption $\lim_{t \rightarrow \infty} \sigma_{\varsigma_t}^2 = 0$ allows for heterogeneous belief shocks that converge to zero, hence, giving rise to non-stationary transition dynamics.

²² This is the sense in which we have deterministic evolutionary dynamics.

Proposition 15.26 (Crawford, 1995) Suppose that $\lim_{t \rightarrow \infty} \alpha_t = 0$, $\sigma_{s_0}^2 > 0$, $\lim_{t \rightarrow \infty} \sigma_{s_t}^2 = 0$ and $\beta_t = \beta$, then the unique solution to (15.58) and (15.59), is given by:

$$\begin{aligned} s_{it} &= \alpha_0 + \sum_{j=0}^{t-1} \beta g_j + z_{it} \\ M_t &= \alpha_0 + \sum_{j=0}^{t-1} \beta g_j + g_t \end{aligned}$$

where

$$z_{it} = \sum_{j=0}^t (1 - \beta)^{t-j} \text{ and } g_j = f(z_{1j}, z_{2j}, \dots, z_{1nj}). \quad (15.61)$$

Proposition 15.26 allows for drift ($\alpha_t \neq 0$) that disappears in the time limit ($\lim_{t \rightarrow \infty} \alpha_t = 0$). Thus, the eventual outcome is determined by cumulative drift up to that point and as belief uncertainty is eliminated ($\lim_{t \rightarrow \infty} \sigma_{s_t}^2 = 0$) on account of learning by the players, the system settles down into one of the asymptotically stable states. In the absence of noise, it stays there forever. In the large-group minimum-action games in Van Huyck et al. (1990), the strong downward drift causes the outcome to converge to the minimum possible and history plays no role. By contrast, in the median action games in Van Huyck et al. (1991), there is no drift and history determines the outcomes.

We can use Proposition 15.26 to compute the expected values of the players' choices and the order statistic.

Proposition 15.27 (Crawford, 1995) Suppose that Proposition 15.26 holds, and that the following conditions are satisfied. (i) The z_{it} defined in (15.61) are iid across players and have a common variance across players that equals $\sigma_{z_t}^2$. (ii) $\frac{z_{it}}{\sigma_{z_t}}$ has mean zero and unit variance (iii) Let $\mu_t = Ef \left(\frac{z_{1t}}{\sigma_{z_t}}, \dots, \frac{z_{nt}}{\sigma_{z_t}} \right)$.

(a) Under these conditions the expected values of s_{it} and M_t , respectively, Es_{it} and EM_t take a simple form.

$$Es_{it} = \alpha_0 + \beta \sum_{j=0}^{t-1} \sigma_{zj} \mu_j \quad (15.62)$$

$$EM_t = \alpha_0 + \beta \sum_{j=0}^{t-1} \sigma_{zj} \mu_j + \sigma_{zt} \mu_t. \quad (15.63)$$

(b) In addition to the assumptions stated above, let $\frac{z_{it}}{\sigma_{z_t}}$ be normally distributed, so $\mu_t = \mu$ for all t and let $\lim_{t \rightarrow \infty} \sum_{j=0}^t \sigma_{zj} = \theta$, then

$$\lim_{t \rightarrow \infty} Es_{it} = \lim_{t \rightarrow \infty} M_t = \alpha_0 + \beta \mu \theta. \quad (15.64)$$

Proposition 15.27(a) shows that the drift in the model (second terms in (15.62), (15.63)) depends on the behavioral parameters of the model as well as the variance in the beliefs of the players. (15.64) shows the mean level of coordination (the expected strategy of each player equals the order statistic which is a symmetric Nash equilibrium of the game). Thus, mean coordination also depends on the behavioral parameters of the model, number of players, and the dispersion of player beliefs (as represented by the terms μ, θ). Consider the games in Van Huyck et al. (1990, 1991). In the median and the random-pairing minimum games,²³ due to symmetry, $\mu = 0$, thus, (15.64) implies that $\lim_{t \rightarrow \infty} Es_{it} = \lim_{t \rightarrow \infty} M_t = \alpha_0$ and there is no predicted drift.

²³ In the random pairing minimum games, subjects only observed the current pair's minimum. However, given the payoff parameters, it is optimal for risk-neutral players to try to match the population minimum, of which the pair minimum can be viewed as a noisy estimate.

However, for the large-group minimum treatment, Crawford (1991) shows that $\mu = -1.74$, thus, there is a downward trend towards the minimum in large groups, which is consistent with the experimental data. This leads to a lack of history dependence in this treatment (unlike the median action game). This is confirmed in simulated trials when the game is run 500 times (the Van Huyck et al. experiments were run for 9 trials).

15.7 Rule-based learning

In most models of learning, such as reinforcement learning, fictitious play, EWA, individual players learn about which strategies to use. However, it might be that in many contexts, players also learn about *which rules to use*. Rules could themselves be alternative models of learning such as reinforcement learning, belief-based learning, EWA, aspiration adaptation learning, level- k reasoning, tit-for-tat, and maximin. Models in which players choose probabilistically among a set of rules in each time period, and update the probabilities of choosing alternative rules, based on the history of play, are known as models of *rule-based learning*; for instance, Stahl (1999, 2000, 2001), Stahl and Haruvy (2002).

As motivation for rule learning, Stahl and Haruvy (2002) give the following example of human behavior in a 3×3 coordination game. Consider a single population of players in which players are randomly matched to play the bilateral cooperation game shown in Figure 15.14. The strategy C is dominated by a mixed strategy in which strategies A and B are played with identical probabilities.

The experimental results over various rounds of play are shown in Figure 15.15. The vertical and horizontal axes are, respectively, the probabilities of playing B and A. Any point in the probability triangle represents a triple (p_A, p_B, p_C) , where p_i is the probability of playing $i = A, B, C$, and p_C is found residually from $p_C = 1 - p_A - p_B$. The player is indifferent between A and B when $p_B = 0.5 - \frac{1}{3}p_A$; this equation is shown as the dotted line, or *separatix* in Figure 15.15. Above the separatix, B is preferred to A, and below it A is preferred to B. Of particular interest is the dynamic path shown in the region $p_B < 0.5 - \frac{1}{3}p_A$ that begins at 1. Since it is in the region where A is preferred, *myopic rational best response* (e.g., belief learning and EWA) implies that play should continue to stay in this region. However, from rounds 4 to 5, play jumps across the separatix and eventually converges to all play B ($p_B = 1$). This is inconsistent with myopic best response models and provides one rationale for studying rule-based learning.

	A	B	C
A	20, 20	0, 0	60, 10
B	0, 0	60, 60	0, 25
C	10, 60	25, 0	25, 25

Binmore and Samuelson (1997) provide one possible explanation of similar, separatix crossing, behavior. Players may have aspiration levels and if the current payoff is below the aspiration level, they may engage in experimentation with their next round strategies. For instance, unless a large fraction of the population plays the strategy C, players who choose A as their best response (rounds 1 to 4 in Figure 15.15) may find that their payoffs are mostly low numbers, 20 or 0, possibly below their aspiration level. If players then experiment with B, provided a high number of other players play B, they would experience a payoff of 60, possibly above their aspiration level. They then stop experimenting and all play B may be the eventual outcome. However, the experimental results of Stahl and Haruvy (2002) do not support this particular channel of aspiration based learning.

15.7.1 A formal model of rule learning

Let us now consider a formal model of rule learning. Consider a two-player game $G(2, S, \pi)$ in which (i) players from the same population are randomly matched together in bilateral encounters, and (ii) in each period, every player is matched with every other player. The pure strategy set of each player is given by $S = (s_1, s_2, \dots, s_n)$. The probability distribution of pure strategies in S belongs to the set Σ , with typical element σ .

Denote by p^t , the empirical distribution of pure strategies in the population in period t . For any $s \in S$, $\pi(s, p)$ is the expected payoff of a player from playing the strategy s when the frequency distribution of pure strategies in the population is given by p . Denote by p^0 , the mixed strategy $(\frac{1}{n}, \frac{1}{n}, \dots, \frac{1}{n})$ in which all pure strategies are played with an identical probability. At the

beginning of period t , the history of the game is given by $h^t = \{p^0, p^1, \dots, p^{t-1}\}$, where we have assumed that the null history at time $t = 1$, is p^0 .

At the end of each period, players receive information about their own payoffs, and the choices made by the other players. Thus, the information available to any player at the beginning of period t is given by $\Omega^t = (G, h^t)$.

Definition 15.20 A behavioral rule, ρ_j , is a mapping from the available information to mixed strategies, i.e., $\rho_j : \Omega^t \rightarrow \Sigma$. We denote by $\rho_j(\Omega^t)$ the mixed strategy that is generated by rule ρ_j when the available information is Ω^t . Denote the set of all behavioral rules under consideration by $R = \{\rho_1, \rho_2, \dots, \rho_r\}$.

At any time t , the rules in the set R are selected using a probability measure φ such that $\varphi(\rho_j, t)$ gives the probability of choosing the rule $\rho_j \in R$ at time t . We assume that there are propensities or attractions of using rules (formally defined below) so that $w(\rho_j, t)$ is the log propensity to use rule $\rho_j \in R$ at time t . We assume that

$$\varphi(\rho_j, t) = \frac{e^{w(\rho_j, t)}}{\sum_{\rho_k \in R} e^{w(\rho_k, t)}}. \quad (15.65)$$

Thus, each rule is chosen with the probability given by (15.65). In turn, each rule prescribes probabilistic play of pure strategies that is given in Definition 15.20. Thus, at time t , the probability that pure strategy $s_k \in S$ is played, $p_k(t)$, is given by

$$p_k(t) = \sum_{\rho_j \in R} \varphi(\rho_j, t) \rho_j(s_k), \forall s_k \in S,$$

where $\rho_j(s_k)$ is the probability with which strategy s_k is played under rule ρ_j . Thus, $p^t = (p_1(t), p_2(t), \dots, p_n(t))$.

Rules that perform better in one period are more likely to be chosen in the next period. This idea, sometimes known as the *law of effect*, is implemented in the model by the following evolution of log propensities that is similar to reinforcement learning,

$$w(\rho_j, t+1) = \beta_0 w(\rho_j, t) + g(\rho_j, \Omega^{t+1}), t \geq 1, \beta_0 \in (0, 1] \text{ and } \forall \rho_j \in R, \quad (15.66)$$

where $g(\rho_j, \Omega^{t+1})$ is the reinforcement to the propensity of playing ρ_j . $g(\rho_j, \Omega^{t+1})$ is defined as the expected payoff that would have occurred if at time t the individual had played the rule ρ_j when the actual frequency of strategies played was p^t , thus,

$$g(\rho_j, \Omega^{t+1}) = \beta_1 \pi(\rho_j, p^t), \beta_1 > 0. \quad (15.67)$$

Equations (15.66) and (15.67) feed into (15.65) to determine the probabilities of drawing various rules in any time period. These probabilities are identical for all players. However, for each player, in each period, a separate and independent draw from the distribution φ determines the choice of a rule. This is the only source of heterogeneity among individuals in the population. In order to operationalize the model, we need to specify two elements. (1) The set of rules, R , and (2) the initial vector $w(\rho, 1)$ of log propensities to play all the rules.

The model allows the specification of a wide array of rules.

Example 15.8

- (i) Replicator dynamics obtains by setting the number of rules equal to the number of strategies, so $r = n$, and for each $\rho_j \in R$, and for all t

$$\rho_j(s_t) = \begin{cases} 1 & \text{if } s_t = s_j \\ 0 & \text{otherwise} \end{cases}.$$

Thus each rule prescribes one hardwired pure strategy in the set S .

- (ii) Belief-based models such as Cournot dynamics arise when at any time t , $R = \{\rho_1\}$ and ρ_1 prescribes a best response to the time $t - 1$ strategy of the opponents, i.e.,

$$\rho_1(s_k) = \begin{cases} 1 & \text{if } s_k \in \arg \max_{s \in S} \pi(s, p^{t-1}) \\ 0 & \text{otherwise} \end{cases}.$$

We now describe a class of rules, the family of *evidence based rules*. In these rules, players base their choice of a rule on the basis of the *evidence* for and against a rule. In Stahl and Haruvy (2002), evidence, in turn, is generated from the following three archetypical theories of the mind.

(1) *Null model of other players*: In this case, for the initial period $t = 1$, and based on the principle of insufficient reason, players think that each action of the opponent is equally likely. Then the evidence in favor of each action $s_k \in S$ in period $t = 1$ is given by $y_1(s_k, \Omega^1) = \pi(s_k, p^0)$, where $p^0 = (\frac{1}{n}, \frac{1}{n}, \dots, \frac{1}{n})$.

Let p^1 be the vector of empirically observed frequencies of play in period $t = 1$; p_k^1 is the observed frequency of s_k . For period $t = 2$, the evidence in favor of each action, $s_k \in S$, arises by using simple distributed lag forecasting, so $y_1(s_k, \Omega^2) = \pi(s_k, (1 - \theta)p_k^0 + \theta p_k^1)$, where $\theta \in [0, 1]$. Letting $q_k^0(\theta) = p_k^0$, we can write the evidence as $y_1(s_k, \Omega^2) = \pi(s_k, q_k^2(\theta))$, where $q_k^2(\theta) = \theta q_k^0 + (1 - \theta)p_k^1$. Using this recursive chain, in general, for any $t \geq 1$, the evidence in favor of action $s_k \in S$ is²⁴

$$y_1(s_k, \Omega^t) = \pi(s_k, q_k^t(\theta)), \quad (15.68)$$

where

$$q_k^t(\theta) = \theta q_k^{t-1} + (1 - \theta)p_k^{t-1}, \theta \in [0, 1]. \quad (15.69)$$

The vector q^t is defined by $(q_1^t, \dots, q_k^t, \dots, q_n^t)$

(2) *Level-2 model of others*: In Part 4 of the book, we discussed level- k models at length. Stahl and Wilson (1995) formulated level-2 players who believe that all other players are level-1. In any period t , level-1 players play a best response to $q^t(\theta)$, defined in (15.69). Denote this best response by $b(q^t(\theta)) \in \Sigma$, which puts equal probability on all pure strategy best responses to $q^t(\theta)$, but zero probability on all other pure strategies. This may be termed as a *second order theory of the mind*. Thus, the level-2 evidence in favor of action $s_k \in S$ at time t is the expected payoff from playing s_k , i.e.,

$$y_2(s_k, \Omega^t) = \pi(s_k, b(q^t(\theta))). \quad (15.70)$$

²⁴ Notice that using this definition we have $q^1(\theta) = \theta q^0 + (1 - \theta)p^0 = q^0(\theta)$.

(3) *Nash equilibrium theory*: In this case, the evidence in favor of action $s_k \in S$, at time t , is the expected payoff from playing s_k when others are assumed to play a Nash equilibrium, p^{NE} , of the game G , i.e.,

$$y_3(s_k, \Omega^t) = \pi(s_k, p^{NE}). \quad (15.71)$$

The three kinds of evidence, y_1 , y_2 , and y_3 in (15.68)–(15.71), are weighted using respective weights v_1 , v_2 , and v_3 to generate the average evidence in favor of action $s_k \in S$ at time t

$$\bar{y}(s_k, \Omega^t) = v_1 y_1(s_k, \Omega^t) + v_2 y_2(s_k, \Omega^t) + v_3 y_3(s_k, \Omega^t).$$

On account of ease of estimation, the multinomial logit specification is used to specify the probabilities of using various pure strategies. Define the vector $v = (v_1, v_2, v_3)$. The probability of choosing action $s_k \in S$ at time t for any player is

$$\hat{p}_k(\Omega^t, v, \theta) = \frac{e^{\bar{y}(s_k, \Omega^t)}}{\sum_{s_l \in S} e^{\bar{y}(s_l, \Omega^t)}}. \quad (15.72)$$

Equation (15.72) defines a mapping, $\hat{p} : \Omega^t \rightarrow \Sigma$, hence, using Definition 15.20, it is a behavioral rule.

Stahl (2000) discusses another possible theory of the mind, *follow the herd*. This corresponds to a level-0 player in a level- k model. Such an individual follows the herd in the sense that the past is followed with inertia, as in (15.69). The follow-the-herd theory specifies that the evidence in favor of any action $s_k \in S$ at time t

$$y_0(s_k, \Omega^t) = \ln q_k^t(\theta).$$

Thus, if the only theory of mind were follow-the-herd model, then in conjunction with (15.72) this will ensure that $\hat{p}_k$ at time t equals q^t . In general, one may introduce an extra weight v_0 and integrate y_0 into the definition of $\bar{y}$. In this case we define the vector $v = (v_0, v_1, v_2, v_3)$ and the parametric vector as (v, θ) . The model can be extended to allow for other behavioral rules, or to consider combinations of a subset of the rules.

The initial vector of propensities $w(\rho, 1)$ is specified as normally distributed in rule space with mean $(\bar{v}, \bar{\theta})$ and variance σ_w^2 to be determined from the data. In the experiments, subjects play one game for T periods followed by another game for T periods. Thus, one needs to specify the *transference of learning* from one game to the other, i.e., the vector of propensities $w(\rho, T+1)$ in the first period of the second game. This is specified as

$$w(\rho, T+1) = (1 - \tau) w(\rho, 1) + \tau w(\rho, T^+), \tau \in [0, 1], \quad (15.73)$$

where $w(\rho, T^+)$ indicates an update to propensities in period $T+1$ based on the new game. If $\tau = 1$, then the experience from the older game is irrelevant, while if $\tau = 0$, then the older experience is the only relevant information used; (15.73) allows for any convex combination of the two.

15.7.2 Evidence from rule-based models

Stahl (1999, 2000) and Stahl and Haruvy (2002) conduct a comprehensive horse race between the main models. We omit a discussion of the results in Stahl (1999) because subjects play each of the 15 games over two periods, which does not give them an adequate opportunity to learn. These results are superseded by the comprehensive exercise in Stahl (2000) who uses a computer search over billions of randomly generated 5×5 matrices to identify the most suitable games for testing.

One of these games is shown in Figure 15.16. Each player was matched with every other player and received the average payoff over all matchings. These games have the following features. The Nash equilibrium (strategy ne) is a strict equilibrium. Strategy b1 is a best response to the belief that the opponent randomizes uniformly among the various strategies. Strategy b2 is a best response to b1. The strategy wd corresponds to the “worldly type” in Stahl and Wilson (1995); in the model outlined above, this corresponds to the specification $v_1 = 0.015$, $v_2 = 0.035$, and $v_3 = 0.05$. The final strategy is either the maximax strategy (mx), or the strictly dominated strategy dm (dm is not applicable to Figure 15.16).

The results are shown in Table 15.7. Maximizing the log likelihood (LL) for each participant and then summing across the 91 participants gives an unrestricted LL value of -1896.44 . Uniformly random play ($\sigma_w^2 = \bar{v} = \beta_1 = 0$ and $\beta_0 = 1$), labeled “Noise” in Table 15.7, yields a LL of -4393.75 . The difference in the likelihoods multiplied with 2 is distributed as a χ^2 variable with 819 degrees of freedom (d.f.) and has a p-value lower than 10^{-587} , thus, the model is informative.

The choices of participants are typically not the Nash equilibrium, so consider Nash with choice errors. This involves introducing a parameter ε to take account of trembles in choice and setting $\bar{v}_1 = \bar{v}_2 = 0$, $\beta_0 = 1$, $\beta_1 = 0$, and $\sigma_w^2 = 0.25$. Then, for each participant, values of $(\bar{v}_2, \bar{\theta})$ that maximized the LL were found; summed across 91 participants, this gives -3917.14 . However, when we compare this LL value with the value under the unrestricted model, -1896.44 , Nash equilibrium predictions with noise are decisively rejected despite the higher number of parameters in the unrestricted rule learning model.

If we impose no rule learning ($\beta_0 = 1$, $\beta_1 = 0$), then the aggregate maximized LL does much better than Nash at -2303.01 , but is rejected in favor of rule-learning. At the individual level, no rule learning can be rejected for 54.9% of the participants. Cournot dynamics in which the only non-zero parameters are v_1 and θ is also rejected in favor of rule learning (and also in favor of no-

rule learning). Finally, significant population heterogeneity is found and each of the parameters of the rule learning model is statistically significant in the aggregate.

Stahl and Haruvy (2002) introduce several further rules. They find no evidence for *aspiration based experimentation*, *reciprocity-based cooperation*, or the *tit-for-tat* rules. However, there is strong evidence for a simple cooperation rule in which reinforcements to existing propensities depend on the payoffs. This takes the form of playing the symmetric payoff dominant action and an initial propensity to cooperate.

15.8 Multiple games, complexity, and categorization

In most of the learning models considered so far, the object of interest was learning in a single game. Grimm and Mengel (2012) explore the possibility that subjects learn while playing multiple games. In different treatments, they control for the amount of information that subjects have access to. The main idea is that when players play a large number of games under limited information, they economize on scarce cognitive resources by *categorizing* the available games. Three kinds of behaviors under categorization are explored, as we now explain.

Suppose that we have six games (as in the experiments reported in this section), indexed by $\gamma = \{1, \dots, 6\}$ and game γ occurs with frequency $f(\gamma)$. In any game γ , the payoff matrix is $\Pi(\gamma)$, the generic action of player i is $a_i(\gamma)$, the mixed strategy profile of all other players is $\sigma_{-i}(\gamma)$ and player i 's beliefs about $\sigma_{-i}(\gamma)$ are denoted by $\mu_i(\gamma)$.

Suppose that the decision maker forms a *partition* of the games and $G_j \subseteq \{1, \dots, 6\}$ is a *category* of games. Here we assume that the partition is exogenous, but there have been attempts at forming endogenous partitions; see, for instance, Samuelson (2001), Fryer and Jackson (2008), and Mengel (2012). Define the *average game matrix* for category G_j to be

$$\bar{G}_j = \sum_{\gamma \in G_j} \left(\frac{f(\gamma)}{\sum_{\gamma \in G_j} f(\gamma)} \right) \Pi(\gamma).$$

Also, define the average behavior of players other than player i in category G_j by

$$\bar{\sigma}_{-i}(G_j) = \sum_{\gamma \in G_j} \left(\frac{f(\gamma)}{\sum_{\gamma \in G_j} f(\gamma)} \right) \sigma_{-i}(\gamma).$$

Denote the beliefs of player i about $\bar{\sigma}_{-i}(G_j)$ by $\bar{\mu}_i(G_j)$.

We can now define the various modes of optimization in categorized games. Let $BR_i(\gamma, \mu_i(\gamma))$ be the best response of player i in game γ when his beliefs about the strategies of others are given by $\mu_i(\gamma)$.

1. *Best response bundling* (BRB). In this case, for any category of games, G_j , players have distinct beliefs, $\mu_i(\gamma)$, about the play of others for each game γ in G_j . However, they act as if they are facing the average game matrix $\bar{G}_j$. Thus, their chosen action, $a_i(\gamma)$, satisfies

$$a_i(\gamma) \in BR_i(\bar{G}_j, \mu_i(\gamma)), \gamma \in G_j.$$

2. *Belief bundling* (BB): In this case, behavior is similar to the case of *analogy-based expectations equilibrium* that we considered in Part 4 of the book. So players apply a common set of beliefs, $\bar{\mu}_i(G_j)$, to all games in category G_j , but they treat the payoffs from each game separately (unlike the case of BRB). Hence, their chosen action, $a_i(\gamma)$, satisfies

$$a_i(\gamma) \in BR_i(\gamma, \bar{\mu}_i(G_j)), \gamma \in G_j.$$

3. *Action bundling* (AB): In this case, players apply the average payoffs to any game in category G_j (as in BRB) and also use the average beliefs about the strategies of others in category G_j (as in BB). Hence, their chosen action, $a_i(\gamma)$, satisfies

$$a_i(\gamma) \in BR_i(\bar{G}_j, \bar{\mu}_i(G_j)), \gamma \in G_j.$$

If the category G_j is a singleton, $G_j = \{\gamma\}$, then action bundling is equivalent to $a_i(\gamma) \in BR_i(\gamma, \mu_i(\gamma))$, as in the neoclassical case.

The six games used in the experiments are shown in Figure 15.17. Games 4, 5, and 6 are derived, respectively, from games 1, 2, and 3 by adding 5 or 10 to the payoffs. All games have a strict Nash equilibrium with corresponding payoffs shown by bold numbers; this also corresponds to the maximin prediction. In games 2 and 5, the equilibrium is in strictly dominated strategies, which is quite easy to spot. In games 3 and 6, iterated deletion of strictly dominated strategies leads to the unique Nash equilibrium. Finally, in games 1 and 4, the Nash equilibrium can be achieved by deletion of weakly dominated strategies. In each treatment (see below), the games to be played in each round are picked randomly using a uniform distribution. Subjects are initially assigned to the roles of row and column players and their role is unchanged throughout. In each round, subjects are randomly rematched with others in a group of eight players over 100 rounds.

In treatments that have the letter F (few games) subjects play only games 1 and 2, while in treatments that have the letter M (many games) subjects played all six games. The treatments are

Payoff matrices, payoffs associated with the unique strict Nash equilibrium are in bold.

as follows. In the *highly accessible treatments*, FI and MI, payoff matrices are displayed prominently on the decision screen in front of the subjects, and the play of the opponent over the last five rounds is revealed. At the other extreme are the two *low accessibility treatments*, F and M, in which participants observe the payoff matrices for a limited time and do not observe the past play of opponents. Finally, there were two *intermediate accessibility treatments*, M+G and M+F. In treatment M+G, the payoff information is displayed prominently on the decision screen (as in MI), but the average action choices of the opponents are not revealed. Finally, in Treatment M+F, average past play of the opponent is revealed, but payoff information is not.

Two further treatments are run to check for learning spillovers; these are M* and M**. In treatment M*, in games 1 and 4, the row player's payoffs from (A, a), (A, b) and (B, b) are reduced by 5; the Nash equilibrium is unchanged and there are no changes in any other game. In treatment M**, actions B and C in games 2 and 5 are relabeled, so the Nash equilibrium is (B, b) rather than (C, b); there are no changes in other games.

The results are as follows.

1. *Complexity and learning*: Does greater complexity of games hinder learning? Games 2 and 5 are the simplest because there is a Nash equilibrium in strictly dominated strategies. In these games, the overall share of Nash choices is more than 98% across all treatments. Games 3 and 6 are slightly more complex because the Nash equilibrium is in iterated deletion of strictly dominated strategies. In the highly accessible treatment, MI, players learn to play the Nash equilibrium in 94% cases in game 3 and 85% in game 6. However, at the other extreme, in the low accessibility treatment, M, only 50% of row players play their part of the Nash equilibrium despite the column players playing their part of the equilibrium. The results for the most difficult games, 1 and 4, in which Nash equilibrium is achieved by eliminating weakly dominated strategies, is shown in Table 15.8.

It is clear that complexity hinders convergence to a Nash equilibrium. In the easiest treatment, F, more than 95% of the row and column players learn to play the Nash equilibrium in game 1. This is not very surprising because this is a fairly low dimensional game and the

Table 15.8 Frequencies of various choices of actions in games 1 and 4. Data from the last 50 rounds. The Nash equilibrium (A, a) is shown in bold. RP denotes row player and CP denotes column player.

Game 1 (RP)	A	B	C	(CP)	a	b	c
FI	0.90	0.08	0.02	FI	0.92	0.07	0.00
F	0.96	0.04	0.00	F	0.95	0.03	0.02
MI	0.62	0.32	0.06	MI	0.74	0.26	0.00
M	0.37	0.50	0.13	M	0.45	0.55	0.00
Game 4 (RP)	A	B	C	(CP)	a	b	c
MI	0.76	0.20	0.03	MI	0.83	0.17	0.00
M	0.40	0.52	0.07	M	0.48	0.52	0.00

number of learning rounds (100) is quite high. However, in the most difficult treatment, M, only 37% of row players and 45% of column players learn to play a Nash equilibrium. For game 4, the corresponding percentages are 40% and 48%.²⁵ The overall complexity of even the most complex games here is relatively low, and the number of rounds is high, hence, the results are sobering for classical game theory.

2. *Framing effects*: It is plausible to argue that the treatments M, M*, and M** are equally complex. Thus, if there is any difference in the behavior of subjects across these three treatments, then it is likely to be due to framing effects and possibly due to learning spillovers (which is the authors' preferred explanation).²⁶ In these treatments, games 3 and 6 are identical and the Nash equilibrium is (A, b). Yet, while the proportion of column players who play b is nearly identical in all treatments, a significantly higher proportion of row players play A in treatment M** relative to treatment M (71% as compared to 50% in game 3; and 66% as compared to 44% in game 6). There are also significantly less C choices in treatment M** relative to treatment M.
3. *Play in strategically equivalent games*: The following pairs of games are strategically equivalent: 1 and 4; 2 and 5; 3 and 6. Between pairs of these equivalent games, and for the last 50 periods, the difference in choice frequencies of all strategies are statistically insignificant. This result holds also for the most complex treatment, M. Thus, learning ensures that strategically equivalent games are played in the same manner.
4. *Source of complexity*: Consider the two pairs of strategically equivalent games, 1 and 4, and 3 and 6. In both games, the row player should play A in a Nash equilibrium. Figure 15.18 shows the predicted frequencies of row players who play A , based on logit regressions in the six-game treatments (M, MI, M+F, and M+G).

In all cases, learning drives choices towards all-play A , but with varying degrees of success. Complexity plays a role. The Nash choices are highest in the highly accessible

²⁵ Oechssler and Schipper (2003) show that subjects are not very good at guessing the payoff functions of the opponents when they do not have this information, yet they often learn to play the Nash equilibrium.

²⁶ Bednar et al. (2012) consider players who play two different games with different opponents. They find evidence of behavioral spillovers from one game to the other. Individuals develop common behaviors across games, which could be a form of categorization.

treatment, MI, lowest in the least accessible treatment, M, and intermediate in the treatments, M+F and M+G. Among the two intermediate treatments, M+F and M+G, there are more Nash choices in the latter. These results suggest that displaying payoff information prominently is more conducive for Nash learning as compared to revealing information about average past play of opponents.

Behavior in the two treatments, M+F and M, is quite similar, which suggests that information on average past play of opponents is not critical to Nash learning. The behavior in treatments M+G and M differs. This is particularly true in games 3 and 6 where there are relatively more Nash choices in the treatment M+G. Thus, providing payoff information on the screens contributes to a reduction in the underlying complexity of the game. In a comparison of treatments M+G and MI there are more Nash choices in the latter, which again suggests a role of complexity (players have information about the opponent’s past choices in MI, but not in M+G). In a comparison of games 1 and 4, the most difficult games, the differences between the treatments M+G and M+F are more muted (only in game 4 does the difference achieve statistical significance at the 10% level).

5. *Modes of categorization:* Consider two exogenous, but plausible, partitions of the six games. The first partition separates the most difficult games, 1 and 4, in a separate category to give $\{\{1, 4\}, \{2, 3, 5, 6\}\}$. The second partition is the finest; it obtains when pairs of similar games

are grouped, i.e., $\{\{1, 4\}, \{2, 5\}, \{3, 6\}\}$. Consider action, or best response bundling in which there is a distribution of the population that holds either of the two given partitions.²⁷ The authors show that this explains well 90% of the behavior in treatment M, which, as we noted above, significantly departs from the predicted Nash behavior. This mode of categorization explains better than belief-based categorization.

6. *Influence of cognitive ability*: Subjects who score more highly in the *cognitive reflection test* choose the Nash equilibrium more often. Further, 85% of these high achievers exhibit identical choices in strategically equivalent games.

15.9 Possibility and impossibility of rational learning

Under reinforcement learning, players only observe the payoffs arising from their own past experience. By contrast, under fictitious play, players observe the past frequency of play of the opponent and attempt to infer the mixed strategies that the opponent is likely to play. In both cases, players behave as *automata* and do not evaluate the efficiency of their learning rule. In this section, we consider two alternative learning rules, *regret learning* and *hypothesis learning*, which allow players to periodically evaluate the efficiency of their learning strategy.

Other models of learning that we have considered above also incorporate some of these features. For instance, regret from forgone payoffs is incorporated in EWA and impulse matching learning (Sections 15.4, 15.6). Players also evaluate the efficiency of their learning strategies in models of rule learning (Section 15.7). Furthermore, these models are consistent with a range of empirical evidence.

Situations in which a single agent/animal interacts with nature, which was the original application of reinforcement learning in biology, are simpler relative to multi-player interactions. For instance, if players know that others are trying to learn something about their behavior, then they might alter their behavior. One must address similar feedback considerations in multi-agent learning situations. Learning might fail despite players being fully rational in the classical sense and despite there being infinite repetitions of the game. This “impossibility of learning” result was demonstrated by Foster and Young (2001).²⁸ Paradoxically, relaxing rationality can facilitate learning as we shall see below; see, for instance, the account in Young (2004) that we draw upon below.

We first illustrate the idea of *regret matching*. Consider the two-player coordination game in Figure 15.19 that has two pure strategy coordination Nash equilibria and one in mixed strategies. None of the players knows the actual game being played. But they can observe the history of play and the payoffs for each combination of actions played. Suppose that the row player observes the sequence of actions and own-payoffs shown in Table 15.9.

The undiscounted sum of payoffs to the row player, over the ten periods, is 3. Suppose that players are interested in minimizing their *ex-post regret*, which can be computed as follows. Fix the column player’s period by period strategy over the ten periods as in Table 15.9. Now give the row player an opportunity to play a fixed strategy, either s_1 or s_2 , in each of the ten periods. If the row player had chosen s_1 (respectively, s_2) in every period, keeping fixed the strategy of the

²⁷ Under the partition $\{\{1, 4\}, \{2, 5\}, \{3, 6\}\}$, under BRB, in response to the observed frequencies of play of the column players, row players should choose A or B in category $\{1, 4\}$, C in category $\{2, 5\}$ and A in category $\{3, 6\}$. The best responses under the partition $\{\{1, 4\}, \{2, 3, 5, 6\}\}$ depend on the frequencies of the various games.

²⁸ See also Binmore (1987) and Jordan (1992, 1993) for results of a similar nature.

	s_1	s_2
s_1	1, 1	0, 0
s_2	0, 0	1, 1

column player, he would have received a payoff of 4 (respectively, 6). Thus, the player's forgone payoffs from not playing s_1 and s_2 , respectively, throughout, are $4 - 3 = 1$ and $6 - 3 = 3$.

Regret is defined as the average forgone payoff over a given time period. Hence, regret from not playing s_1 throughout is $\frac{1}{10} = 0.1$, while the regret from not playing s_2 throughout is $\frac{3}{10} = 0.3$. While the past cannot be undone, the idea behind *regret learning* is that since not playing s_2 has been relatively more regrettable, in future the player should play s_2 more often.

The idea of a state of play which leaves *no regret* in the mind of the player goes back to Hannan (1957).²⁹ Consider a single player playing a game against nature. The player can choose actions from the finite set $A = (a_1, a_2, \dots, a_n)$. Nature has the finite action set $B = (b_1, b_2, \dots, b_m)$. The payoff function of the player is given by $\pi : A \times B \rightarrow \mathbb{R}$. The action profile at time $\tau = 1, 2, \dots$ is denoted by the tuple (a^τ, b^τ) . Hence, at any time T , the history of play is given by

$$h^T = [(a^1, b^1), (a^2, b^2), \dots, (a^T, b^T)]. \quad (15.74)$$

The regret from not playing action $a_i \in A$ at time T , denoted by r_i^T , is defined as

$$r_i^T = \bar{u}_i^T - \bar{u}^T, \quad (15.75)$$

where $\bar{u}^T = \frac{1}{T} \sum_{\tau=1}^T \pi(a^\tau, b^\tau)$ is the average payoff to the player at time T , and $\bar{u}_i^T = \frac{1}{T} \sum_{\tau=1}^T \pi(a_i, b^\tau)$ is the hypothetical average payoff to the player, had he played the action a_i in all past periods. Denote by $r^T = (r_1^T, r_2^T, \dots, r_n^T)$, the regret vector that summarizes the regret from each $a_i \in A$.

Definition 15.21 (No-Regret over histories) A history of play h^T has no-regret if

$$\text{as } T \rightarrow \infty, \max_{a_i \in A} r_i^T \leq 0. \quad (15.76)$$

²⁹ See also Foster and Vohra (1993) and Fudenberg and Levine (1995).

Suppose that we have a behavioral rule for the player $\phi : h^T \rightarrow \Delta A$, which describes a probability distribution over the actions of the player at time $T + 1$, given the history of play upto that time, h^T .

Definition 15.22 (No-Regret over behavioral rules) *A behavioral rule for the player, ϕ , satisfies “no regret” if almost surely, all realizations of histories generated by ϕ , satisfy (15.76).*

The next definition formalizes the basic idea in *regret matching*, namely, that in each period, players play their pure strategies with probabilities that equal the relative regret from the strategies. So strategies associated with greater regret are played with higher probabilities.

Definition 15.23 (Regret Matching (RM); Hart and Mas-Colell, 2000) *Suppose that an individual maps his vector of regrets r^T , available at the end of period T , into a vector of probabilities of play next period, $p^{T+1} : r^T \rightarrow [0, 1]^n$, by using the following rule*

$$p_i^{T+1} = \frac{\max\{r_i^T, 0\}}{\sum_i \max\{r_i^T, 0\}}, \quad (15.77)$$

where p_i^{T+1} is the probability of playing action $a_i \in A$ at time $T+1$. When $\sum_i \max\{r_i^T, 0\} = 0$, then we can choose p_i^{T+1} to be any number. If an individual plays his pure strategies with probabilities that satisfy (15.77), then he is said to be following regret matching (RM).

Theorem 15.1 (Hart and Mas-Colell, 2000) *Consider a finite normal form game in which all players use regret matching. Then, almost surely, in the limiting case, RM is a behavioral strategy that has no regret against any sequence of play by the opponent.*

From (15.75), RM can be viewed as a form of *aspiration level learning* where the aspiration level is given by the historical average payoff.

Foster and Vohra (1993) propose *regret matching with ε -experimentation*, in which a player only needs to know the actual payoffs in the past, but need not know the strategies of the other player. The main difference from RM is that with some small probability ε , players make mistakes, or trembles, or they simply experiment and choose randomly among all their actions with equal probability. With probability $1 - \varepsilon$, players use RM. It can then be shown that for small enough noise, ε , *regret matching with ε -experimentation*, leads to extremely small regret for all histories of play. Foster and Vohra (1998) allow for a time dependent noise, i.e., $\varepsilon(t)$. They show that if $\varepsilon(t) \rightarrow 0$ at a sufficiently slow rate, then there is no regret in the long run.

The central result with RM is that the frequency of joint play is related to the set of *coarse correlated equilibria*.

Theorem 15.2 (Hart and Mas-Colell, 2000) *Suppose that all players use RM. Then the empirical frequency of joint play of actions of all players converges (almost surely) to the set of coarse correlated equilibria.*

A encouraging feature of these results is that rules such as RM are computationally simple and require no more computations than are needed, say, for reinforcement learning. However, these rules do well only in the very long run of play. There is no guarantee that the outcome of such rules over short fixed periods of play converges to the coarse correlated equilibrium, or to anything at all.

A natural question in the context of learning models is: do players learn, and what does it mean to learn? Consider a two-player game. Suppose that players are *Bayesian rational* in the following sense. (1) They form posterior Bayesian beliefs about the likelihood of the future play of their

opponent, conditional on the history of play so far. (2) At each stage, players choose strategies to maximize their intertemporal payoffs, given their forecasts of what the other player is expected to do.

Suppose that the history of play at time t is given by h^t (see (15.74)). Conditional on the history, the beliefs of a player about the other player's behavior for the next period are given by the probability distribution p_{-i}^{t+1} . Suppose that the actual behavior of the opponent in period $t + 1$ is given by q_{-i}^{t+1} .

Definition 15.24 (*Predictive error*) The predictive error is given by the distance between p_{-i}^{t+1} and q_{-i}^{t+1} , i.e., $d(p_{-i}^{t+1}, q_{-i}^{t+1})$, where d is the Euclidean metric.

Definition 15.25 (*Learning to predict in the strong sense*) A player is said to learn to predict in the strong sense if, almost surely, $\lim_{t \rightarrow \infty} d(p_{-i}^{t+1}, q_{-i}^{t+1}) = 0$.

Definition 15.26 (*Learning to predict in the weak sense*) A player is said to learn to predict in the weak sense if, almost surely, the mean square error goes to zero, i.e., $\lim_{t \rightarrow \infty} \frac{1}{t} \sum_{s \leq t} d(p_{-i}^{s+1}, q_{-i}^{s+1})^2 = 0$.

Blackwell and Dubins (1962) gave the absolute continuity condition. Roughly speaking, players always put positive probability on histories that could have arisen under their joint play so far.³⁰ Kalai and Lehrer (1993) showed that under Bayesian rationality and absolute continuity, players will learn to predict in the strong sense and we get convergence to a Nash equilibrium.

Suppose that each player does not know the payoffs of the other player. This makes the forecasting of the future play of the opponent difficult. Foster and Young (2001) show that if there is enough ex-ante uncertainty about the payoffs of the opponent, then it is possible to get the following two results. (1) No learning takes place, even in a weak sense, and even in the long run. (2) Play does not converge to a Nash equilibrium. The contrast between these results and the Kalai–Lehrer results is what Young (2004) refers to as the *possible* and the *impossible* in multi-agent learning. In his words: “A consequence of this result is that there exist no general, model-based procedures for multi-agent learning when players are perfectly rational and they have sufficiently incomplete knowledge of their opponents’ payoff functions.”

Hart and Mas-Colell (2006) also give a negative result. They focus on learning rules that are *uncoupled*. An uncoupled learning rule does not depend on the payoffs of the opponent. Reinforcement learning and regret matching (RM) are examples of such a rule. They show that under certain conditions no uncoupled learning rules exist such that the period by period behavior of players converges almost surely to a Nash equilibrium of the game (or even to a ε -equilibrium of the game). These conditions include the finiteness of action spaces, and a state variable that uses the last τ periods of play. RM in which regret is computed from the last τ periods of play is an example.

We now provide a brief discussion of a learning rule, *hypothesis testing*, that is also uncoupled, but it does not satisfy all the conditions of the Hart and Mas-Colell (2006) result. This has desirable long-run properties in that it is able to achieve an ε -equilibrium of the game. Consider the following version of hypothesis testing in Foster and Young (2003) that draws on the standard theory of hypothesis testing in statistics.³¹ Consider two players A and B whose finite pure strategy sets are S_A and S_B respectively, with generic elements a_i and b_i . The model is not restricted

³⁰ For the formal definition of the absolute continuity condition, see Fudenberg and Levine (1998) and Young (2004).

³¹ Also see Arthur (1994) and Jehiel (1995, 1998) for earlier treatments.

to two players; we make this restriction purely for pedagogical convenience. Probability distributions over these sets are given by Σ_A and Σ_B , respectively; the respective typical elements of these sets are given by p_A and p_B .

Suppose that we consider everything from player A's point of view (the analogous arguments for player B are obvious). Then "a model" for player A at some time t is a probability distribution $p_B^t \in \Sigma_B$, so the space of possible models is given simply by the set Σ_B . At time t , player A believes that player B will play p_B^t from time t onwards. Denote the payoff to player A from playing his action a_i every period from period t onwards by $u_{At}(a_i, p_B^t)$. Player A then plays each of the pure strategies in S_A , according to a *quantal response function*:

$$q_A^t(a_i) = \frac{\exp u_{At}(a_i, p_B^t)}{\sum_j \exp u_{At}(a_j, p_B^t)}. \quad (15.78)$$

The steps involved in hypothesis testing are as follows:

Step I. (Model formulation and action choice) At time t , players A and B pick models of their opponent's play, respectively, $p_B^t \in \Sigma_B$ and $p_A^t \in \Sigma_A$. Each player then plays the respective mixed strategy q_A^t, q_B^t over his actions, which is given by the quantal response function. This feature of the model is similar to smooth fictitious play. However, while the model is continuously updated in smooth fictitious play, here it is only updated if it fails; see below.

Step II. (Data collection phase) If a player is not collecting data, then he initiates data collection from the next period with a probability $\frac{1}{\tau}$, $\tau > 0$. Should a data collection phase begin, it lasts over τ periods.

Step III. (Hypothesis testing) Once data is collected, then over the τ periods of the sample, the player computes the empirical frequency of play of the opponent $\bar{p}_{-i}$. Players then specify a rejection region, choosing to reject their model in Step I if $d(\bar{p}_{-i}, p_{-i}^t) > \gamma_i$ (where $d(\bar{p}_{-i}, p_{-i}^t)$ is the Euclidean distance between $\bar{p}_{-i}$ and p_{-i}^t). If $d(\bar{p}_{-i}, p_{-i}^t) \leq \gamma_i$, the model is accepted. If a model is rejected, then with some probability ρ , the same model is retained, but with probability $1 - \rho$, a new model is chosen from the feasible set.

Foster and Young (2003) show that under certain plausible conditions, hypothesis testing leads to an ε -equilibrium of the game. These conditions are related to the sizes of the sample, the test tolerance, and a normalization of the utility function; for details, see Foster and Young (2003). While this result is similar to Kalai and Lehrer (1993), however, in this case the rationality of players is limited. They do not, for instance, need to know the payoffs of other players. Nor is information always used optimally: Players can get by without sampling at all for several periods and when they sample, they hold fixed their model of the other player. Also players have no repeated game strategies. Hence, paradoxically, relaxing rationality induces a good limiting outcome for the players.

CHAPTER 16

Stochastic Social Dynamics

16.1 Introduction

In the study of learning under deterministic dynamics (Chapters 14, 15), we have used the concept of an *asymptotically stable steady state*, which has two important features. First, when there are multiple steady states, the outcome is history-dependent, i.e., it depends on initial conditions. Second, shocks/mutations are rare events, so once the system reaches a steady state, it stays there forever.

In many cases, however, there could be multiple sources of *persistent randomness*, such as continuous mutation, taste shocks, and play of mixed strategies. Asymptotic stability is no longer the appropriate notion of stability in this case. Starting from an asymptotically stable state, persistent randomness can gradually, and over time, tip the system out of the basin of attraction of one asymptotically stable state, into the basin of attraction of another. The appropriate modification to asymptotic stability, in this case, is to consider the long-run likelihood of the system remaining in various possible steady states.

If, in the long run, the system is likely to stay in the neighborhood of a particular steady state, then it is called a *stochastically stable state* (Foster and Young, 1990). If such a state is unique, then the initial state of the system does not matter. Such a state is said to be *ergodic*. This framework can be used to understand the evolution of institutions and norms as the result of gradual, small, adjustments arising from adaptively learning individuals.

Section 16.2 introduces the basic concepts and considers two introductory applications (Kandori et al., 1993; Young, 1993a). In order to derive the outcome under stochastic dynamics, we introduce some noise into the system. Any player when faced with an opportunity to revise his strategy, chooses the best response with high probability and, with some small complementary probability, mutates by randomizing among all his choices.

In Section 16.2.1, we consider a 2×2 coordination game that has two Nash equilibria; both are asymptotically stable. Under stochastic dynamics, the multiplicity of the steady states is narrowed down to a unique stochastically stable state that is also the risk dominant equilibrium. The risk dominance property of the stochastically stable states need not hold for higher dimensional games.

Section 16.2.2 uses the method of directed graphs to derive the stochastically stable steady states in a model of technology adoption for a 3×3 game. In this model, strategies correspond to a choice of technology and the stochastically stable state corresponds to the coordinated outcome with the lowest joint payoffs for both players.

Section 16.3 begins our formal study of *perturbed Markov dynamics*. Players have a memory of the play in the last T time periods. They take a sample of size $\tau \leq T$ from memory, and play

a best response to the sampled frequencies of the play of opponents, with some high probability. However, with a low complementary probability, ε , they randomly choose among their pure strategies. The set of states in this model are all possible T period histories of the strategies played by the players.

This structure gives rise to a Markov process on the set of states, denoted by $P^{T,\tau,\varepsilon}$. We may also refer to this as adaptive play with memory length T , sample size τ , and error rate ε . The associated transition matrix on the set of states is given by P^ε . It gives the probability of transiting from any state to any other possible state. We begin by stating a fundamental result that helps us determine the unique stationary distribution as well as the stochastically stable states (Young, 1993a). We then consider some applications to 2×2 games.

Section 16.3.1 gives an application to symmetric 2×2 games in which we allow for inertia, and replace best response by *imitate the best* (Alós-Ferrer, 2000). Under imitate the best, the stochastically stable state may allow for the play of strictly dominated strategies, although this result does not arise when players play best replies. Section 16.3.2 shows that in 2×2 games, the stochastically stable state is also the risk dominant state (Kandori et al., 1993; Young, 1993a). Finally, in Section 16.3.2, we consider several extensions of the basic model, such as players who use different sample sizes, heterogeneity among players, and alternative noise structures (Young, 1998).

Section 16.4 considers results from 3×3 games (Young, 1993a, 1998). Many of the results of 2×2 coordination games do not generalize to these games. Not only might there be no strict risk dominant equilibrium for 3×3 games, but even if it exists, there is no guarantee that it coincides with stochastic stability. However, for a class of games, acyclic games, several of the results generalize. For instance, in this class of games, the unperturbed dynamics converge to one of the conventions, a Nash equilibrium, irrespective of the initial state.

Section 16.4.1 notes that the low rationality adaptive play environment of perturbed dynamics often generates a Nash equilibrium. It does so without requiring the stringent requirements of the epistemic conditions for a Nash equilibrium. However, in Section 16.4.2, we show that stochastic dynamics might pick an inefficient norm. In particular, stochastic dynamics will have a tendency of picking a convention that is distributionally more fair relative to conventions that are associated with extreme payoff inequities.

Section 16.4.3 briefly considers applications of stochastic dynamics to public goods games (Myatt and Wallace, 2005, 2008). We consider public goods games that exhibit threshold externalities, i.e., they require a certain minimum number of players to contribute, otherwise no public good materializes. The method of analysis is again to calculate the least cost of moving between the basins of attractions of two equilibria. In one equilibrium, the public good materializes, and in another, nobody contributes. While the applications are novel and interesting, they leave open the question of how one might use them to explain the results of experiments on public goods games with and without punishment (see Part 2 of the book).

Section 16.5 considers games played by boundedly rational players whose direct interaction is local, but indirect interaction is global (Blume, 1993, 1995). These are games played on graphs in which each individual is located at the vertex of a tree and is influenced by the behavior of the immediate neighbors. We characterize the features of long-run frequency of play and give an application to agrarian contracts (Young and Burke, 2001).

16.2 Fixing ideas in stochastic dynamics

In deterministic situations, random shocks are treated as one-off events, isolated and rare. Hence, once the deterministic system is in some steady state, the concept of *asymptotic stability* requires

that if a rare, but small, deviation occurs, the system reverts back to the asymptotically stable state. However, in many strategic situations, several possible sources of *persistent randomness* exist. For instance, players might play mixed strategies, players might be randomly matched with each other, random mutations might alter the types of players, payoffs might be subjected to random shocks, and there might be immigration, or emigration of players within distinct populations.

The behavior of a system subjected to persistent random shocks, possibly from several sources, is fundamentally different from deterministic dynamics. The long-run behavior of such a system cannot simply be understood by taking expectations of the relevant random variables. Under persistent randomness, the system never really settles down. It is ever-changing, and in a constant state of flux. These persistent shocks, even if they arise with a small probability, can accumulate gradually over time and force the system out of the basin of attraction of an asymptotically stable steady state. The focus under persistent randomness, then, is on the long-run frequency with which various strategies are played. It is possible, of course, as in other dynamic models, that the long run might entail an interval of time that is unrealistically long. However, when players interact locally, or in small geographic neighborhoods, the speed of convergence may be fast (Ellison, 1993; Young, 1998). Moreover, when the noise level is small, but non-vanishing, the process can reach a neighborhood of the stochastically stable equilibrium quite quickly (Kreindler and Young, 2013, 2014).

The basic ingredients of this approach are as follows. First, players have *limited information*, or *limited cognitive ability*, thus, their memory goes back only a finite number of past periods. Second, players are *boundedly rational* in the sense that although they learn from the limited history of play by the opponent, they play *myopic best replies* (as under fictitious play). Third, players play their myopic best replies with a probability $1 - \varepsilon$, where ε is small. With the complementary probability ε , players *mutate*, or make *mistakes* by randomly choosing any pure strategy in their strategy set, S . *Mutation* is taken here as a reduced form for the unmodeled behavioral biases of players. Relative to the classic case of full Bayesian rationality, this is a relatively low rationality framework.

In the absence of mutations, we get deterministic dynamics and the system might settle down to some long-run asymptotically stable state. When there are multiple asymptotically stable states, then history plays a powerful role in choosing the eventual outcome. However, with persistent noise created by ε , however small, the system might eventually *tip out* of the basin of attraction of an asymptotically stable state, and over time, enter into the basin of attraction of another asymptotically stable state. This gives rise to a *punctuated equilibrium*.

In a punctuated equilibrium, a long period of stay in one asymptotically stable state is followed by a tipping into another asymptotically stable state. In this case, we would like to know which of the asymptotically stable states have a greater likelihood of being observed in the long run, as the noise $\varepsilon \rightarrow 0$. We describe such states as *stochastically stable states*. Certain stochastically stable states might eventually be reached with great likelihood, *irrespective of the initial conditions*; these states are said to be *ergodic*. The basic machinery of analysis is described in Appendix C.

How does this framework help us to understand the evolution of institutions? One theory is that institutions arise through the actions of important, or pivotal individuals, or events. For instance, the importance of Napoleon to the legal code, Bismark to social security, and Gandhi to non-violence. However, the thrust of stochastic dynamics is that small individuals, who use adaptive learning, and their small mutations play a key role. Whilst individually small, such mutations can accumulate and tip an equilibrium from one state of the system to another and one of the states might be stochastically stable, or even ergodic.

Wallace and Young (2014) illustrate the basic method of analysis for the simple 2×2 coordination game shown in Figure 16.1. The two *evolutionary stable strategies* (see Definition 14.4) are the two monomorphic equilibria in which all play s_1 , or all play s_2 .

Let x_t be the proportion of players in the single population who play the strategy s_1 at time t . Starting from the monomorphic population in which all play s_1 , suppose that there is an invasion by a small fraction $1 - x_t$ of mutants who play s_2 . Let $\bar{\sigma}_t$ be the average strategy in the population at time t , given by $\bar{\sigma}_t = x_t s_1 + (1 - x_t) s_2$. Then the replicator dynamics in (14.25) are given by $\dot{x}_t = [\pi(s_1, \bar{\sigma}_t) - \pi(\bar{\sigma}_t, \bar{\sigma}_t)] x_t$, where $\pi(s_1, \bar{\sigma}_t) = x_t$ and $\pi(\bar{\sigma}_t, \bar{\sigma}_t) = x_t^2 + 2(1 - x_t)^2$. Under stochastic dynamics, we can write the replicator dynamics as a stochastic differential equation

$$\dot{x}_t = [x_t - x_t^2 - 2(1 - x_t)^2] x_t + \varepsilon dW_t, \quad (16.1)$$

where W is a Wiener process such that $W_t - W_0 \sim N(0, dt)$.

Figure 16.2 shows a simulated plot of (16.1) for a relatively high value of $\varepsilon = 0.6$ and $x_0 = 0.5$. It is clear that the system spends most of its time in the monomorphic state s_2 , but very little in the monomorphic state s_1 . This becomes even more stark as the noise term ε shrinks further. In

s_1	9, 9	0, 7
s_2	7, 0	8, 8

Figure 16.3 A symmetric two-player coordination game.

the limit as $\varepsilon \rightarrow 0$, the system spends all its time in the neighborhood of the monomorphic state s_2 , irrespective of the history of play. Thus, the monomorphic state s_2 is the stochastically stable state. In the rest of the chapter, we outline various applications of this basic idea for discrete time models, based on the frameworks developed simultaneously by Kandori et al. (1993) and Young (1993a).

16.2.1 Stochastic dynamics in a coordination game

Let us fix ideas on the difference between deterministic and stochastic dynamics in a concrete example. Consider the symmetric two-player coordination game in Figure 16.3. There are two Nash equilibria in the game, (s_1, s_1) and (s_2, s_2) .

Consider the deterministic dynamics of the game using replicator dynamics as an illustration. Thus, assume, as in evolutionary game theory, that individuals are *hardwired* to play either s_1 or s_2 . Suppose that initially the entire population plays s_1 , but a small fraction x of the population mutates and begins to play s_2 . Individuals in the population are randomly paired to play the coordination game. Thus, the average strategy in the population is given by $\bar{\sigma} = xs_2 + (1-x)s_1$.

If the population is large, it is *as if* each individual meets an opponent who plays the mixed strategy $\bar{\sigma}$. Thus, the payoff of individuals from playing, respectively, the strategies s_1 and s_2 , is given by, $\pi(s_1, \bar{\sigma}) = 9(1-x)$ and $\pi(s_2, \bar{\sigma}) = 7+x$. The payoff of the average strategy against itself is given by $\pi(\bar{\sigma}, \bar{\sigma}) = x\pi(s_2, \bar{\sigma}) + (1-x)\pi(s_1, \bar{\sigma})$, or $\pi(\bar{\sigma}, \bar{\sigma}) = 10x^2 - 11x + 9$. The replicator dynamics are described by $\dot{x} = x[\pi(s_2, \bar{\sigma}) - \pi(\bar{\sigma}, \bar{\sigma})]$, or

$$\dot{x} = f(x) = -2x(5x^2 - 6x + 1). \quad (16.2)$$

The steady state is found by solving $\dot{x} = 0$. There are three solutions: $x^* = 0$, $x^* = 1$, and $x^* = 1/5$. The solutions $x^* = 0$ and $x^* = 1$ correspond to a monomorphic equilibrium in which everyone plays, respectively, s_1 and s_2 . The solution $x^* = 1/5$ corresponds to a polymorphic equilibrium in which the strategies s_1 and s_2 are played by, respectively, 80% and 20% of the population.

To check for asymptotic stability, we evaluate $f'(x) = -30x^2 + 24x - 2$ at the three steady states to get: $f'(0) = -2 < 0$, $f'(1) = -8 < 0$, and $f'(1/5) = 1.6 > 0$. Hence, there are two asymptotically stable steady states, $x^* = 0$, $x^* = 1$, while $x^* = 1/5$ is asymptotically unstable. Once the deterministic system achieves a state where all play s_2 , or all play s_1 , then the system never escapes that state. In the terminology of Appendix C, the two *recurrent classes* are composed of the *absorbing states* s_1 and s_2 .

Let us now consider the outcome under stochastic dynamics. Suppose that in a large population, players are randomly matched with each other to play the coordination game in Figure 16.3 across many periods. In any period, only one randomly selected player, the *experimenting player*, gets an opportunity to choose his strategy in the coordination game. Before the experimenting

player chooses his strategy, he takes a random sample of size m of the population and receives an honest report of the strategies that each sampled player intends to play. Suppose that it is found that y players intend to play s_1 , while the remaining $m - y$ players intend to play s_2 .

The experimenting player then infers that a fraction $\frac{y}{m}$ of the population plays s_1 and the remaining, $1 - \frac{y}{m}$, plays s_2 . The experimenting player then plays a best response to these frequencies with some high probability $1 - \varepsilon$, where $\varepsilon > 0$ is small. However, with probability ε , the player chooses, for whatever reason (lack of deliberation, bounded rationality, mutation), to randomize equally between the two actions, s_1 and s_2 . We no longer have a deterministic process. Instead, we have a *perturbed process with noise* ε . In any period, behavior will be unpredictable. However, we can find the stationary distribution of play (see Appendix C), as follows.

1. Identify the *recurrence classes*, C_1 and C_2 , of the unperturbed system in which players play their best response with probability 1. In this example, the recurrence classes are the singleton sets $C_1 = \{s_1\}$, $C_2 = \{s_2\}$. Singleton recurrence classes are also known as the *absorbing states*.
2. A *tree* that is rooted at a node belonging to the j th recurrence class is known as a j -tree. The second step is to find all j -trees. There are two trees in this example; a 1-*tree* that is rooted at s_1 and a 2-*tree* that is rooted at s_2 ; see Figure 16.4 where the root is indicated with an arrow (s_1 in the left panel and s_2 in the right panel).
3. Suppose that we start with a 1-tree and its terminal node at which all individuals play s_2 ; see left panel in Figure 16.4. We now want to find the *directed path of least resistance* from s_2 to s_1 . This is called a 2,1 path and the resistance along this path is denoted by ρ_{21} . We then repeat an identical calculation for a 2-tree, rooted at s_2 . In this case, starting with the terminal node at s_1 , we are interested in calculating the least resistance, ρ_{12} along the directed path 1,2.

To calculate ρ_{21} , suppose that initially all players play s_2 . The best response is also to play s_2 ; see Figure 16.3 in which (s_2, s_2) is a Nash equilibrium. How can play move in the direction of s_1 ? This occurs when an experimenting player who has a chance to choose his strategy, mutates with probability ε and randomizes equally between s_1 and s_2 . Hence, s_1 is played with a probability $\frac{\varepsilon}{2}$. In particular, we want to find the path of least resistance from s_2 to s_1 . Hence, we wish to consider a series of successive mutations in the direction of s_1 , each of which happens with probability $\frac{\varepsilon}{2}$ in each period. We are interested in having a certain critical minimum percentage of players who play s_1 such that, thereafter, no further mutations are needed and the best response of each player is to play s_1 . Should this happen, the system naturally proceeds towards s_1 without any further mutations. Such a point is sometimes known as a *tipping point*.

What fraction of the players need to play s_1 for the tipping point to be achieved? Strategy s_1 becomes a best response by an experimenting player if

$$9\frac{y}{m} \geq 7\frac{y}{m} + 8(1 - \frac{y}{m}). \quad (16.3)$$

Solving for the cutoff value of $\frac{y}{m}$ from (16.3) we get $(\frac{y}{m})^* = \frac{4}{5}$, so 80% of the players must play s_1 for s_1 to be a best response. The number of such players in a sample of size m is $y^* = \frac{4}{5}m$. Starting from a situation where all play s_2 we require y^* successive mutations in the direction of s_1 to arrive at a tipping point; this gives the path of least resistance. Each mutation is independent of the other and has an identical probability of $\frac{\varepsilon}{2}$. Thus, $y^* = \frac{4}{5}m$ successive mutations have a probability of $(\frac{\varepsilon}{2})^{\frac{4}{5}m}$, hence, $\rho_{21} = \frac{4}{5}m$. Proceeding in an analogous manner, in the case of the

Figure 16.4 A 1-tree and 2-tree for the coordination game.

2-tree that is rooted at s_2 and starting from its terminal node s_1 we get that $\rho_{12} = 1 - \gamma^* = \frac{1}{5}m$. This situation is depicted in Figure 16.4.

4. The *stochastic potential* of the 1-tree is $\frac{4}{5}m$, while that of the 2-tree is $\frac{1}{5}m$.¹
5. The *stochastically stable state* is contained in the tree with the minimum stochastic potential. Since $\frac{1}{5}m < \frac{4}{5}m$, the stochastically stable state is s_2 . This is because the resistance (or cost) of going from state s_1 to state s_2 is lower than the resistance in the opposite direction. In other words, the equilibrium that has a wider basin of attraction is more difficult to escape from. Hence, it is the one that is stochastically stable.

Under deterministic dynamics, s_1 and s_2 are both asymptotically stable steady states. However, under stochastic dynamics, the multiplicity of the steady states is narrowed down to the unique stochastically stable state s_2 . Using Figure 16.3, and the definition of risk dominance for symmetric 2×2 games we get

$$(9 - 7)(9 - 7) < (8 - 0)(8 - 0).$$

Hence, the stochastically stable steady state picks out the risk dominant equilibrium in this symmetric 2×2 coordination game. This result was shown in Kandori et al. (1993) and Young (1993a). For a discussion of this result under more general assumptions, see Blume (2003).

16.2.2 A model of technology adoption

Consider the following model of technology adoption that is adapted from Young (2006). There is a large number of individuals and three possible technologies, s_1 , s_2 , and s_3 . In any period, a single player (the “experimenting player”) is chosen randomly to make a technology choice. As in the coordination game in Section 16.2.1, the experimenting player asks a sample of m other individuals about their existing choice, who report back honestly. The number of other individuals found to be using technology s_i is y_i , $i = 1, 2, 3$. Thus, it is *as if* the experimenting player is “playing the field” where the proportion of s_i players is given by $\frac{y_i}{m}$. The payoff matrix in pairwise

¹ If there are several nodes in a recurrence class then the stochastic potential for a j -tree is the minimum value of resistance across all the possible nodes of the j -tree (see the model of technology adoption below and Appendix C).

Figure 16.6 1-trees (first row), 2-trees (second row), 3-trees (third row) for the technology adoption game.

bilateral matchings is shown in Figure 16.5. There are three Nash equilibria: all adopt s_1 , all adopt s_2 , and all adopt s_3 .

The experimenting player then plays a best response to the observed frequencies of play with some high probability $1 - \varepsilon$, where $\varepsilon > 0$ is small. With probability ε , the player experiences a mutation, or makes a mistake, and randomizes equally between the three technology choices, s_1, s_2, s_3 . Hence, we have a perturbed process with noise ε . In any period, behavior is unpredictable.

The aim is to find the stationary distribution of play. We proceed by identifying the recurrence classes of the unperturbed dynamics in which players play a best response with probability 1. There are three recurrence classes, $C_1 = \{s_1\}$, $C_2 = \{s_2\}$, and $C_3 = \{s_3\}$; each is a singleton and contains one absorbing state of the system. We now draw the relevant j -trees. There are three trees: A 1-tree that is rooted at s_1 , a 2-tree that is rooted at s_2 , and a 3-tree that is rooted at s_3 . In each case, there are three possible ways of reaching a root, starting from one of the terminal nodes. For instance, for the 1-tree, the possibilities are shown in the first row of Figure 16.6. These are: (i) $s_3 \rightarrow s_2 \rightarrow s_1$, (ii) $s_3 \rightarrow s_1, s_2 \rightarrow s_1$, and (iii) $s_2 \rightarrow s_3 \rightarrow s_1$. The second and third rows in Figure 16.6 show the possibilities for a 2-tree and a 3-tree.

Next, we calculate the *path of least resistance* at each directed edge of each tree. For instance, consider the left most tree in the first row in Figure 16.6. Suppose that initially all players play s_3 and we have consecutive mutations that involve the play s_2 . What fraction of players, $\frac{\gamma}{m}$, do we need to play s_2 , so that s_2 becomes a best response? This is given by the solution to $3\frac{\gamma}{m} \geq$

$5(1 - \frac{y}{m})$ or $\frac{y}{m} \geq \frac{5}{8}$, thus, $\rho_{32} = \frac{5}{8}$, as shown in Figure 16.6. Now suppose that all players play s_2 . What fraction of players $\frac{y}{m}$ should play s_1 , so that s_1 becomes a best response? Using the required computation $7\frac{y}{m} \geq 3(1 - \frac{y}{m})$, we get $\frac{y}{m} \geq \frac{3}{10}$, thus, $\rho_{21} = \frac{3}{10}$, which completes the calculations for the leftmost tree in the first row of Figure 16.6. One can proceed in this manner to compute all the numbers in Figure 16.6 for the minimum resistance, ρ_{ij} , of going from recurrence class i to the recurrence class j .

We now calculate the *stochastic potential* of each tree. For each tree we calculate the lowest resistance of an ij -path. Consider first the three 1-trees in the first row of Figure 16.6. The resistance of the path to s_1 for the three trees, from left to right, is $\frac{5}{8} + \frac{3}{10}$, $\min\{\frac{5}{12}, \frac{3}{10}\}$, and $\frac{3}{8} + \frac{5}{12}$, or 0.925, 0.30, and 0.79. Clearly the lowest stochastic potential, 0.30, among the trees in the first row of Figure 16.6, is found for the middle tree.

Finally, in order to find the stochastically stable state, we choose the tree with the least stochastic potential. This turns out to be the case for the 1-tree in the middle (stochastic potential 0.30). Hence, the root of that tree, i.e., the technology s_1 , is the stochastically stable state. Notice also that it is also the only symmetric Nash equilibrium that is Pareto optimal.

16.3 Perturbed Markov dynamics in 2×2 games

Consider a symmetric game in which the set of players is $N = \{1, \dots, n\}$. The model is consistent with each player drawn from a different population of players. Player $i \in N$ has the pure strategy set S_i and let $S = S_1 \times \dots \times S_n$. The payoff function is given by $\pi_i : S \rightarrow \mathbb{R}$, $i \in N$. All players know that the game is symmetric with respect to strategies and payoffs. Suppose that we are in some baseline time period, t . Then the profile of strategies played by all players, τ time periods ago (relative to the baseline time) is denoted by $s^{t-\tau} = (s_1^{t-\tau}, s_2^{t-\tau}, \dots, s_n^{t-\tau}) \in S$; $s^{t-\tau}$ is called the τ -period lagged population strategy profile. We denote by $\pi_i^{t-\tau}$, the payoff of the i th player, τ periods ago when he choose the strategy $s_i^{t-\tau}$. Denote by Σ_i , the set of mixed strategy profiles for player i . The essential features of the game, G , are as follows.

1. *Limited memory*: All players have a finite memory of $T \geq 0$ past periods. If $T = 0$, then players have no memory, except for current strategies/payoffs. A *state* of the system, ω^t , at the end of period t (or, just at the beginning of period $t + 1$), is the current strategy profile and a vector of T -period lagged population strategy profiles, i.e.,

$$\omega^t = [s^t, s^{t-1}, \dots, s^{t-T+1}]. \quad (16.4)$$

Suppose that the initial state is ω^0 . Ω^T is the set of all possible states of the form given in (16.4), or the *state space*; notice that each state lasts over T periods. Payoffs in any period are uniquely determined by the population strategy profile in that period. This information is known to all players.

2. *Sampling from memory*: At any time $t + 1$, players look back at their T period memory of the game, as in (16.4), and take a random sample of observations from the last $\tau \leq T$ periods. In the special case of no memory, $T = 0$; this rule simply reduces to imitate the best current action by any player.
3. *Behavioral strategies*: Each player takes the sample of observations in step 2 as the frequencies with which others will play in the current period. Each player then plays a best reply

to these frequencies with a high probability $1 - \varepsilon$, and with a low probability $\varepsilon > 0$ chooses to randomize among the set of pure strategies.

In conjunction, these rules describe a Markov process on Ω^T , denoted by $P^{T,\tau,\varepsilon}$; sometimes this is referred to as adaptive play with memory length T , sample size τ , and error rate ε . The Markov transition matrix in this case, P^ε , has elements of the form $P_{\omega,\omega'}$, which give the probability of moving from one T -period history, ω , to another T -period history, ω' , from one period to the next. There is some probability of going from any one state to any other state in finite time, hence, the Markov chain is irreducible. The typical probability vector at time t is denoted by the row vector $\lambda_t = [\lambda_t(s_1), \lambda_t(s_2), \dots, \lambda_t(s_n)]$, where $(s_1, \dots, s_n) \in S$, i.e., $\lambda_t(s_i)$ is the probability that at time t , player i plays his strategy s_i . Denote the probability vector corresponding to the Markov process $P^{T,\tau,\varepsilon}$ by $\lambda^{T,\tau,\varepsilon}$. We shall mainly use the following proposition to find the stochastically stable states of the underlying stochastic process.

Proposition 16.28 (Young, 1993a): Consider a regular, perturbed, Markov process $P^{T,\tau,\varepsilon}$ (Definition 16.63 in Appendix C) with the associated transition matrix P^ε . Let $P^{T,\tau,0}$ have the stationary distribution λ^* , i.e., $\lambda^* = \lambda^* P^0$. Then there exists a unique stationary distribution $\lambda^{T,\tau,\varepsilon}$ such that $\lim_{\varepsilon \rightarrow 0} \lambda^{T,\tau,\varepsilon} = \lambda^*$. The set of stochastically stable states (those with $\lambda^*(s) > 0$) are the recurrent classes (Definition 16.56 in Appendix C) of $P^{T,\tau,\varepsilon}$ that have minimum stochastic potential

We now consider two applications of this framework.

16.3.1 Dominated strategies as stochastically stable states

The example in this section is drawn from Alós-Ferrer (2000). The results are sensitive to the choice of behavioral rule followed. In order to expose the reader to a variety of behavioral rules, here we illustrate the solution when instead of best replies, players play *imitate the best*.² Clearly, the results differ when players play best replies. The assumptions are as follows.

1. *Limited memory*: All players have a finite memory of $T \geq 0$ past periods and the state, or history, at the end of time t is given by (16.4).
2. *Bounded rationality and imitation*: Players do not optimize in the classical sense. They look back at their T period memory of the game, and *imitate the best*. In other words, at time $t + 1$, they choose the strategy of the player that generated the highest payoff in periods $t, t - 1, \dots, t - T + 1$. Denote this behavioral rule for the i th player by $b_i(\omega^t)$. Denote by $\pi_j^{t-\tau}$, $0 \leq \tau \leq T + 1$, the payoff of player $j \in N$ from his strategy s_j , τ time periods ago, then

$$s_j \in b_i(\omega^t) \Leftrightarrow \pi_j^{t-\tau} \geq \pi_k^{t-t'} \text{ for all } k = 1, \dots, n \text{ and } \tau, t' = 0, 1, \dots, T + 1. \quad (16.5)$$

In the special case of no memory, i.e., $T = 0$, this rule simply reduces to imitate the best current action by any player. A range of different decision rules is used in several papers.³

² Under the decision rules specified in Kandori et al. (1993) and Rhode and Stegeman (1996), one gets the surprising result that coordination on strictly dominated strategies is a stochastically stable state (see also below). However, under alternative behavioral rules, as, for instance, in Sandholm (1998), convergence to Nash equilibrium is guaranteed.

³ See, for instance, Robson and Vega-Redondo (1996), Vega-Redondo (1997), Kandori et al. (1993).

	A	B
A	4, 4	1, 2
B	2, 1	0, 0

Figure 16.7 A symmetric, 2×2 normal form game.

Source: Alós-Ferrer (2000).

3. *Exogenous inertia*: In any period, each player gets an opportunity to revise his strategy with probability $1 - \theta$. With the complementary probability $\theta > 0$, he is unable to revise. The probability of a revision opportunity is identical and independent across players. The no-inertia case is denoted by $\theta = 0$.
4. *Mutation*: When a player gets a chance to revise his strategy, he chooses the behavioral rule in (16.5) with a probability $1 - \varepsilon$, where $\varepsilon > 0$ is small. And with probability ε , he mutates by randomly choosing any other pure strategy in his strategy set, S .

Consider the symmetric payoff matrix in the 2×2 case, shown in Figure 16.7. We will show that the long-run play might involve strictly dominated strategies. Using iterated deletion of strictly dominated strategies, there is a unique Nash equilibrium (A, A) . The only two recurrent classes are the monomorphic equilibria (A, A) and (B, B) . We will use Ellison's (2000) cost function approach for the proofs in this section (see Appendix C for Ellison's method).

Definition 16.27 Denote by $\text{mon}(A, T)$ the monomorphic state in which both players play A for T periods. Likewise $\text{mon}(B, T)$ is the monomorphic play of B for T periods.

Recall from Appendix C that the cost function $c(x, y)$ gives the minimum number of mutations required to transit from the state $\text{mon}(x, T)$ to the state $\text{mon}(y, T)$.

Lemma 16.2 Under the assumptions made above, and for the game shown in Figure 16.7, $c(B, A) = 2$ independently of T, θ .

Proof: Suppose that in some period, the state is $\text{mon}(B, T)$. We are interested in reaching a *tipping point*, such that no further mutations or noise is needed to reach $\text{mon}(A, T)$. “No further noise is needed” in the sense that, once the tipping point is reached, whenever players get a revision opportunity, they choose to imitate the best, but do not mutate ($\varepsilon = 0$).

Suppose that starting from $\text{mon}(B, T)$, only one player mutates. In this case, we show that the tipping point is not reached. In any period, suppose that one of the two players, the experimenting player, gets an opportunity to revise her strategy (a probability $1 - \theta$ event). Conditional on the revision opportunity, the experimenting player mutates with probability ε and plays A . In the following period, the mutating player gets a payoff of $1 > 0$, while the other player gets $2 > 1 > 0$. With no further mutations, players rely only on imitate the best rule, which prescribes B even to player 1.

Can two simultaneous mutations lead to $\text{mon}(A, T)$, starting from $\text{mon}(B, T)$? Suppose that both players were to simultaneously get a chance to revise their strategies (a probability $(1 - \theta)^2$ event). If both players mutate simultaneously, they both get a payoff of 4; a probability ε^2 event, conditional on the revision opportunity arising for both players. This achieves a tipping point, as no further mutations are needed for all players to play the strategy A . The reason is that in the absence of mutations, players rely on imitate the best rule. Whenever any player gets an

opportunity to revise they will choose A because in their memory, it has led to the highest payoff. Hence, two successive mutations are sufficient, so $c(B, A) = 2$. ■

To apply Ellison's (2000) approach, we need to compute the cost $c(A, B)$ and then compare it to $c(B, A)$.

Proposition 16.29 *If $T = 0$ and $\theta \geq 0$, then the only stochastically stable strategy is B .*

Proof: Recall from (16.4) that memory stretches back to T periods. So $T = 0$ implies that only the current payoffs are remembered in the next period. When $T = 0$, then, $\text{mon}(A, 0) = (A, A)$, i.e., the row and the column players play A . How can we move to the equilibrium $\text{mon}(B, 0)$? A single player mutation to strategy A will not work. Suppose that when a player has a chance to mutate (with ex-ante probability $(1 - \theta)\epsilon$), he chooses B , so that either of the two states (A, B) or (B, A) is achieved.⁴ The mutant who plays B gets a payoff of $2 > 1$, while the non-mutant gets $1 < 2$. Can one arrive now at the state $\text{mon}(B, 0)$ without further mutations, i.e., are we at a tipping point?

The current payoffs corresponding to (A, B) or (B, A) are remembered in the next period ($T = 0$), just prior to taking one's action, and the payoff from playing B is greater. Thus, in the absence of mutation, and relying purely on imitation, the individual not playing B will also switch to B . This argument holds for $\theta \geq 0$, hence, $c(A, B) = 1$. Since, $c(A, B) < c(B, A)$, it is easier to escape from the recurrent class (A, A) than from the recurrent class (B, B) , hence, using the result in Ellison (2000) (see Appendix C) the only stochastically stable strategy is B . ■

The next proposition shows that the only stochastically stable strategy can be in strictly dominated strategies.

Proposition 16.30 *If $T > 0$ and $\theta > 0$, then the only stochastically stable state is $\text{mon}(B, T)$.*

Proof: Suppose that we begin with $\text{mon}(A, T)$. Let a player who has a chance to revise his strategy mutate and play B instead. The mutant obtains 2, while the non-mutant obtains 1. Either of the two states (A, B) or (B, A) is achieved, depending on whether the mutant was a row, or a column player. Is this a tipping point? If yes, then in the absence of further mutations, the state (B, B) can be achieved.

(i) Suppose that subsequent to the mutation, state (A, B) occurs. Then, it is possible that with inertia ($\theta > 0$), no player actually gets an opportunity to revise their strategy for the next T periods. So it is possible that the resulting T -period profile is $(A, B), \dots, (A, B)$. After the T periods have elapsed, the memory of the payoffs (A, A) would have been erased and given an opportunity to revise, a player would mimic the play of B (because $2 > 1$).

(ii) Suppose that subsequent to the mutation, state (B, A) occurs. The argument now proceeds as in (i) because the game is symmetric.

Hence, in each case, only one mutation is needed to achieve the state (B, B) starting from $\text{mon}(A, T)$, so $c(A, B) = 1 < c(B, A) = 2$. Thus, the only stochastically stable strategy is B . ■

Proposition 16.31 *If $T \geq 2$ and $\theta = 0$, then, the only stochastically stable strategy is A . But if $T = 1$, then both A and B are stochastically stable.*

Proof: Suppose that we start at $\text{mon}(A, T)$. As before, let a player who has a chance to revise his strategy mutate and play B instead. The mutant obtains 2, while the non-mutant obtains 1; either

⁴ To reiterate, (A, B) is the state in which the row player plays A and the column player plays B . (B, A) represents the converse situation.

of the two states (A, B) or (B, A) is achieved. We need to check if this is a tipping point, i.e., in the absence of further mutations will one achieve the state (B, B) ?

Since $\theta = 0$ there is no inertia. Thus, at the next opportunity to revise (next period), the highest remembered payoffs are from the state $mon(A, T)$, so any player will choose A . Therefore, one round of mutation is not sufficient to transit to the state (B, B) . Nor will two mutations work. The only possible transition to the state (B, B) is a sequence of mutations such that we have the play (A, B) or (B, A) for T periods, so that the payoffs from the profile (A, A) are erased from memory. In this case, when a player gets an opportunity to revise, he/she would then choose B (because $2 > 1$). Thus, for A to be the stochastically stable state, we require $c(A, B) = T \geq c(B, A) = 2$. Check that if $T = 1$, then $c(A, B) = c(B, A) = 2$, so both states A, B are stochastically stable. ■

16.3.2 Risk dominance under perturbed dynamics

Consider the Markov process $P^{T, \tau, \varepsilon}$ described above and suppose that the game G has several strict Nash equilibria; let a Nash equilibrium be denoted by $s^* = (s_1^*, s_2^*, \dots, s_n^*)$. Consider the state $mon(s^*, T)$, i.e., the Nash equilibrium s^* is played for the last T periods, i.e., for as long as the players can remember. Now suppose that player i wishes to choose one of his strategies in any period. All $\tau \leq T$ sample points will reveal the play of s_{-i}^* by the opponents to which the best response of player i is s_i^* . And this holds true for all players. So, in the absence of any mutations, $\varepsilon = 0$, all players again play the population profile s^* . And they do it every period. Hence, we get the following definition.

Definition 16.28 (Conventions): A convention is a state of the system that is self-perpetuating. As far back as anyone can remember in any period, people have always played it.

If we consider the Markov process without noise, i.e., $P^{T, \tau, 0}$, then we can show that the conventions are the only *absorbing states*; starting from an absorbing state, we cannot reach another state in finite time. Each of the conventions constitutes a *recurrent class*, i.e., the Markov process is not ergodic and is not irreducible. We now ask which conventions does the long-run play converge to? The answer for the unperturbed system is clear—it depends on the history of the game. However, for the perturbed system, the risk dominant equilibrium plays a central role.

Proposition 16.32 Consider a 2×2 coordination game, G , with the associated Markov process $P^{T, \tau, \varepsilon}$, then:

- (a) The unperturbed Markov process $P^{T, \tau, 0}$ converges to one of the conventions.
- (b) The stochastically stable states of the perturbed Markov process $P^{T, \tau, \varepsilon}$ are the risk-dominant conventions.

Proof: Consider the 2×2 coordination game, G , shown in Figure 16.8. By definition, G has two strict Nash equilibria (L, L) and (R, R) .

	L	R
L	a_{11}, b_{11}	a_{12}, b_{12}
R	a_{21}, b_{21}	a_{22}, b_{22}

Figure 16.8 A 2×2 coordination game.

Recall from (16.4) that a state in this model is an entire T -period history of play. Thus, in terms of the two conventions, we can define the two states as the following T -period population profiles,

$$\omega_1 = [(L, L), (L, L), \dots, (L, L)], \omega_2 = [(R, R), (R, R), \dots, (R, R)], \quad (16.6)$$

or we may denote them, respectively, by $\text{mon}(L, T)$ and $\text{mon}(R, T)$. To prove (a) we need to show that the only recurrent classes correspond to the two conventions. In other words, we want to show that the union of the two basins of attractions $B(\omega_1)$ and $B(\omega_2)$ comprises the entire state space. Consider the unperturbed Markov process $P^{T, \tau, 0}$ and begin from any convention. The best response of any player to a sample of size τ , given that the Nash equilibrium is strict, is to play her part of the Nash equilibrium profile in every period.

(b) Denote by ρ_{12} , the minimum resistance of all paths that begin in the state ω_1 and terminate in the basin of attraction of the other state, $B(\omega_2)$. Conversely, let ρ_{21} be the minimum resistance of all paths that start in the state ω_2 and terminate in the basin of attraction $B(\omega_1)$. Once a path reaches the basin of attraction of any state, then no further noise, or mutations, are needed to converge to that state; best responses, by themselves, guarantee such convergence to that state. For any real number x let $\lceil x \rceil$ denote the least integer greater than or equal to x ; so if $x = 1.7$ then $\lceil x \rceil = 2$, while if $x = 3$ then $\lceil x \rceil = 3$.

Suppose that the row player thinks that the column player will play R with probability q , then it is optimal to play R if

$$a_{21}(1 - q) + a_{22}q \geq a_{11}(1 - q) + a_{12}q,$$

or,

$$q \geq \underline{q} = \frac{a_{11} - a_{21}}{a_{11} + a_{22} - a_{21} - a_{12}}. \quad (16.7)$$

Suppose that we are in the state ω_1 where all play L . Then, for the row player to decide to switch from L to R , he must have a sample from the last τ periods such that there are $\lceil \underline{q}\tau \rceil$ instances of play of R by the column player, where $\underline{q}$ is given by (16.7).

Let there be at least $\lceil \underline{q}\tau \rceil$ successive plays of R by the column player. So the probability assigned to the column player playing R is at least $\frac{\lceil \underline{q}\tau \rceil}{\tau}$, which is greater than or equal to $\underline{q}$. Thus, it would be optimal for the row player to play R . How can the row player observe such a sample starting from the state ω_1 ? The probability of making one mutation is ε , so the probability of making $\lceil \underline{q}\tau \rceil$ mutations is $\varepsilon^{\lceil \underline{q}\tau \rceil}$ (because mutations are independent across time periods).

Analogously, starting in state ω_1 , we ask what will induce the column player to play R ? Suppose that the column player believes that the row player plays R with probability p . Proceeding as in the case of the row player, it must be that the row player makes a mutation and plays R for $\lceil \underline{p}\tau \rceil$ successive instances in the sample chosen by the column player, where

$$\underline{p} = \frac{b_{11} - b_{21}}{b_{11} + b_{22} - b_{21} - b_{12}}. \quad (16.8)$$

The probability of this happening is $\varepsilon^{\lceil \underline{p}\tau \rceil}$. Since we are interested in the path of least resistance, define

$$\rho_{12} = \min \left\{ \lceil \underline{q}\tau \rceil, \lceil \underline{p}\tau \rceil \right\}. \quad (16.9)$$

Why is this sufficient to ensure that play enters $B(\omega_2)$? Given (16.9), at least one of the players plays R . Suppose, for the sake of argument, that this is the row player who has observed $\lceil \underline{q}\tau \rceil$ instances of play by the column player in his sample. The continuing play of R by the row player leads the column player to gradually assign a greater probability to the row player playing R . When the row player is observed to play R for $\lceil \underline{p}\tau \rceil$ successive instances (recall that we are interested in the path of least resistance), it becomes optimal for the column player to also play R .

By a completely analogous argument, one can find that

$$\rho_{21} = \min \left\{ \lceil (1 - \underline{q})\tau \rceil, \lceil (1 - \underline{p})\tau \rceil \right\}. \quad (16.10)$$

From Appendix C, we know that ω_1 is stochastically stable if, and only if, it has relatively greater minimum resistance. In other words, we need a relatively larger number of successive mutations to escape from the basin of attraction of state ω_1 as compared to state ω_2 . Thus, ω_1 is stochastically stable if, and only if,

$$\rho_{12} \geq \rho_{21}. \quad (16.11)$$

Substituting (16.9), (16.10) in (16.11), we get

$$\min \left\{ \lceil \underline{q}\tau \rceil, \lceil \underline{p}\tau \rceil \right\} \geq \min \left\{ \lceil (1 - \underline{q})\tau \rceil, \lceil (1 - \underline{p})\tau \rceil \right\}. \quad (16.12)$$

From the Appendix on game theory we know that (L, L) is the risk dominant equilibrium if

$$\min \left\{ \underline{q}, \underline{p} \right\} \geq \min \left\{ 1 - \underline{q}, 1 - \underline{p} \right\}. \quad (16.13)$$

Risk dominance of (L, L) (see (16.13)) implies (16.12) for a large enough sample, τ . ■

16.3.3 Extensions of the basic model

In the models considered so far, there was homogeneity with respect to (i) the length of samples drawn by each player, and (ii) the rate of mutation of each player, as captured in a common term, ε . Furthermore, if there was a separate population of row players and column players, then there was within-population homogeneity of payoffs. All these assumptions can be relaxed. See Young (1998) for a nice exposition of these issues that we draw on below.

(1) *Heterogeneity in sample size*: Suppose that the row player uses a sample of length τ_R , while the column player uses a sample of length τ_C . The players have the same mutation rate, ε . We say that a player is *better informed* if he has a longer sample. An important consideration here is to see if better informed players receive a relatively higher payoff. For the generic 2×2 coordination

	L	R
L	8, 6	0, 0
R	0, 0	5, 7

Figure 16.9 A coordination game with a *better informed* player.

game, G , in Proposition 16.32, the analog of (16.12), which guarantees that (L, L) is stochastically stable, is given by:

$$\min \left\{ \left\lceil \underline{q} \tau_R \right\rceil, \left\lceil \underline{p} \tau_C \right\rceil \right\} \geq \min \left\{ \left\lceil (1 - \underline{q}) \tau_R \right\rceil, \left\lceil (1 - \underline{p}) \tau_C \right\rceil \right\}. \quad (16.14)$$

For illustrative purposes, consider the game in Figure 16.9.

Define the two states as $\omega_1 = \text{mon}(L, T)$ and $\omega_2 = \text{mon}(R, T)$, and let the sample sizes of the row and column players be, respectively, τ_R and τ_C . Using the definitions of $\underline{q}, \underline{p}$ in (16.7), (16.8) we get

$$\underline{q} = \frac{8}{13}; \underline{p} = \frac{6}{13}; 1 - \underline{q} = \frac{5}{13}; 1 - \underline{p} = \frac{7}{13}. \quad (16.15)$$

Substituting (16.15) in (16.14) we get

$$\min \left\{ \left\lceil \frac{8}{13} \tau_R \right\rceil, \left\lceil \frac{6}{13} \tau_C \right\rceil \right\} \geq \min \left\{ \left\lceil \frac{5}{13} \tau_R \right\rceil, \left\lceil \frac{7}{13} \tau_C \right\rceil \right\}. \quad (16.16)$$

For large values of x , $x \approx \lceil x \rceil$. Suppose that τ_R, τ_C are large. One set of circumstances in which (L, L) is stochastically stable is the following. Suppose that (i) $\frac{8}{13} \tau_R \leq \frac{6}{13} \tau_C$, or equivalently $\frac{\tau_R}{\tau_C} \leq \frac{3}{4}$, and (ii) $\frac{7}{13} \tau_C \geq \frac{5}{13} \tau_R$, so that $\frac{\tau_R}{\tau_C} \leq \frac{7}{5}$. Let $\frac{\tau_R}{\tau_C} \leq \min \left\{ \frac{3}{4}, \frac{7}{5} \right\} = \frac{3}{4}$, thus, the row player takes a sample no larger than 75% of the sample taken by the column player. Then, for the game shown in the game in Figure 16.9, (L, L) is stochastically stable.

The row player prefers the equilibrium (L, L) to the equilibrium (R, R) . Paradoxically, having less information helps the row player to achieve a better outcome. The intuition is that less information imparts greater flexibility to the row player in reacting to errors by the opponent, which are to his advantage. However, “less information is better” is by no means a robust result. It can be easily overturned by altering the payoffs. The drawback of less information is that one is too quick to react to errors from the opponent, which are unfavorable.

(2) *Heterogenous payoffs and alternative noise specifications*: Consider two distinct populations of row and column players. In each period, there are pairwise interactions between row and column players. There is within-population heterogeneity. Suppose that there are n_r row players and n_c column players. Suppose that the sample size of the r th row player is $\tau(r)$, $r = 1, \dots, n_r$ and the sample size of the c th column player is $\tau(c)$, $c = 1, \dots, n_c$. The payoff matrix of the r th row player is given by $[a_{ij}(r)]_{2 \times 2}$ and that of the c th column player is given by $[b_{ij}(c)]_{2 \times 2}$, where the subscripts i, j refer, respectively, to the i th row and the j th column. This gives rise to within-population heterogeneity of payoffs.

For the r th row player, compute $\underline{q}(r)$, and for the c th column player compute $\underline{p}(c)$. Then the type of a row player can be denoted by $(\tau(r), \underline{q}(r))$, while the type of a column player can be denoted by $(\tau(c), \underline{p}(c))$. Consider the coordination game in Proposition 16.32 and let (L, L) and (R, R) be the two strict Nash equilibria. The main result is that convention (L, L) is stochastically stable if the following analog of (16.12) holds:

$$\min \left\{ \left\lceil \underline{q}\tau(r) \right\rceil, \left\lceil \underline{p}\tau(c) \right\rceil : \forall r, c \right\} \geq \min \left\{ \left\lceil (1 - \underline{q})\tau(r) \right\rceil, \left\lceil (1 - \underline{p})\tau(c) \right\rceil : \forall r, c \right\}. \quad (16.17)$$

The proof is along the same lines as Proposition 16.32.

So far we have modeled noise as follows. When a player gets an opportunity to revise his strategy, then with some small probability ε , he randomly chooses one of his strategies with equal probability. What if, instead, the player has a preference for particular strategies and, when mutating, chooses among his pure strategies with unequal probabilities. To fix ideas, suppose that we consider the generic 2×2 game, as in Proposition 16.32.

Suppose that each player, when mutating, chooses strategy L with probability $\rho \neq 0.5$ and strategy R with probability $1 - \rho$.⁵ Define the states ω_1, ω_2 as in (16.6). Young (1998) shows that the probability of transiting from state ω_1 to ω_2 is proportional to $[(1 - \rho)\varepsilon]^{\min\{\lceil \underline{q}\tau_R \rceil, \lceil \underline{p}\tau_C \rceil\}}$ and the probability of transiting in the opposite direction is proportional to $[\theta\varepsilon]^{\min\{\lceil (1 - \underline{q})\tau \rceil, \lceil (1 - \underline{p})\tau \rceil\}}$. As an example, suppose that the players have a strong preference to play R when they mutate, i.e., ρ is very close to zero. In this case, the probability of transiting from ω_1 to ω_2 is relatively higher than that in the opposite direction. State ω_2 would then be the stochastically stable state.

16.4 Memory, conventions, and risk dominance in 3×3 games

Not all of the results for 2×2 coordination games that we have considered above, hold for higher dimensional games. The main result is that the correspondence between risk dominance and stochastic stability disappears. However, for a certain class of games, the set of *acyclic games* (defined below), we can speak about the relation between the set of Nash equilibria, minimum stochastic potential, and stochastic stability.

Consider the generic 3×3 coordination game in Figure 16.10. The three strict Nash equilibria are (L, L) , (M, M) , (R, R) ; these are also the three coordination equilibria of the game.

	L	M	R
L	a_{11}, b_{11}	a_{12}, b_{12}	a_{13}, b_{13}
M	a_{21}, b_{21}	a_{22}, b_{22}	a_{23}, b_{23}
R	a_{31}, b_{31}	a_{32}, b_{32}	a_{33}, b_{33}

Figure 16.10 A generic 3×3 coordination game.

Definition 16.29 (*Risk dominance for 3×3 coordination games*): Suppose that the indices $i, j \in \{L, M, R\}$. We say that equilibrium (i, i) risk dominates equilibrium (j, j) if

$$(a_{ii} - a_{ji})(b_{ii} - b_{ij}) > (a_{jj} - a_{ij})(b_{jj} - b_{ji}); i \neq j; i, j \in \{L, M, R\}. \quad (16.18)$$

Definition 16.30 (*Strict risk dominance*) An equilibrium is strictly risk dominant if it risk dominates all the other coordination equilibria.

Example 16.9 There might be no strict risk dominant equilibrium; see, e.g., the game in Figure 16.11. For this game, we get the following cycle: (L, L) risk dominates (R, R) , (R, R) risk dominates (M, M) , (M, M) risk dominates (L, L) . Hence, there is no strict risk dominant equilibrium.

The problem raised in Example 16.9 is compounded by the fact that, for 3×3 coordination games (and games of higher order) risk dominance might not coincide with stochastic stability. We demonstrate this by using the payoff matrix in Figure 16.12.

Since all the off-diagonal elements in Figure 16.12 are zero, (16.18) reduces to the following statement: Equilibrium (i, i) risk dominates equilibrium (j, j) if:

$$a_{ii}b_{ii} > a_{jj}b_{jj}; i \neq j; i, j = L, M, R. \quad (16.19)$$

In this special case, risk dominance simply requires us to check for the highest product of individual payoffs when they play identical strategies. Hence, the risk dominant equilibrium is (L, L) . We now show that this equilibrium is not stochastically stable. We consider the perturbed Markov process $P^{T, \tau, \varepsilon}$, i.e., each player has a memory of T periods, uses a sample size of τ periods and

	<i>L</i>	<i>M</i>	<i>R</i>
<i>L</i>	5, 60	0, 0	0, 0
<i>M</i>	0, 0	7, 40	0, 0
<i>R</i>	0, 0	0, 0	100, 1

mutates (i.e., chooses each pure strategy with equal probability) with probability ε ; otherwise, with probability $1 - \varepsilon$, he plays his best response to the frequencies of observed play of the opponents in the sample.

Define the three states as follows.

$$\omega_1 = \text{mon}(L, T), \omega_2 = \text{mon}(M, T), \omega_3 = \text{mon}(R, T).$$

Thus, *each state is a T -period history* in which one of the three conventions, L , M , or R , is played by each player. Suppose that we are in some state $\omega_j = \text{mon}(j, T)$, $j = L, M, R$. How can the system then tip into the basin of attraction of another state $\omega_k = \text{mon}(k, M)$, $j \neq k$, $k = L, M, R$?

Since we are interested in the path of least resistance, we proceed as follows. What is the minimum number of times the column player must consecutively play strategy k such that when the row player samples the past τ periods, he finds it a best response to play strategy k as well? Suppose that the required frequency of play by the column player is q^* ; q^* equals the minimum number of required consecutive plays of k by the column player, divided by τ . Since we began in the state $\omega_j = \text{mon}(j, T)$, in the relevant memory of the row player, strategies k and j are played with respective frequencies q^* and $1 - q^*$. Thus, for the row player, q^* can be found as the solution to

$$q^* a_{kk} = (1 - q^*) a_{jj} \Leftrightarrow q^* = \frac{a_{jj}}{a_{jj} + a_{kk}}. \quad (16.20)$$

Starting from state ω_j , we now find the minimum number of times the row player must play strategy k such that using his sample of past τ observations, the column player also finds it optimal to play strategy k . Denote the resulting frequency of play of k by the row player by p^* . Analogous to (16.20), we can find p^* as follows.

$$p^* b_{kk} = (1 - p^*) b_{jj} \Leftrightarrow p^* = \frac{b_{jj}}{b_{jj} + b_{kk}}. \quad (16.21)$$

Since we are interested in the path of least resistance, as in (16.9), we find that the minimum resistance, ρ_{jk} , of moving from state ω_j to state ω_k is given by

$$\rho_{jk} = \min \{ \lceil q^* \tau \rceil, \lceil p^* \tau \rceil \}. \quad (16.22)$$

It is important to note that for 3×3 games, the formula in (16.22) holds only when the off-diagonal elements are zero. Such a formula always holds for 2×2 games, even if the off-diagonal elements are non-zero. For 3×3 games on the other hand, the path of least resistance from state ω_j to state ω_k might actually involve the intermediate play of some other state ω_i . For games of even higher dimension, the path of least resistance from one state to another might involve the intermediate play of several other states. Hence, higher dimensional games become even more difficult to handle.

Once we are able to compute the minimum resistance in moving from any one state to another, using (16.22), the stochastically stable state has the minimum stochastic potential (see Proposition 16.28). As usual, we draw, in Figure 16.13, the rooted 3-trees (see Appendix C and Figure 16.6, above) to compute the minimum stochastic potential. This involves the computation of the minimum resistance for each of the 3-trees in each row, and then the choice of the row with the minimum resistance across all rows. A simple calculation shows that the stochastically stable state is ω_2 , while the risk dominance criterion chooses state ω_1 .

Figure 16.13 Non-equivalence between risk dominance and stochastic stability

The main results for games with dimension higher than 2×2 are for the class of *acyclic games* (Young, 1993a). Essentially, these are games such that the best reply graph has no directed cycles. Another method of identifying acyclic games is described below.

Let the set of players be $N = \{1, \dots, n\}$ and let all players have identical strategy sets. Player $i \in N$ has the pure strategy set S and the possible strategy profiles of players belong to $S = S \times \dots \times S$. The utility function is given by $u_i : S \rightarrow \mathbb{R}$, $i \in N$. The game is described by $G(N, S, u)$.

Definition 16.31 (*Weighted potential game*) G is a weighted potential game if for $i \in N$ there exists weights $w_i \in \mathbb{R}_+$ and a potential function $\phi : S \rightarrow \mathbb{R}$, such that the following restriction is satisfied.

$$w_i u_i(s'_i, s_{-i}) - w_i u_i(s_i, s_{-i}) = \phi(s'_i, s_{-i}) - \phi(s_i, s_{-i}) \quad \forall s'_i, s_i \in S_i, s_{-i} \in S_{-i} \text{ and } \forall i \in N.$$

The idea behind the weighted potential game is that the utility functions of players can be rescaled such that the change in own utility arising from a unilateral change in strategy equals the change in potential. Every weighted potential game has at least one Nash equilibrium in pure strategies.

Example 16.10 Consider the 2×2 symmetric game in Figure 16.7. The potential function for this game is

$$\phi(A, A) = 2, \phi(A, B) = \phi(B, A) = 0, \phi(B, B) = -1.$$

When $w_i = 1$ for all $i \in N$, then we call G in Definition 16.31 simply a potential game. A generalization of this game is the ordinal potential game.

Definition 16.32 (*Ordinal potential game*) G is an ordinal potential game if there is an ordinal potential function $\phi : S \rightarrow \mathbb{R}$, such that the following restriction is satisfied.

$$\text{sign}[u_i(s'_i, s_{-i}) - u_i(s_i, s_{-i})] = \text{sign}[\phi(s'_i, s_{-i}) - \phi(s_i, s_{-i})] \quad \forall s'_i, s_i \in S_i, s_{-i} \in S_{-i} \text{ and } \forall i.$$

Definition 16.33 (*Acyclic game*) If G is an ordinal potential game such that no player is indifferent between any two distinct strategies, then G is also an acyclic game.

Coordination games are examples of acyclic games. The reason is that once we reach any of the coordination equilibria, then there are no directed edges pointing away from such equilibria. This eliminates the possibility of directed cycles. There are two main results for acyclic games. (1) The unperturbed process, $P^{T,\tau,0}$, converges to one of the conventions *from any arbitrary initial state*. (2) For small enough noise, ε , and small $\frac{\tau}{T}$, in a perturbed Markov process, $P^{T,\tau,\varepsilon}$, play converges with arbitrarily high probability to the convention which minimizes the stochastic potential.

16.4.1 Boundedly rational play and fully rational outcomes

Unlike the textbook fully rational players, players in models of stochastic evolution exhibit limited memory, myopia, and adaptive learning (e.g., forming expectations based on a sample of past observations). Should we expect the nature of economic outcomes to be different (ignoring issues of the time taken to achieve equilibrium)? Not necessarily. We have shown that the risk dominant equilibrium arises as a stochastically stable outcome for 2×2 games. When the off-diagonal elements are zero, then, this outcome corresponds to the Pareto optimal outcome in coordination games. In higher dimensional games, similar results arise for the class of acyclic games.

Despite being myopic, if players play static best replies, then they do not play strictly dominated actions.⁶ However, this framework rules out dominated actions based on a low rationality argument, which stands in contrast to classical justifications based on common knowledge and infinite regress of beliefs. Models of stochastic evolution are also able to show that the asymmetric Nash bargaining solution arises from a low rationality environment (Young, 1993b). As Young (1998) puts it: “Interpreted in this way, the evolutionary approach is a means of reconstructing game theory with minimal requirements about knowledge and rationality.”

16.4.2 Of norms and social evolution

Conventions are rules of individual behavior that coordinate expectations on some action profile of the participants. For instance, in meetings between two people, there are a range of conventions, e.g., shaking hands, hugging, and kissing on the cheeks. Conventions typically arise when there are multiple equilibria and one needs a mechanism to coordinate expectations on a particular equilibrium. A *norm* is a slightly stronger form of convention that carries with it some social sanction, if violated.

Norms can be enforced through a variety of mechanisms. Norms are self-enforcing when the need for a coordination motive makes it optimal for individuals to follow them. In some cases, it is the threat of punishment, e.g., social ostracization of some sort, that makes it incentive compatible for players to comply with norms. Other mechanisms for norm enforcement are feelings of shame, guilt, or a tug on one’s conscience, that arise when a norm is not followed (Elster, 1989, 1999; Coleman, 1990). In this spirit, Hume ([1739]1978) used the concept of a virtuous or right action. In many cases, however, the boundaries between norms and conventions are quite blurred, so we use norms to refer to both situations.⁷

How do norms come about? One simplistic answer is that they simply come about through the legal framework, such as rules, laws, official edicts, and judicial rulings. We considered a powerful argument for social norms in Part 4 based on the work of Gintis (2009b) in which social norms

⁶ Under alternative behavioral rules such as *imitate the best*, players may play dominated strategies, see Section 16.3.1.

⁷ For readers interested in pursuing these issues further, see Sugden (1986), Posner (2000), and Bicchieri (2006).

play the role of a correlating device to unify societal expectations. The stochastic evolutionary approach argues that norms come about by the adaptive learning efforts of a large number of individually small players. Furthermore, in many cases, laws and edicts follow the establishment of norms and simply codify what already exists. It is quite straightforward to apply the insights developed in this section to some simple examples of norms.

It turns out that norms that are also stochastically stable states, need not always be efficient (Young, 1998). To illustrate this result, suppose that there is a single population. Individuals are matched each period to engage in a bilateral transaction. Suppose there are two possible commodities, gold (G) and silver (S), that can be used as a medium of exchange. Each period, one individual, termed as the experimenting player, or the *experimenter*, is drawn at random. He chooses either to carry gold or silver. The selected individual has memory T , sample size τ , and he plays with some noise ε . This results in a perturbed Markov process, $P^{T,\tau,\varepsilon}$, over the set of all T period histories.

The payoff matrix is given by the sum of two different payoffs. If two randomly paired individuals carry the same currency, they can engage in a transaction and get transaction utility T_g (if they both carry gold) or T_s (if they both carry silver); otherwise, transaction utility is zero. Hence, based on transaction utility alone, we have a coordination game. Each metal also provides an adornment value that is independent of the transaction value. The adornment value from carrying the two metals G, S is, respectively, A_g, A_s . The matrix of payoffs that represents adornment utility is not a coordination game. Finally, total utility is the sum of transaction and adornment utility, as shown in Figure 16.14.

What norm, G or S, do we expect under stochastic evolution? Efficiency would dictate a choice of the norm, which maximizes

$$T_j + A_j, j = G, S. \quad (16.23)$$

We have seen above that for 2×2 games, the outcome is the risk dominant equilibrium. Using the condition for a risk dominant equilibrium, equilibrium j is the risk dominant equilibrium relative to equilibrium k , $k \neq j$ if and only if $(T_j + A_j - A_k)^2 \geq (T_k + A_k - A_j)^2$, $j, k = G, S$. Suppose that the rightmost payoff matrix in Figure 16.14 describes a coordination game, so $T_j + A_j > A_k$ and $T_k + A_k > A_j$. Then j is the risk dominant equilibrium if

$$T_j + 2A_j \geq T_k + 2A_k. \quad (16.24)$$

From (16.23), efficiency requires maximization of $T_j + A_j$, but from (16.24), stochastic evolution picks out the equilibrium that maximizes $T_j + 2A_j$. Hence, the two need not be the same. In fact, stochastic evolution will pick out the risk dominant equilibrium in this 2×2 game, which

Transaction utility				Adornment utility				Total utility			
G		S		G		S		G		S	
G	T_g, T_g	0, 0	+	G	A_g, A_g	A_g, A_s	=	G	$T_g + A_g, T_g + A_g$	$T_g + A_g, T_s + A_s$	
S	0, 0	T_s, T_s		S	A_s, A_g	A_s, A_s		S	A_s, A_g	$T_s + A_s, T_s + A_s$	

Figure 16.14 Description of utilities from carrying gold (G) or silver (S).

	X	Y	Z
X	5, 1	0, 0	0, 0
Y	0, 0	3, 3	0, 0
Z	0, 0	0, 0	1, 5

maximizes $T + 2A$. This equilibrium puts twice the weight on adornment, which is not efficient. Another example of a norm that is not efficiency enhancing is the norm of etiquette, which probably has limited welfare consequences, as used by economists. For a very readable account of this and other issues, see Young (2008).

Consider the 3×3 coordination game in Figure 16.15. Suppose that the row and the column players are drawn from different populations. For instance, the row player could be the principal and the column player, the agent. There are three norms, (X, X) , (Y, Y) , (Z, Z) , that are the Nash equilibria of the game. The distributional implications of the three equilibria are quite distinct. The two equilibria (X, X) and (Z, Z) represent extreme allocations that heavily benefit one party, while (Y, Y) represents a compromise allocation. None of the equilibria Pareto dominates the other.

Each of the three equilibria represents a potential norm. Which gets chosen? Consider, as before, a perturbed stochastic process, $p^{T, \tau, \varepsilon}$. A simple calculation, that the reader should by now be able to work out, shows that the stochastically stable state is the compromise solution (Y, Y) . It can be shown more generally that in similar games, the outcome of stochastic evolution is a compromise solution; see Young (1998). This is suggestive of the endogenous evolution of fairness.

16.4.3 A brief selection of further applications

In an early application of the concept of stochastic stability Young (1993b) asked: what sort of bargaining norm would arise from limited rationality models, as, for instance, in adaptive play $p^{T, \tau, \varepsilon}$? In this model players are matched randomly from two populations and play a Nash demand game. The two matched players demand respective shares s_1 and s_2 of a pie of fixed size 1. If $s_1 + s_2 \leq 1$, then both players get their demands, otherwise they get nothing.

Young (1993b) showed that when the demands by players are sufficiently divisible and T, τ are sufficiently large, then the stochastically stable bargaining norms are arbitrarily close to the classic Nash bargaining solution. The method of proof should now be standard to the reader. One begins with a history where a particular norm, s_1 or s_2 , is prevalent; one of the norms is the Nash bargaining solution. One then calculates the least resistance required to reach the basin of attraction of another norm and infers the stochastic stability of alternative norms.

Myatt and Wallace (2005) consider public goods games with threshold externalities. Suppose that we have $N = \{1, \dots, n\}$ players. Player $i \in N$ chooses a contribution $g_i \in \{0, 1\}$. If at least $m \geq 2$ players contribute a unit amount, then the public good materializes, otherwise not. Suppose that the benefit to each player from the public good is v and the cost of contribution is c ;

we assume $v > c$. If the public good materializes, then the respective utilities of contributors and non-contributors are $u = v - c$ and $u = v$. If fewer than m players contribute, then the respective utilities of contributors and non-contributors are $u = -c$ and $u = 0$.

In the spirit of adaptive dynamics, $P^{T,\tau,\varepsilon}$, the state at any time t is the vector of contributions of all players. One of the players is chosen at random to revise his contribution. With a high probability $1 - \varepsilon$ he plays a best response to his observed sample of past states with memory T and a sample size $\tau \leq T$. However, with probability $\varepsilon > 0$ he makes a mistake and randomly chooses one of his feasible contribution levels.

The main result is that m players will contribute if $v > mc$. The intuition can be conveyed as follows. Start from an equilibrium where nobody contributes; this is a Nash equilibrium. We now calculate the path of least resistance to an equilibrium where m individuals contribute. This involves $m-1$ consecutive mistakes over $m-1$ periods that take the form of making a contribution even when it is not a best response. In the final, m th, period, the individual who is chosen to revise his strategy will find it a best response to contribute, so no further mistakes are needed. Since each contributing player incurs a cost c of contributing, thus, the total cost of this move between the two equilibria is $(m-1)c$.

Now we need to calculate the cost of moving in the opposite direction, starting from the Nash equilibrium in which m players contribute. Suppose that in the next period, a contributing player is given the choice (experimenter), and makes a mistake with probability ε , so chooses not to contribute. Thus, we are left with $m-1$ contributors, so the public good does not materialize. The cost of this to the experimenter is $v - c$. Suppose that in the next period one of the remaining $m-1$ contributors gets a revision opportunity.⁸ It is now a best response not to contribute ($-c < 0$). Thus, no further mistakes are needed. The total cost of the move from an equilibrium with “ m players contribute” to “nobody contributes” is $v - c$.

Putting together the two costs of moving between the states, it is less costly to move in the direction of m players contributing, starting from nobody contribute if $(m-1)c < v - c$, or $v > mc$, as claimed.

Myatt and Wallace (2008) extend this analysis to introduce valuation and cost heterogeneity into the problem. Suppose now that player $i \in N$ has player-specific valuation v_i and cost c_i . The lowest cost of moving from the state where nobody contributes to all-contribute is that the first $m-1$ lowest cost contributors contribute. Ordering the players from lowest cost to highest cost gives the least cost of moving to a contributions equilibrium to be $\sum_{i=1}^{m-1} c_i$. In moving towards the opposite direction (nobody contribute) newer considerations come into play that were absent in the symmetric case.

The most obvious individual who should drop out from the set of m contributors is the one with the lowest value of $v_i - c_i$ (utility forgone from not contributing, when a contributing individual gets a chance to revise his strategy). However, such an individual may not be part of the team of m contributors. Furthermore, it is possible that it may be less costly to exit upwards ($m+1$ contributors) rather than downwards. This, for instance, would be the case if $\min_{1 \leq i \leq m} (v_i - c_i) > c_{m+1}$. It might be cheaper to transit downwards towards the nobody contributes state by first going up to $m+1$ contributors, then shedding the contributor with the highest $v_i - c_i$ difference among the set of $m+1$ contributors. This enables the public good to be provided during these intermediate steps, but reduces the average cost of public good provision, which, in turn, reduces the cost of moving towards the nobody-contribute state.

⁸ Note that we are interested in the path of least resistance in moving to an equilibrium where nobody contributes. Along this path, we must assume at this step that one of the remaining $m-1$ contributors gets a revision opportunity.

The applications to public goods are important and help build our intuition further about using stochastic dynamics in different problems. Fehr and Schmidt (2006) stress the importance of explaining the extensive empirical evidence that has now accumulated on the pattern of public goods contributions with and without punishment (see Part 2 of the book for details). It is an open question if an analysis of public goods based on stochastic dynamics helps us to explain the relevant evidence. It would appear to be a difficult task because considerations of inequity aversion and reciprocity, for which there is good empirical evidence, help us to track closely the evidence, even in the absence of any stochastic components. Furthermore, adaptive dynamics are backward looking, while the possibility of future punishment in public goods games requires a form of forward induction. These concerns also apply to other settings in which one might apply stochastic dynamics to the results from experimental games that involve forward induction.

16.5 Social networks

In many cases, we would like to get closed-form solutions to the limiting distribution of play under stochastic dynamics; this can be obtained in an interesting case (Blume, 1993, 1995) that we now consider.

So far, we have assumed that individuals learn by imitating, or observing strategies based on a sample drawn randomly from the population. In many cases of actual interest, however, individuals learn from other individuals in their vicinity, e.g., geographical neighbors, network of friends, or colleagues, or trusted role models; for a fuller treatment of social networks, see Jackson (2010). Consider n players. To model individuals in the “vicinity” consider the notion of a *social network* (Γ, V, E) , where Γ is a graph, V the set of its vertices and E the set of its directed edges. Each vertex denotes a player.

The directed edge from vertex i to vertex j is denoted by (i, j) . This directed edge denotes the *social influence* of individual j on individual i . The extent of such influence is measured by a weight $\omega_{ij} \geq 0$. In the discussion below, ω_{ij} is considered to be the *geographical proximity* of the two individuals and, so, in this interpretation, $\omega_{ij} = \omega_{ji}$.

Suppose that player i chooses some action s_i^t at time t from his strategy set S_i and $S = S_1 \times \dots \times S_n$. Denote by $s^t = (s_1^t, s_2^t, \dots, s_n^t) \in S$ the action profile at time t ; call this the *state of the system* at time t . Suppose that the opportunity to revise one’s strategies in any period is a Poisson random variable θ , which is distributed independently and identically across players.

The payoff of each player is composed of two parts. The first part is the utility arising from one’s own choice, $v_i(s_i^t)$. The second part is the externality arising to player i from the choices made by others. The externality is given by

$$\chi_i(s^t) = \sum_{j, j \neq i} \omega_{ij} u(s_i^t, s_j^t), \quad (16.25)$$

where $u(s_i^t, s_j^t)$ is the unweighted externality to player i from player j . This is weighted by the geographical proximity of the two players and summed across all other players to compute the total externality on player i . The total utility of player i is then written as

$$V_i(s^t) = v_i(s_i^t) + \chi_i(s^t) + \varepsilon_i^t, \quad (16.26)$$

where ε_i^t is a random preference shock that is distributed independently across players and has an extreme value distribution.

Each player who gets an opportunity to choose a strategy, chooses s_i^t to maximize (16.26), fixing the strategies of the other players. It can then be shown (see Appendix B) that from an observer's point of view, player i chooses pure strategies in his choice set S_i with probabilities given by a logistic function, i.e.,

$$P(s_i^t | s_{-i}^t) = \frac{\exp \beta \{v_i(s_i^t) + \chi_i(s_i^t, s_{-i}^t)\}}{\sum_{s_j^t \in S_i} \exp \beta \{v_i(s_j^t) + \chi_i(s_j^t, s_{-i}^t)\}}, \quad (16.27)$$

where β is the single parameter of the extreme value distribution.

By reacting as if the actions of the other players are fixed (i.e., reacting to the current state) each player who gets an opportunity to revise chooses according to (16.27). This induces a new state of the system, which depends only on the previous state. Hence, this is a Markov process. Whenever, any player gets an opportunity to revise, (16.27) indicates that each of the available strategies is chosen with a positive probability. Hence, beginning from any state in S we can arrive at any other state in S in finite time. And so, the Markov process is irreducible. We know from Appendix C that, in this case, the Markov process is ergodic and has a unique invariant distribution $\lambda^*(s)$, which is the probability with which the process visits state s in the long run.

Define the *potential* of any state $s = (s_1, \dots, s_n)$ by the sum of all individual payoffs plus half of all externality payoffs, i.e.,

$$\rho(s) = \sum_{i=1}^n v_i(s_i) + \frac{1}{2} \sum_{i=1}^n \chi_i(s). \quad (16.28)$$

Under these assumptions, $\lambda^*(s)$ has a simple distribution, the Gibbs distribution (see Blume, 1993, 1995), which is given by

$$\lambda^*(s) = \frac{\exp \{\beta \rho(s)\}}{\sum_{s' \in S} \exp \{\beta \rho(s')\}}, \quad \beta \geq 0. \quad (16.29)$$

For any two distinct states, s and $\hat{s}$, the log of the likelihood ratio is given by

$$\log \frac{\lambda^*(s)}{\lambda^*(\hat{s})} = \beta [\rho(s) - \rho(\hat{s})].$$

Hence, in the long run, the process is more likely to be in that state whose stochastic potential is higher. Suppose that the only two states are s and $\hat{s}$. Then, for very large β , $\rho(s) > \rho(\hat{s})$ implies that in the long run, the process spends virtually all the time in state s . This intuition motivates the following result.

Proposition 16.33 (Blume, 1993, 1995): *Irrespective of the initial state, the long-run probability of being in state s is proportional to $\exp \{\beta \rho(s)\}$. Furthermore, for large enough β , there is a probability very close to one that the process is in the state which maximizes the potential $\rho(s)$.*

16.5.1 An application to agrarian contracts

Young and Burke (2001) use Blume's framework to explain the pattern of agricultural contracts in Illinois. In particular, they look at the pattern of *share contracts*. In a share contract, the total output is shared in some fixed, agreed upon, proportions between a tenant and a landlord. On any farm, assume that there is one landlord and one tenant. Let the tenant's share on farm i be s_i , so the landlord's share is $1 - s_i$. Denote the yield per acre on the farm to be y_i . So if the farm has a total area of h_i hectares, then the total output is $h_i y_i$. We normalize $h_i \equiv 1$.

Controlling for other agricultural inputs, yields depend primarily on things like soil productivity. In general, one would expect large variations in the tenant's share s_i across farms. However, one observes that in 98% of the cases, the tenant's share is either $\frac{1}{2}$, $\frac{2}{3}$, or $\frac{3}{5}$. In North Illinois, the predominant share is $\frac{1}{2}$, while in the South it is predominantly $\frac{2}{3}$ or $\frac{3}{5}$. The uniformity in any region occurs despite substantial differences in soil quality and productivity. Conversely, across very similar farms there can be large differences in s_i . Young and Burke (2001) provide an explanation.

Consider each farm as a vertex in a graph. All vertices are joined to their respective geographical neighbors. Along each edge, the social influence weight is assumed to be identical. So, for instance, if a farm has eight geographical neighbors, it is equally influenced by all eight neighbors. A tenant on farm i has a reservation wage w_i . In any time period, each farm gets a random contract revision opportunity. The arrival rate of contract revision opportunities on farms is independent and follows a Poisson distribution. When such an opportunity arises, the landlord makes a share offer s_i to the tenant, which must respect the participation constraint of the tenant, $s_i y_i \geq w_i$.

Omitting time superscripts, the monetary payoff of the landlord is given by

$$v_i(s_i) = (1 - s_i)y_i. \quad (16.30)$$

Recall that the externality is given by (16.25). Since each neighbor has exactly the same influence, so if there are n neighbors, $\omega_{ij} = 1/n$. Furthermore, define $u(s_i, s_j)$ to be the following indicator function δ_{ij} :

$$u(s_i, s_j) = \delta_{ij} = \begin{cases} 1 & \text{if } i, j \text{ are neighbors and } s_i = s_j \\ 0 & \text{otherwise} \end{cases}. \quad (16.31)$$

Motivated by (16.26), the total utility of the landlord is given by $[v_i(s_i) + \gamma \chi_i(s)] + \varepsilon_i$, where γ , referred to as a *conformity parameter*, is the relative weight of social influence on a farm, relative to its own monetary payoff. Denote by N_i , the set of neighbors of farm i . Using (16.30), (16.31), and $\omega_{ij} = 1/n$ we get that the utility function of the landlord in the i th farm is given by

$$V_i(s) = \left[(1 - s_i)y_i + \gamma \sum_{j \in N_i} \delta_{ij} \right] + \varepsilon_i. \quad (16.32)$$

If ε_i has an extreme value distribution that is independent across farms, then we can use Proposition 16.33 by defining an appropriate potential function $\rho(s)$.

$$\rho(s) = \sum_{i=1}^n (1 - s_i)y_i + \frac{\gamma}{2} \sum_i \sum_{j \in N_i} \delta_{ij},$$

Figure 16.16 Hypothetical distribution of farms.

Source: Young and Burke (2001) with permission from the American Economic Association.

where $\sum_{i=1}^n (1-s_i)y_i = R(s)$ is the total rent from land and $\frac{1}{2} \sum_i \sum_{j \in N_i} \delta_{ij} = e(s)$ is the *aggregate externality*. Hence, we can write $\rho(s) = R(s) + \gamma e(s)$. From Proposition 16.33, the main feature of the limiting distribution $\lambda^*(s)$ is that

$$\lambda^*(s) \propto \exp \beta [R(s) + \gamma e(s)]. \quad (16.33)$$

If we specify values for β , γ , y_i , and the reservation wage w_i , then we can find the long-run probability distribution of the states of the system. Suppose that there are soils of three qualities: high, medium and low. If there are m farms and each farm has eight geographical neighbors, then there is a total of $4m$ edges. These are shown in Figure 16.16. Each farm is denoted at a vertex by its soil quality, H (high), M (medium), and L (low). Each vertex also has eight directed edges pointing away from it, indicating the social influence of neighboring farms.

Consider the following numerical example. Suppose that $\gamma = 0$. Then, the long-run distribution is one that simply maximizes total rent $R(s)$. Suppose that: (1) Labor market conditions are competitive, and the reservation wage is given by $w_i = 32$. (2) Yields on the soils of the three qualities, high, medium, and low, are respectively 85, 70, 60. (3) Contract negotiations can be concluded only in multiples of 10, so $s_i = 0, 0.10, 0.20, \dots, 1.00$. Since tenants must be given their reservation utilities, the shares of tenants, s_i , on the three quality types, high, middle, and low, are 40%, 50%, and 60%.

In the spirit of models of stochastic social evolution, these long-run states in an ergodic system do not depend on the initial state. By varying the sizes of β and γ , Young and Burke (2001) explain the pattern of contracts in Illinois. In particular, for intermediate values of the conformity parameter, γ , the authors show that stochastic potential is maximized by a set of contracts such that there is *local uniformity*, but *global diversity*, i.e., inter-regional heterogeneity and intra-regional homogeneity, which matches the Illinois case.

APPENDICES

Appendix A: Ordinary differential equations

We review some elementary results in the theory of *ordinary differential equations* (ODE) in this section. There are many good sources (Coddington, 1961; Hirsch and Smale, 1974). A simple treatment for economists can be found in Simon and Blume (1994).

Suppose that we have a vector of real valued functions of time $t \in \mathbb{R}$

$$\mathbf{x}(t) = (x_1(t), x_2(t), \dots, x_n(t)) \in \mathbb{R}^n,$$

where $x_i(t) \in \mathbb{R}$ is a function of time that has continuous partial derivatives. $\mathbf{x}(t)$ can be thought of as a curve in an n -dimensional space. However, in many cases we do not know the exact curve, but rather the rate of change and direction of change of the curve in some region of $\mathbb{R}^n$.

Let a single dot over a variable represent the first time derivative, two dots represent the second time derivative, and so on. It is sometimes more convenient to denote the k th time derivative of some time dependent variable $x_i(t)$ by $\frac{d^k x_i(t)}{dt^k}$. The k th time derivative of the vector $\mathbf{x}(t)$ is to be understood as taking the k th time derivative, for each element of the vector, i.e., for any particular $t \in \mathbb{R}$

$$\frac{d^k \mathbf{x}(t)}{dt^k} = \left(\frac{d^k x_1(t)}{dt^k}, \frac{d^k x_2(t)}{dt^k}, \dots, \frac{d^k x_n(t)}{dt^k} \right) \in \mathbb{R}^n.$$

Definition 16.34 (*Differential equation*): A differential equation describes, at time t , the relation between a vector of n variables, and its time derivatives. This is written compactly as

$$g(t, \mathbf{x}(t), \dot{\mathbf{x}}(t), \ddot{\mathbf{x}}(t), \dots) = 0. \quad (5.A1)$$

The order of a differential equation is the highest time derivative in (5.A1).

We are primarily interested in *ordinary differential equations* (ODE) where the order $k = 1$. In contrast, if in addition to time, t , there was at least one more variable in (5.A1) with respect to which we differentiate, then we would have *partial* instead of *ordinary* differential equations.

Consider the following system of n first order differential equations.

$$\begin{aligned} \dot{x}_1(t) &= f_1(t, \mathbf{x}(t)), \\ \dot{x}_2(t) &= f_2(t, \mathbf{x}(t)), \\ &\vdots \\ \dot{x}_n(t) &= f_n(t, \mathbf{x}(t)), \end{aligned} \quad (5.A2)$$

where $f_i(t, \mathbf{x}(t)) : \mathbb{R}^{n+1} \rightarrow \mathbb{R}$. The system in (5.A2) is compactly written as

$$\dot{\mathbf{x}}(t) = \mathbf{f}(t, \mathbf{x}(t)), \quad (5.A3)$$

where $\dot{\mathbf{x}}(t)$ and $\mathbf{f}$ are column vectors whose i th elements are, respectively, $\dot{x}_i(t)$ and $f_i(t, \mathbf{x}(t))$. An *autonomous ODE* is one where time does not separately enter the function $\mathbf{f}$, i.e.,

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t)). \quad (5.A4)$$
