

OXFORD

THE FOUNDATIONS OF BEHAVIORAL ECONOMIC ANALYSIS

SANJIT DHAMI

Praise for *The Foundations of Behavioral Economic Analysis*

“The publication of this book is a landmark occasion for the field of behavioural economics. Until now there has been no comprehensive survey of the field suitable for graduate students. Professor Dhami has thoroughly and rigorously filled that gap. The book will be placed in a handy place in my office since I plan to consult it regularly.”

Richard H. Thaler, Charles R. Walgreen Distinguished Service Professor of Economics and Behavioral Science, University of Chicago

“*Foundations of Behavioral Economic Analysis* offers a fascinating mix of theory and evidence and is the most comprehensive synthesis of behavioral economics at an advanced level. It will be very useful for advanced researchers as well as for graduate students in behavioral economics and beyond.”

Ernst Fehr, Professor of Economics, University of Zurich

“This book is a tour de force, a literal encyclopedia of behavioral economics. Its extraordinary breadth and depth, spanning all aspects from psychological foundations to the most recent advances and seamlessly integrating theory with experiments, will make it the must-have reference for anyone interested in this field, and more generally in where economics is headed. It will quickly become the standard textbook for all graduate courses in behavioral economics, and a much-thumbed companion for all researchers working at the frontier.”

Roland Benabou, Theodore A. Wells '29 Professor of Economics and Public Affairs, Princeton University

“In *Foundations of Behavioral Economic Analysis*, Sanjit Dhami offers the first summary and exposition of research in this rapidly growing and increasingly influential subfield. The coverage is comprehensive, extending even to the recent subtopics of behavioural welfare economics and neuroeconomics. The book is distinguished by its detailed yet readable coverage of theory and evidence and its balanced discussion of the philosophical and methodological differences and similarities between ‘behavioural’ and neoclassical approaches to microeconomics. Select undergraduates, graduate students, and interested scholars will all gain from this masterful book.”

Vincent P. Crawford, Drummond Professor of Political Economy, University of Oxford, and Research Professor, University of California, San Diego

“Economic theory in the twentieth century developed an extremely powerful repertoire of analytical techniques for studying human behavior, but labored under the rather bizarre misconception that the postulates of rational choice were sufficient to characterize economic behavior. Behavioral economic from the late twentieth century to the present demonstrated the explanatory power of hitching these analytical techniques to empirical data gleaned from laboratory and field experiments. The result has radically transformed economics as a scientific discipline, and the best is surely yet to come. Sanjit Dhami has performed a monumental task in consolidating this research and explaining the results in a rigorous yet accessible manner, while highlighting major controversies and sketching the central research questions facing us today.”

Herbert Gintis, Santa Fe Institute

“For someone, like myself, who started by being ignorant of the richness of the conversation within behavioral economics on a variety of issues, this magisterial volume is the ideal introduction, at once lucid and sophisticated.”

Abhijit V. Banerjee, Ford Foundation International Professor of Economics, Massachusetts Institute of Technology.

“In the development of any field there comes a moment where the results already established must be synthesized, explained and consolidated both for those in the field and those outside. In this amazing volume Sanjit Dhami has done just that and far more. This book will serve as an encyclopedic must-have reference for anyone seeking to do work in this field or just curious about it. The coverage is exhaustive and the exposition extremely clear and at a level suitable for advanced undergraduates, graduate students, and professionals. This is truly an achievement.”

Andrew Schotter Professor of Economics, New York University and Director, Center for Experimental Social Science

“Displaying wit and wisdom, in *Foundations of Behavioral Economic Analysis* Professor Dhami conveys both the substance and the excitement of the burgeoning field of behavioral economics. This remarkable volume will serve as a reference for practitioners and a compelling entry-point for the curious.”

George Loewenstein, Herbert A. Simon Professor of Economics and Psychology, Carnegie Mellon University

“This is a unique and truly remarkable achievement. It is a magnificent overview of behavioral economics, by far the best there is, and it should define the field for at least a generation. But it is much more than that. It is also a brilliant set of original discussions, with pathbreaking thinking on every important topic. An invaluable resource for policymakers, students, and professors—and if they want to try something really special, for everyone else.”

Cass R. Sunstein, coauthor of Nudge and Founder and Director of the Program on Behavioral Economics and Public Policy, Harvard Law School

“The expansion of behavioral economics during the past twenty years has been remarkable, much of it concerning strategic interaction and using tools from game theory. Sanjit Dhami’s amazing book summarizes and even defines the field, broadly as well as in depth. His coverage of theory as well as of experiments is superb. *Foundations of Behavioral Economic Analysis* will be an indispensable resource for students and scholars who wish to understand where the action is.”

Martin Dufwenberg, Karl & Stevie Eller Professor and Director of the Institute for Behavioral Economics at the University Arizona

“Sanjit Dhami’s *Foundations of Behavioral Economic Analysis* is a major and most impressive achievement. It provides an exhaustive account and a masterful synthesis of the state of the art after more than three decades of behavioral economics. For many years to come it will be an indispensable reference for researchers in economics and psychology, and it is bound to become the standard text in graduate and advanced undergraduate courses on behavioural and experimental economics.”

Klaus M. Schmidt, Professor of Economics, University of Munich

“This is the most complete and stimulating book on behavioral economics. With elegance and unprecedented elaborateness, it ties together a wealth of experimental findings, rigorous theoretical insights, and exciting applications across all relevant fields of behavioral research. Sanjit Dhami’s work has been shaped by numerous comments of the leaders in the field. Now,

in the years to come, it will be the standard that shapes how the next generation of students and researchers think about behavior and its science."

Axel Ockenfels, University of Cologne, Speaker of the Cologne Excellence Center of Social and Economic Behavior

"This book covers all relevant theoretical aspects of behavioral economics in great depth. A great strength is its comprehensiveness: it covers the whole field. The book thus is unique in bringing to the fore the unity and diversity of the behavioral approach. The material is well-organized and accessible to a wide audience. It is invaluable to anyone teaching or studying any topic in behavioral economics, showing how the topic fits into the whole."

Peter Wakker, Professor of Economics, Erasmus University Rotterdam

"*Foundations of Behavioral Economic Analysis* will be a central textbook for behavioral economics. One key feature is its appealing focus on the interplay between theory and evidence. For researchers, it will be a great source of information, puzzles, and challenges for the many years to come. It is a major achievement."

Xavier Gabaix, Martin J. Gruber Professor of Finance, New York University, Stern School

PREFACE AND ACKNOWLEDGMENTS

Neoclassical economics is a logically consistent and parsimonious framework of analysis that is based on a relatively small set of core assumptions, and it offers clear, testable, predictions. However, extensive and growing empirical evidence reveals human behavior that is difficult to reconcile within the typical neoclassical models. There has been a parallel development in rigorous theoretical models that explains better the emerging stylized facts on human behavior. These models have borrowed insights from psychology, sociology, anthropology, neuroscience, and evolutionary biology. Yet, these models maintain a distinct economic identity in terms of their approach, rigor, and parsimony. Collectively, these models form the subject matter of behavioral economics, which is possibly the fastest growing and most promising area in economics.

This book is an account of behavioral economics that starts with the basics and takes the reader to the research frontiers in the subject. Depending on how one chooses to use it, the book is suitable for courses at the advanced undergraduate, postgraduate, and research level in economics, and the related social sciences, including, but not restricted to, psychology, management, finance, political science, and sociology. The book should also serve as an essential reference book for anyone generally interested in behavioral economics at any level, and also serve to stimulate the interests of non-specialist academics, specialist academics who are looking for a bird's-eye view of the entire field, and policymakers looking for policy applications of behavioral economics. It would be desirable to assign this book as background reading to courses in economic theory. The book is also, in my view, the minimum subject matter that anyone who writes behavioral economics as their research interest, should be deeply familiar with.

In November 2003, two months after I joined the department of economics at the University of Leicester, I chanced upon an invitation to attend a talk by a colleague, Ali al-Nowaihi, on the subject of *prospect theory*. Ali, a mathematician by training, an economist by profession, and a keen student of the philosophy of science, put forward a Popperian view to evaluate economic theories. He argued that *expected utility theory* was decisively rejected by the evidence, and prospect theory was the most satisfactory decision theory currently available. As a purely neoclassically trained economist, I was troubled by the claims, but also extremely skeptical. For a start, prospect theory sounded like a strange name for a theory, and the evidence was largely “experimental,” a data source, that I knew little about. As my defensive instincts started to kick in, I wondered if prospect theory really was so important, then surely my graduate courses, many taught by leading decision theorists, would have found some reason to mention it. Nor was there any mention of such a theory in conversations with colleagues at the two British universities where I had taught so far, or at seminars or conferences that I had attended.

However, rather than just dismiss Ali, a very likeable and respected figure in the department, I decided to put his seemingly extreme views to the test. One of my majors was in public economics, so I decided to conduct a prospect theory analysis of tax evasion in the hope of explaining the *tax evasion puzzles*, which had been outstanding for three decades (details in Part 1). There was already some preliminary work in this area that Ali had mentioned in passing, but none of the papers explained all the puzzles in one fell swoop, using all components of prospect theory. It took me just a few weeks to work out the results. To my utter amazement, prospect

theory explained the qualitative and quantitative tax evasion puzzles. By contrast, the predictions based on an expected utility analysis were wrong by a factor of up to 100. This led to my first joint publication with Ali, with whom I have spent many years of fruitful collaboration since then.

This initial, and successful, encounter with prospect theory convinced me that I needed to explore behavioral economics in greater depth. Yet, around 2004, there was no definitive graduate text on behavioral economics. To be sure, there were many excellent sets of collected readings, and several insightful surveys and commentaries on selected aspects of behavioral economics that I eagerly read. In particular, while there were many excellent discussions of the experimental evidence, a full treatment of behavioral economic theory and its applications was missing. One could always pursue the journal articles, but the literature was already enormous, rapidly expanding, and scattered, which made it difficult to spot the links between the various models or to clearly visualize how the various pieces of the jigsaw fitted together. This book was motivated initially by the lack of a serious graduate book on the entire subject matter of behavioral economics, my desire to master behavioral economics, and to support my growing research agenda with Ali. In due course, and as the full range of the subject matter gradually dawned upon me, the scope of the book naturally became more ambitious and daring.

I strive to strike a balance between behavioral economic theory, the experimental evidence, and applications of behavioral economics. The choice of theoretical models in this book is dictated, first and foremost, by their ability to explain the empirical evidence. In some cases, where no decisive empirical evidence is available, I make a judgment on which models are more promising than others, although I give a wide berth to most models.

The main prerequisite for the book is training in the first two to three years of a reasonably good British or North American undergraduate degree in economics, or its equivalent. Any further concepts and techniques are introduced in the book, where needed. A prior course in behavioral economics is not a prerequisite for the book.

The book is divided into nine parts that cover decision making under risk, uncertainty, and ambiguity; other-regarding preferences; behavioral time discounting; models of behavioral game theory and learning; role of emotions in decision making; models of bounded rationality; judgment heuristics and mental accounting; behavioral welfare economics; and neuroeconomics. The book also considers a range of applications of the theory to most areas in economics that include microeconomics, contract theory, macroeconomics, industrial organization, labor economics, development economics, public economics, political economy, and finance. A set of exercises at the end of each part, except the part on neuroeconomics, serves to enhance the reader's understanding of the subject.

Behavioral economics is now a mainstream area in economics. One just has to look at the growing and large number of journal publications and Ph.D. theses every year; the Nobel Prizes to Herbert Simon, Daniel Kahneman, Robert Shiller, Alvin Roth, Vernon Smith, and George Akerlof; the John Bates Clarke medal to Matthew Rabin; the growing importance of behavioral economics among policymakers, as witnessed by the 2015 World Bank Development Report, and the formation of the behavioral insights team in the UK; and the choice of Richard Thaler as the incoming President of the American Economic Association.

It is fair to say that no self-respecting economics department can now afford to omit a course in behavioral economics from its undergraduate or graduate curriculum; indeed, doing so would be grossly unjust to its students and a retrogressive step. Nor can any academic economist, who wishes to retain professional honesty and a balanced opinion on the subject, afford to be unfamiliar with the subject matter of behavioral economics; I am often amused by the ignorance and

arrogance of many who pass judgment on behavioral economics with supreme confidence, yet appear to have little understanding of it.

This book has taken more than ten years to write, and my debts are deep and profound. My first and foremost debt and gratitude is to my loving family without which this book could not have been written. To my parents, Manohar and Baljeet, for their unconditional lifelong love and support, and instilling in me the core values of honesty, commitment, and hard work. To my wife, Shammi, and my son, Sahaj, for their patience, sacrifice, unflinching support, and constant encouragement. When I started writing this book, Sahaj was in primary school, and in the month of its first publication, he could be packing his bags to join a university. I do not recommend this as the best template to encourage your son to write any books in the future. However, there are close parallels between Sahaj's educational journey from primary school to university, with my own journey in behavioral economics.

I owe a deep intellectual debt to my long-time coauthor and friend, Ali al-Nowaihi. I first learnt about prospect theory from him. I also owe my appreciation of methodology and the philosophy of science entirely to him. He has undertaken a larger burden of our joint research in the last few years, allowing me to be immersed in the book. For all these reasons, he is very much a coauthor of the book in spirit.

I am extremely grateful to many academics and Ph.D. students who unselfishly and generously contributed their time and efforts to reading drafts of various parts of the book. The participation of so many leading behavioral economists in the making of this book is unprecedented and has really made it into a public project for which I shall always be very grateful. Herbert Gintis, Martin Dufwenberg, and Vincent Crawford deserve special mention for being so very gracious with their inputs into most parts of the book, and very quickly responding to my queries.

Many others also played a critical role in the writing of this book and commented on material closer to their areas of interest, and/or offered valuable encouragement and advice. In particular, I wish to thank Mohammed Abdellaoui, Ali al-Nowaihi, Dan Ariely, Douglas Barrett, Björn Bartling, Karna Basu, Kaushik Basu, Pierpaolo Battigalli, Roland Benabou, Florian Biermann, Gary Bolton, Subir Bose, David Colander, Andrew Colman, Patricio Dalton, Alexandra Dias, Florian Englmaier, Armin Falk, Ernst Fehr, Urs Fischbacher, Xavier Gabaix, Sayantan Ghosal, Uri Gneezy, Werner Guth, Shaun Hargreaves Heap, Fabian Herweg, Karla Hoff, Philippe Jehiel, David Laibson, George Loewenstein, Michel Marechal, Friederike Mengel, Joshua Miller, Axel Ockenfels, Amnon Rapoport, Ludovic Renou, Alvin Roth, Klaus Schmidt, Andrei Shleifer, Dennis Snower, Joe Stiglitz, Cass Sunstein, Richard Thaler, Jean-Robert Tyran, Peter Wakker, Klaus Waelde, Eyal Winter, and Peyton Young. I owe a profound intellectual debt to many others who did not read the book manuscript but whose work has greatly inspired me. These include Daniel Kahneman, Amos Tversky, Colin Camerer, Matthew Rabin, Herbert Simon, Robert Shiller, and George Akerlof. I am also very grateful to two successive Heads of the economics department at Leicester, Steve Hall and Chris Wallace, who tried to free up as much of my time as possible for writing the book.

I would like to specially acknowledge the enormous amount of work put in by two extremely conscientious and able Ph.D. students, Teimuraz Gogsadze and Junaid Arshad. They closely read and commented on successive drafts of the manuscript at all stages, offered very useful advice, and served as excellent sounding boards for new ideas. Jingyi Mao came up with a very nice cover for the book in a burst of creativity, for which I am very grateful. Other Ph.D. students who carefully read and commented on selected parts of the manuscript include: Ala Avoyan, Nino Dognohadze, Sneha Gaddam, Narges Hajimoladarvish, Emma Manifold, Jingyi Mao, Alexandros Rigos, David Tsirekidze, Yongli Wang, Mengxing Wei, and Mariam Zaldastanishvili.

I would be remiss not to thank the large number of other researchers whose work has made this book possible. I must also sincerely apologize to authors who feel that their work has been inadequately cited or not given the importance they feel that it deserves. To such authors, I say, omission of your papers does not mean that I necessarily viewed your papers as unimportant. In mitigation, I do not intend my book to be a survey of all the experimental results on all topics in behavioral economics; there are already excellent sources with this objective. And, quite possibly, I was simply unaware of your important work, which is in keeping with the evidence on limited attention and bounded rationality that plays an important role in this book.

I am very grateful to the team at Oxford University Press who have done an excellent job at all stages of this book. In particular, I would like to thank Adam Swallow, the commissioning editor for economics and finance at OUP for his patience, good cheer, organizational skills, and sound advice. Scott Parris, the economics editor at the US office of OUP, who retired just as this book was about to come out, was the first to spot the importance of this project. He offered very valuable advice and encouragement throughout the writing stage and played a key role in my decision to go with OUP. I must also thank Niko Pfund, the President of Oxford University Press USA, for his continued interest in the manuscript over several years, despite his many other responsibilities. The production and marketing teams at OUP were a pleasure to work with. Jon Billam took on the challenge of copy-editing an unusually large book with great enthusiasm. I am also very grateful to Emma Slaughter, the production editor for the book; Kim Stringer, the indexer; Kim Allen, the proofreader; Carla Hodge-Degler who took over as production editor from Emma; and to Leigh-Ann Bard, the marketing manager for the book.

PART 1 Behavioral Economics of Risk, Uncertainty, and Ambiguity

Introduction to Part 1	79
1 The Evidence on Human Choice under Risk and Uncertainty	83
1.1 Introduction	83
1.2 The elements of classical decision theory	84
1.3 Subjective expected utility theory (SEU)	89
1.4 Eliciting the utility function under EU	92
1.5 Violations of expected utility theory	95
2 Behavioral Models of Decision Making	110
2.1 Introduction	110
2.2 Probability weighting functions	115
2.3 Rank dependent utility theory (RDU)	124
2.4 Prospect theory (PT)	130
2.5 Elicitation of utility and probability weighting functions in PT	140
2.6 The axiomatic foundations of PT	148
2.7 Third generation PT and stochastic reference points	152
2.8 Stochastic reference points in PT under rational expectations	153
2.9 Limitations of PT	172
2.10 A selection of other behavioral theories	181
2.11 Human behavior for extreme probability events	191
2.12 Risk preferences and time preferences	199
3 Applications of Behavioral Decision Theory	213
3.1 Introduction	213

3.2	The endowment effect and exchange asymmetries	217
3.3	Prospect theory preferences in primates	235
3.4	Myopic loss aversion	239
3.5	Why do people pay taxes?	242
3.6	Explanation of Rabin's paradox using PT	248
3.7	Goals as reference points	250
3.8	Why is it so hard to find a taxi on a rainy day in New York?	256
3.9	Some implications of inverse S-shaped weighting functions	263
3.10	Contracts as reference points	264
3.11	Moral hazard, loss aversion, and optimal contracts	272
3.12	Renegotiation, long-term contracts, and loss aversion	278
4	Human Behavior under Ambiguity	284
4.1	Introduction	284
4.2	A problem for SEU: The Ellsberg paradox	286
4.3	Neoclassical models of ambiguity	288
4.4	Behavioral models of ambiguity	301
	Exercises for Part 1	310
	References for Part 1	316
 PART 2 Other-Regarding Preferences		
Introduction to Part 2		339
5	The Evidence on Human Sociality	344
5.1	Introduction	344
5.2	Ultimatum and dictator games	349
5.3	Gift exchange and trust games	357
5.4	Public goods games	370
5.5	How representative is the lab evidence?	386
5.6	Indirect reciprocity	395
6	Models of Other-Regarding Preferences	398
6.1	Introduction	398
6.2	The Fehr–Schmidt model	401
6.3	The ERC model	410
6.4	Fairness and stochastic dominance	412
6.5	Behavioral political economy	417
6.6	Fairness, general equilibrium, and welfare	426
6.7	Evidence on models of social preference and reciprocity	431
6.8	A discussion of other promising models	444
7	Human Morality and Social Identity	453
7.1	Introduction	453
7.2	Human virtues	455
7.3	Social identity	465

8	Incentives and Other-Regarding Preferences	478
8.1	Introduction	478
8.2	Moral hazard and other-regarding preferences	483
8.3	Incomplete contracts under other-regarding preferences	495

PART 6 Emotions

Introduction to Part 6	1223
17 Emotions and Human Behavior	1226
17.1 Introduction	1226
17.2 Visceral influences and the rationality of emotions	1229
17.3 Cue-conditioned behavior and habit formation	1235
17.4 Anticipation and delay under certainty	1242
17.5 Fear and anxiety under uncertainty	1245
17.6 Projection bias	1250
17.7 Temptation preferences: a revealed preference approach	1258
17.8 Temptation and conflicts between commitment and flexibility	1266
17.9 Happiness economics	1270
18 Interactions between Emotions and Cognition	1288
18.1 Introduction	1288
18.2 Emotions and a two-modules view of the brain	1290
18.3 A dual selves model with costly commitment	1298
18.4 Information asymmetries between emotions and cognition	1304
18.5 Strategic ignorance, confidence, and self-esteem	1308
Exercises for Part 6	1322
References for Part 6	1328

PART 7 Bounded Rationality

Introduction to Part 7	1339
19 Judgment Heuristics	1342
19.1 Introduction	1342
19.2 The law of small numbers	1350
19.3 Conjunction fallacy	1361
19.4 The availability heuristic	1365

19.5	The affect heuristic	1367
19.6	Anchoring and adjustment	1370
19.7	Base rate neglect and conservatism	1375
19.8	Hindsight bias	1383
19.9	Confirmation bias	1389
19.10	Other judgment heuristics	1395
19.11	Dual process models and judgment heuristics	1398
19.12	Coarse thinking and persuasion	1401
19.13	Mental models	1407
19.14	Herbert Simon's approach to bounded rationality	1409
19.15	The great rationality debate	1426
19.16	Shrouded attributes	1431
19.17	Limited attention	1436
19.18	Do experts exhibit biases?	1449
20	Mental Accounting	1451
20.1	Introduction	1451
20.2	Framing and mental accounting	1455
20.3	Prospect theory and mental accounting	1456
20.4	The behavioral life-cycle model	1459
20.5	The red and black of mental accounting	1463
20.6	Choice bracketing	1469
20.7	Coherent arbitrariness	1471
20.8	Sunk costs and mental accounting	1473
20.9	Some other mental accounting phenomena	1476
21	Bounded Rationality in Financial Markets	1485
21.1	Introduction	1485
21.2	The efficient markets hypothesis	1488
21.3	Noise trader risk	1502
21.4	The limits to arbitrage	1509
21.5	Gradual flow of information	1516
21.6	Stock market underreaction and overreaction	1520
21.7	Behavioral corporate finance	1526

	References for Part 7	1552

PART 8 Behavioral Welfare Economics

Introduction to Part 8	1577
22 Behavioral Welfare Economics	1579
22.1 Introduction	1579
22.2 Fixing basic ideas	1583
22.3 Soft paternalism	1590
22.4 Regulation under imperfect self-information	1601
22.5 Choice and non-choice data: What is the scope of economics?	1603

22.6 Choice-based behavioral welfare economics	1611
22.7 Revealed preference under limited attention	1618
22.8 The contractarian approach	1623
22.9 Behavioral public finance and welfare	1625
Exercises for Part 8	1635
References for Part 8	1638

PART 9 Neuroeconomics

Introduction to Part 9	1643
23 Neuroeconomics	1644
23.1 Introduction	1644
23.2 A brief introduction to the brain	1648
23.3 An introduction to neuroeconomic techniques	1655
23.4 The neuroeconomics of risky decisions	1661
23.5 The neuroeconomics of social preferences	1669
23.6 The neuroeconomics of time preferences	1686
23.7 The neuroeconomics of strategic interaction	1689
23.8 Pharmacoeconomics: an application to the social effects of oxytocin	1692

<i>Appendix on Game Theory</i>	1703
<i>Index of Named Authors</i>	1725
<i>Subject Index</i>	1736

LIST OF FIGURES

1	The power form of the utility function under prospect theory.	27
2	A plot of the Prelec function for $\beta = 1$ and $\alpha = 0.5$.	28
3	A plot of the discount rate for the one-parameter hyperbolic discounting function with varying time delay.	38
4	Distribution of choices by different subject pools in a p-beauty contest game.	42
5	Choices of game theorist subjects in a p-beauty contest game.	43
6	Response of quality to price in a competitive equilibrium.	50
7	Response of quality to price for local and non-local dealers in the lab and in the field.	51
8	Public good contributions in the presence and absence of punishments.	52
1.1	Illustration of the common ratio effect in a probability triangle.	100
1.2	Concave indifference curves.	102
1.3	Convex indifference curves.	103
2.1	Relative risk premium for the Student and the Representative population.	117
2.2	Non-parametrically estimated probability weighting functions for the Student and Representative population based on aggregate data.	118
2.3	Plots of $w(p) = e^{-(\ln p)^{0.5}}$ and $w(p) = e^{-(\ln p)^2}$.	120
2.4	An illustration of optimism and pessimism as the shape of the probability weighting function varies.	126
2.5	Shapes of decision weights when there are multiple outcomes under RDU.	127
2.6	The utility function under prospect theory.	132
2.7	Indifference curves under RDU over the full range of probabilities (left panel) and with the boundaries truncated (right panel).	137
2.8	Non-parametric estimates of utility for gains and losses under PT and EU based on median data.	143
2.9	Parametric estimates of the power form of utility for gains and losses under PT based on median data.	144
2.10	The case of two choice sets.	158
2.11	Histogram of accumulated earnings (in euros) at which a subject stopped.	170
2.12	Decision tree for experiment 1 in Ericson and Fuster (2011).	171
2.13	Median relative risk premium (<i>RRP</i>) for different types of decision makers as the probability, p , is varied.	177
2.14	Stake dependent probability weights in the domain of losses and gains (upper panel) and 95% confidence bands based on the percentile bootstrap method (lower panel).	178
2.15	Two types of decision makers for the student and the representative population.	180
2.16	A hypothetical probability weighting function.	192
2.17	The composite Prelec weighting function (CPF).	196
2.18	Reduction of lotteries when both time and risk are present, in three different cases.	200
2.19	Average consumption, $\bar{c}_t$, in various conditions.	202

2.20	A plot of the estimated discount rate $\hat{\theta}$ (vertical axis) and the time delay t (horizontal axis).	210
2.21	A choice between a compound lottery and its equivalent simple lottery.	211
2.22	Estimated Prelec weighting functions.	212
3.1	Fraction of successful par and birdie putts by distance to the hole.	228
3.2	Crossing of indifference curves when there is an endowment effect.	231
3.3	Tests of capuchin monkey preferences.	236
3.4	Choices made by chimpanzees in different conditions.	238
3.5	Average bets of students and professionals.	240
3.6	Amount invested in each treatment.	241
3.7	Plot of (3.30) for the case of $\lambda = 2$.	249
3.8	An illustration of the equilibrium in the Crawford–Meng (2011) model.	262
3.9	Valuations and costs in two states of the world.	269
3.10	Valuations and costs in three states of the world.	269
3.11	Quality dependent valuation and cost data in two states of the world.	270
3.12	Sequence of moves in a bilateral trade model with renegotiation.	279
4.1	Source-dependent probability weighting functions.	307
4.2	Subject heterogeneity for three subjects expressed in terms of their source functions.	308
5.1	The relation between effort and rent in the gift exchange game.	358
5.2	The effect of the equity norm on effort levels.	361
5.3	Behavior of workers' effort levels in the library task.	362
5.4	The relation between reciprocity and tenure.	363
5.5	Productivity of workers in different wage conditions.	364
5.6	Average responses for the positive reciprocity questions (left panel) and negative reciprocity questions (right panel).	365
5.7	Measures of trust and trustworthiness in a meta study.	367
5.8	The trust game in Huck et al. (2012).	369
5.9	Evolution of average contributions in three different treatments in the presence and in the absence of punishments.	374
5.10	Explaining the pattern of contributions when there is heterogeneity in social preferences.	378
5.11	Choice of institutions and contributions.	379
5.12	Contest expenditures in the treatments without punishment.	381
5.13	Actual and equilibrium rent dissipation.	383
5.14	Prosocial and antisocial punishment in the public goods game (left panel) and the relation between antisocial punishment and contributions (right panel).	384
5.15	Mean contributions in the P treatment (left panel) and the N treatment (right panel).	385
5.16	Results for the single- and double-anonymous treatments.	388
5.17	Workers' performance response to the wage increase (vertical axis), conditional on their fairness perceptions.	389
5.18	Checking the external validity of lab data on social preferences.	391
5.19	Average time spent on monitoring by different behavioral types. The bars represent standard errors of the means.	393
5.20	Third party punishments in the dictator game.	397
6.1	The SSS and SFS economies.	425
6.2	The SSS, SSF, and FSF economies.	426

6.3	Modified ultimatum game.	435
6.4	Effect on b as a changes.	437
6.5	Normal form representation of a two-player, sequential, social dilemma game.	440
6.6	Cumulative distribution of the second player's cooperative decision (c1 to c6).	441
6.7	Two variations of the ultimatum game, indexed by the parameters x and y .	442
6.8	Average rejection rates in the UG^*x game.	443
6.9	Average rejection rates in the UG^*+y game.	443
7.1	Results for the baseline treatment.	458
7.2	Messages sent by player A in each state.	460
7.3	The battle of sexes (BOS) game and the prisoner's dilemma game (PD).	470
7.4	Cooperation rates and beliefs in the modified trust game. Bars represent standard errors of the means.	471
7.5	Group membership and punishment. Bars represent standard errors of the means.	472
8.1	Share of bonus contracts and incentive contracts over successive rounds.	506
8.2	Relation between the actual bonus paid by the principal and effort level of the agent.	507
8.3	A comparison of the length of the worker-firm relationship under the two treatments.	518
8.4	Average temporal wage in each treatment.	519
8.5	Average temporal effort in each treatment.	520
8.6	Average earnings per trade of the workers and firms in each treatment.	521
8.7	Comparison of mean effort levels under various treatments.	522
8.8	Payoffs of the principal and agent in treatment RANDOM (left panel) and treatment FIXED (right panel).	525
8.9	Share of employment contracts in different treatments (left panel). Frequency of power abuse and share of employment contracts in each treatment (right panel).	526
8.10	Diagrammatic representation of the condition in (8.77).	530
8.11	Loci of combinations of (u_I, u_E) on which (8.86) binds.	533
8.12	A trust game that differentiates between voluntary and involuntary trust.	536
8.13	Effort and rents in three cases.	541
8.14	Effect of intentions in the trust game.	542
8.15	Median choice of action by the agent over when the principal does, and does not, control.	543
8.16	Mean earnings as a percentage of maximum earnings in different games.	545
8.17	Mean earnings as a percentage of maximum earnings in different games.	545
8.18	Average profits and average effort levels conditional on the employees' reputations.	547
8.19	Share of contract-F in each treatment.	548
8.20	Buyer/seller profits as a function of buyer/seller choices.	549
8.21	Average number of parents who arrive late.	551
8.22	Percentage of blood donors under varying levels of incentives.	553
8.23	The effect of incentives on prosocial behavior in different treatments.	555
8.24	Total public goods contributions over successive rounds when the incentives are varied.	557
8.25	Number of weekly visits to the gym. Error bars reflect one standard error.	561
9.1	A plot of the discount rate in (9.30) for the one-parameter hyperbolic discounting function with varying time delay.	596
9.2	Sequential choices for the Ok and Masatlioglu (2007) example.	602

10.1	The discount factors for various discount functions: Exponential (continuous bold curve), quasi-hyperbolic (lighter step function), and generalized hyperbolic (dashed curve).	616
10.2	Sequence of outcome–time pairs.	626
10.3	The delay and the speedup functions.	639
11.1	Diagrammatic illustration of the equilibrium in the Diamond–Kőszegi model.	669
12.1	The extensive form and the strategically equivalent normal form in the baseline treatment.	725
12.2	An extensive form and the strategically equivalent normal form.	727
12.3	Checking for three steps of iterated deletion of dominated strategies.	728
12.4	Four-move and six-move centipede games.	729
12.5	A three-player centipede game.	731
12.6	A six-move centipede game.	732
12.7	Percentage of all-B play in various rounds.	737
12.8	O’Neill’s zero-sum game to test for an MSE.	739
12.9	The payoff matrix for games 1 and 3.	742
12.10	The payoff matrix for games 2 and 4.	742
12.11	A three-player matching pennies game.	744
12.12	The matching pennies and the unprofitable game.	745
12.13	Distribution of locations for pooled data.	746
12.14	The pursuer–evader game and the 4×4 game in Levitt et al. (2010).	755
12.15	Type-I game ($z = 600$) and Type-II game ($z = 500$).	759
12.16	Coordination game (100 treatment).	762
12.17	Game 2R, game R, and game 0.6R.	768
12.18	A simple coordination game (SCG).	771
12.19	Median choice in sessions 1–10 over 15 periods in the continental divide game.	773
12.20	Average minimum effort levels over rounds 11–20 for different treatments.	775
12.21	Three equivalent stag-hunt games.	777
12.22	Minimum action chosen under different treatments in Block-I games.	781
12.23	Time paths of equilibria.	782
12.24	Three coordination games.	783
12.25	Average minimum effort in different treatments and rounds.	784
12.26	Average minimum effort level in different treatments and rounds.	785
12.27	A coordination stage game.	786
12.28	Frequency of agreements and disagreements over the whole period (left panel) and in the last 30 seconds (right panel).	793
12.29	Opening offers to player 2 for cells 1, 2, 5, and 6 in Table 12.22.	797
12.30	Opening offers to player 2 for cells 3, 4, 7, and 8 in Table 12.22.	798
12.31	Predictions of the model (bold line) versus the actual data in Roth et al. (1991) (dotted line) for offers and rejections in ultimatum games.	800
12.32	Player 1’s offer of the pie to player 2.	802
12.33	Optimal linear bidding functions for sellers and buyers.	807
12.34	Optimal bidding strategies for buyers and sellers in experiment 1 (left panel) and in experiment 2 (right panel).	809
12.35	The trade and no-trade regions in a two-sided asymmetric information bargaining game.	810

12.36	Trade outcomes for the no-communication, written, and face to face treatments.	812
12.37	Games G1 and G2.	814
12.38	Description of a bargaining table for one of the 24 games in Isoni et al. (2013).	815
12.39	The MOUSELAB computer display for the three-round bargaining game.	817
12.40	The signaling game in Brandts and Holt (1992).	820
12.41	Results for Treatment I.	826
12.42	Results for Treatment II.	828
12.43	Contribution rates under asymmetric information.	838
12.44	Contribution rates under full information.	839
12.45	Relative frequencies of cooperation, coordination, and efficiency.	842
12.46	The set of possible payoffs in a correlated equilibrium.	845
12.47	Percentage of actions consistent with the recommended play in the various treatments.	847
12.48	Beliefs for different recommendations for periods 31–60.	848
12.49	Symmetric game of chicken in Duffy and Feltovich (2010).	848
12.50	Equilibria in the game of chicken in Duffy–Feltovich.	850
12.51	The best response functions and equilibria in various cases.	854
12.52	Average degree of cooperation in each round for complements and substitutes.	855
12.53	Average degree of cooperation for non-JPM and JPM pairs.	856
12.54	A partial representation of the Fehr–Tyran (2008) experimental setting.	857
12.55	Payoff matrix for type y players in the substitutes case for the post-shock period.	859
12.56	Average nominal price across time in the complements and substitutes treatment.	860
12.57	Actual average prices and average best replies in the complements and substitutes treatments (Periods 16–18).	861
12.58	A plot of the demand and supply curves in Table 12.34.	866
12.59	The time path of prices over successive rounds of the experiment.	867
12.60	Price dynamics.	870
12.61	Price dynamics with ZI-C and ZI-U robot traders and humans.	873
13.1	Two-player matching pennies game.	884
13.2	QRE and Nash equilibrium for the cases $x = 1$ and $x = 3$.	885
13.3	Three normal form games.	886
13.4	Predictions of the quantal response equilibrium for games A, B, and C for various values of λ .	887
13.5	The bilateral crises game.	889
13.6	Claims, over time, for various values of R .	893
13.7	Average claims, logit predictions, and the Nash prediction in the traveller's dilemma game.	894
13.8	Results for the p-beauty contest game when $p = 2/3$.	898
13.9	Results for the p-beauty contest using diverse subject pools with $p = 2/3$, $a = 0$, $b = 100$.	899
13.10	The non-incentivized Chicago skyscrapers game in Crawford et al. (2008) with permission from American Economic Association.	905
13.11	Results with incentivized experiments in Crawford et al. (2008) with permission from American Economic Association.	905
13.12	Battle of Sexes game in Crawford (2007); $a > 1$.	908

13.13	A stag-hunt game.	912
13.14	A two-player market entry game ($a > 1$).	916
13.15	MOUSELAB interface in one of the games in Costa-Gomes et al. (2001) with permission of The Econometric Society.	917
13.16	The bravery game.	926
13.17	A guilt game.	927
13.18	The confidence game in Geanakoplos et al. (1989).	931
13.19	A simple example of a sequential move psychological game.	933
13.20	Dependence of utilities on beliefs of others.	935
13.21	Sequential prisoner's dilemma game.	937
13.22	Correlation between contributions and first order beliefs in a public goods game.	944
13.23	The effect of c and μ_R on p .	949
13.24	The relation between contributions and second order beliefs in the public goods game.	951
13.25	A partnership game in the absence and presence of guilt.	952
13.26	The effect of communication/promises on partnerships.	954
13.27	Bubble plots of the relation between induced second order beliefs and contributions in the dictator game (left panel) and the amount sent back by trustees in the trust game (right panel).	955
13.28	The distribution of the coefficients on guesses that are significant at the 5% level.	959
13.29	A psychological game in which utility depends on plans that are off the equilibrium path of play.	961
13.30	A coordination game.	963
13.31	A sequential move game.	967
13.32	Games G1 and G2 in Huck et al. (2011).	968
13.33	The prisoner's dilemma game.	977
13.34	A coordination game.	984
13.35	Logit best responses for the game in Figure 13.34 when the payoff from (R, S) is $(-14, 4)$.	985
13.36	An experimental game from Colman et al. (2014).	987
13.37	Actual and fitted bids as a function of the signals.	997
4.E1	Percentage of (B, B) choices in various rounds.	1004
4.E2	Three simple strategic form games and the choices of players.	1005
4.E3	An asymmetric matching pennies game in Goeree et al. (2005)	1006
4.E4	The Far Pavilions Game.	1007
4.E5	A zero-sum game of hide-and-seek.	1007
4.E6	Payoffs in the n -player stag-hunt game. The column player represents the group average and the row player is any of the n players.	1008
4.E7	Game 4 from Binmore et al. (2001).	1009
4.E8	A hawk-dove game.	1009
4.E9	A Trust game in extensive form.	1010
4.E10	Two normal form games from Jehiel (2005).	1010
14.1	The two-player prisoner's dilemma game.	1042
14.2	Relation between replicator dynamics, evolutionary stable strategies, and Nash equilibria.	1051

14.3	Graph of the replicator dynamics for the PD game.	1054
14.4	Payoff matrix for the two-period tit-for-tat game.	1055
14.5	Dynamics of the tit-for-tat strategy in a repeated prisoner's dilemma game.	1057
14.6	Payoff matrix for the game of chicken.	1057
14.7	A plot of the dynamic equation of motion in the game of chicken.	1058
14.8	The rock-scissors-paper game.	1059
14.9	Orbits for the rock-scissors-paper game.	1061
14.10	A two-player coordination game.	1061
14.11	Coordination game in the two-population case.	1062
14.12	A prisoner's dilemma game.	1074
14.13	Prisoner's dilemma game, modified to take account of inclusive fitness.	1074
14.14	Prisoner's dilemma game, modified to take account of direct reciprocity.	1078
14.15	Indirect reciprocity and the prisoner's dilemma game.	1079
14.16	Fitness levels from each strategy in two different populations.	1080
14.17	A two-population, 2×2 strategic form game.	1085
15.1	Results of fitting the data from 5 simple classes of 2×2 games.	1104
15.2	A symmetric 2×2 coordination game.	1109
15.3	Non-convergence of probabilities under fictitious play.	1110
15.4	A symmetric two-player coordination game.	1111
15.5	A 2×2 stage game.	1112
15.6	A comparison of stated and fictitious play beliefs.	1113
15.7	Three stag-hunt games with varying levels of the optimization premium.	1116
15.8	Introducing complexity through the channel of asymmetric information.	1119
15.9	Aggregate behavior across all experiments over 40 rounds of play.	1120
15.10	The EWA cube.	1124
15.11	Original game (left) and transformed game (right) based on an aspiration level of 7 for the row player and 6 for the column player.	1135
15.12	Q values for various learning models. Stationary concepts depicted in dark bars and learning models are depicted in light bars.	1137
15.13	Q values of various models with and without loss aversion.	1138
15.14	A 3×3 coordination game.	1142
15.15	Choice frequencies over various rounds of play.	1143
15.16	A 5×5 strategic form game from Stahl (2000).	1147
15.17	Six normal form games used in the experiments of Grimm and Mengel (2012).	1150
15.18	Predicted shares of A choices by row player, based on logit regressions, in treatments M, MI, M+F, and M+G.	1152
15.19	A 2×2 coordination game.	1154
16.1	A 2×2 coordination game.	1161
16.2	Simulated plot of the transitions between the two states.	1161
16.3	A symmetric two-player coordination game.	1162
16.4	A 1-tree and 2-tree for the coordination game.	1164
16.5	Payoff matrix for the technology adoption game.	1165
16.6	1-trees (first row), 2-trees (second row), 3-trees (third row) for the technology adoption game.	1165
16.7	A symmetric, 2×2 normal form game.	1168

16.8	A 2×2 coordination game.	1170
16.9	A coordination game with a <i>better informed</i> player.	1173
16.10	A generic 3×3 coordination game.	1174
16.11	No strict risk dominant equilibrium.	1175
16.12	A 3×3 coordination game.	1175
16.13	Non-equivalence between risk dominance and stochastic stability	1177
16.14	Description of utilities from carrying gold (G) or silver (S).	1179
16.15	A 3×3 coordination game in which the two players are drawn from different populations.	1180
16.16	Hypothetical distribution of farms.	1185
5.A1	Stability of steady states.	1191
5.A2	Stability of the steady state in a first order non-linear differential equation.	1192
5.A3	j -trees for two recurrence classes with one state each.	1202
5.A4	1-tree (first row), 2-tree (second row), 3-tree (third row) for the case of three recurrence classes with one state each.	1203
5.E1	A 2×2 game.	1205
5.E2	The stag-hunt game.	1205
5.E3	A hawk-dove game.	1206
5.E4	Evolutionary stable strategies are not unbeatable.	1206
17.1	Skin conductance response (SCR) amplitude and heart rate (HR), 0–12 s after offer presentation onset.	1232
17.2	Schematic description of the “risk as feelings” thesis.	1235
17.3	Dynamics in the cue-dependent model.	1241
17.4	Maximum payment as a proportion of current value to obtain/avoid outcomes at selected time delays.	1243
17.5	Mean happiness and real household income for a cross section of Americans in 1994.	1274
17.6	Relation between mean happiness and real per capita GDP for the US between 1975 and 1997.	1275
17.7	The Easterlin paradox for Japan, over the period 1958–1991.	1276
17.8	Before-win and after-win happiness of people who unexpectedly win the lottery.	1277
17.9	Comparisons of own incomes with the incomes of others in a cross section of countries with different income levels.	1279

8.2	The relevant economic information in each state of the world.	522
9.1	Choices among temporal sequences of meals.	603
10.1	Examples of discount functions when there is a reference point for time.	637
10.2	The delay function, speedup function, and generating function corresponding to common discount functions.	640
11.1	Optimal consumption profiles for two values of the coefficient of relative risk aversion, 0.5 (columns 2–4) and 1.5 (columns 5–7).	655
12.1	Treatments 2–7.	726
12.2	Conditional probability of choosing action D.	730
12.3	Conditional probabilities of action D at each of the six nodes.	733
12.4	Experimental results.	739
12.5	Percentage of subjects choosing various strategies in the 4×4 and 6×6 games.	743
12.6	Results for the symmetric condition.	747
12.7	Frequencies of card choices in various treatments.	750
12.8	Results for the 2×2 pursuer–evader game.	756
12.9	Results for the 4×4 game.	757
12.10	Checking for primary and secondary salience.	760
12.11	Responses compiled from Table 2 of Mehta et al. (1994).	760
12.12	Payoff matrix for game-I.	764
12.13	Payoff matrix for game-III.	764
12.14	Payoff matrix for treatment A.	766
12.15	Experimental results.	768

12.16	Experimental results.	770
12.17	Payoff matrix for the continental divide game.	773
12.18	A median action game (payoffs in cents).	776
12.19	Distribution of fifth period group minimum in various minimum action games.	778
12.20	Frequency of Pareto optimal coordination in period 10.	780
12.21	Description of the four bargaining games.	790
12.22	Description of various bargaining games in Ochs and Roth (1989).	796
12.23	Type-contingent messages sent by senders and message-contingent actions of the receivers for the matchings in each of the parts, a, b, and c.	821
12.24	Type-contingent payoffs of the incumbent in the market entry game.	823
12.25	Payoffs of the entrant in the two treatments.	823
12.26	Payoff matrix in an entry deterrence game.	829
12.27	Predictions of the equilibrium actions of the weak monopolist and the entrant.	829
12.28	Type-contingent assets and end of period value of firms.	832
12.29	Equilibrium predictions of the signaling model in Cadsby et al. (1990).	833
12.30	Actual and predicted results of the signaling model in Cadsby et al. (1990).	834
12.31	Relative frequencies of cooperation, coordination, and efficiency.	841
12.32	A description of the various treatments in Cason and Sharma (2007).	846
12.33	Frequencies of observed outcomes at the aggregate level.	851
12.34	Buyers' valuations, sellers' costs, and market data.	865
12.35	Some of the data from a double auction experiment reported in Davis and Holt (1993, p. 129).	869
13.1	Game 8 from Costa-Gomes et al. (2001).	903
13.2	Equilibrium actions in a level- k model without communication.	909
13.3	Optimal choice of messages and actions in the two-stage game with communication.	910
13.4	Percentage of voters from each political party expecting their own candidate to win in the US presidential elections.	976
4.E1	Goeree and Holt's replication of the Beard-Beil (1994) findings.	1003
4.E2	A signaling game from Goeree and Holt (2001).	1004
14.1	Number of conjugal unions of each type.	1069
14.2	Number of offspring for each conjugal pair.	1069
15.1	A comparison of the results of alternative learning models.	1105
15.2	Summary of the treatments in Huck et al. (1999).	1113
15.3	Results averaged across 40 rounds of play. * denotes significantly different from the predicted value at 5% and ** denotes significantly different at 0.1% level.	1119
15.4	Hit rates and the best fits arising from an application of various learning models to different games.	1128
15.5	Estimates for the parameters of the sophisticated and adaptive EWA models. Standard errors in parentheses.	1130
15.6	Average defection period, $k = 1, 2, \dots, 10$, for experienced subjects.	1134
15.7	Fits of various learning models based on a comparison of the log likelihoods.	1148
15.8	Frequencies of various choices of actions in games 1 and 4.	1151
15.9	Sequence of actions and own-payoffs in a two-player coordination game.	1154
17.1	Responses to the income comparison question.	1279
19.1	Assessed probability that the next flip of a coin will be heads (H), given a sequence of three flips; each flip is either heads (H) or tails (T).	1353
19.2	Violations of the conjunction fallacy.	1363

19.3	Empirical evidence for the <i>availability</i> and <i>affect</i> heuristics.	1367
19.4	Percentage of responses consistent with Bayes' rule in different empirical studies.	1377
19.5	Probability that the coin is head-biased, conditional on the observations.	1380
19.6	Mean probabilities assigned to each of four outcomes, 1–4, in the four events, A–D.	1385
19.7	Median values across decision makers.	1390
19.8	Different usages of the System 1–System 2 terms.	1399
19.9	The cue values for each of the four cities.	1419
21.1	States and transition probabilities in the mean reverting model (M).	1521
21.2	States and transition probabilities in the trending model (T).	1521
21.3	Markov transition probabilities for the two states of the world.	1522
21.4	Simulations for the Barberis et al. (1998) model.	1525
7.E1	A summary of the composition of two different dinner sets.	1545
7.E2	Two different problems given to two groups of subjects in a between-groups design.	1545
22.1	Fraction of subjects who pay the fee in each treatment.	1608
8.E1	Payoffs in state 1.	1635
8.E2	Payoffs in state 2.	1636
8.E3	Payoffs for each pair of actions and psychological states.	1636

Introduction

The *neoclassical framework* in economics provides a coherent and internally consistent body of theory that offers rigorous, parsimonious, and falsifiable models of human behavior. Augmented with auxiliary assumptions, it is flexible enough to analyze a wide range of phenomena and its qualitative predictions often accord with one's gut feeling about many phenomena. For instance, under suitable assumptions, consumers buy less when the price is higher, and more when their incomes are higher; socially undesirable activity typically falls when the probability of detection and fines is higher; workers often respond positively to monetary incentives; in many cases, changes in tax rates and devaluations have had the predicted effects on economic activity; banning certain activities often drives them underground.

Throughout the book, I avoid the loaded term *standard economics* to refer to *neoclassical economics* because this might give the latter a certain empirical sanctity. In actual practice, the neoclassical framework includes, but is not restricted exclusively to, consistent preferences, subjective expected utility, Bayes' rule to update probabilities, self-regarding preferences, emotionless deliberation, exponential discounting, unlimited cognitive abilities, unlimited attention, unlimited willpower, and frame and context independence of preferences. Neoclassical economics is also typically underpinned by optimization based solution methods and an equilibrium approach.

In principle, the neoclassical framework is capable of relaxing many of its standard assumptions. For instance, it can allow for reference dependence preferences, social preferences, frame dependent preferences, and non-exponential models of discounting. However, these extensions are rare in actual practice, and when they are made, the neoclassical framework typically does not have fundamental new insights to offer. For instance, adding reference dependent preferences generates few, if any, insights in the absence of a theory about how human behavior differs in the domains of gains and losses relative to a reference point. Similarly, adding other-regarding preferences without attempting to fit such a model to the behavior of humans, particularly to the evidence from experimental games, offers little progress. For these reasons, my use of the term *neoclassical economics* in this book, is shorthand for *the typical practice in neoclassical economics*.

The intellectual developments in neoclassical economics that preoccupied some of the best brains in economics in the twentieth century are truly impressive. However, its empirical success in predicting and explaining human behavior is modest. Indeed, an impressive thorough and detailed body of experimental, neuroeconomic, and field evidence, based on several decades of work, raises serious concerns about the core assumptions and predictions of neoclassical models. This has been matched by impressive theoretical developments, drawing on insights from psychology, biology, anthropology, sociology and other social sciences, that has come to be known as *behavioral economics*. These models have had much greater empirical success relative to neoclassical models.

Increasing the explanatory power of neoclassical economics is very worthwhile in its own right, but Thaler (2015) adds another reason for studying behavioral economics in his inimitable style: “Behavioral economics is more interesting and more fun than regular economics. It is the undismal science.”

This book offers an account of formal behavioral economic theory, its applications, and a discussion of the underlying experimental and field evidence.¹

I do not feel it is necessary to enter into a very detailed discussion, often quite fruitless, about the definition and scope of behavioral economics. There is a danger that one may propose definitions that are either too broad and have ambiguous scope, or too narrow with limited scope; each of these outcomes would be unfair for a newly emerging field. Any falsifiable theory that replaces/modifies any of the core features of neoclassical economics, by alternatives that have a better empirical foundation in human behavior is a potential member of the class of behavioral economic theories, if it can pass stringent empirical tests.

The standard toolkit in neoclassical economics is adequate for the study of behavioral economics, which, in many cases, offers a conservative, yet empirically critical, extension to neoclassical models. Most behavioral models adopt the same underlying optimization framework, are typically underpinned by axiomatic foundations, are parsimonious, rigorous, falsifiable, and internally consistent. I use the word “rigorous” purely for its practical appeal to most neoclassical economists but I agree with the sentiments expressed by Gintis (2009, p. xviii): “The economic theorist’s overvaluation of rigor is a symptom of their undervaluation of explanatory power. The truth is its own justification and needs no help from rigor.”

Let us note three points upfront lest there be any confusion. First, behavioral economics is an enhancement of neoclassical economics to take account of more empirically supported evidence on human behavior, and not its antithesis. Second, there is no paradigmatic battle between behavioral economics and neoclassical economics. As in every science, we progress by taking account of evidence that suggests a refinement and improvement of existing models. In this case, the relevant improvement appears to have the steepest gradient in the direction of constructively incorporating insights from other social sciences, but most notably from psychology. Third, although the book provides a great deal of evidence that is contrary to many of the core assumptions of neoclassical economics, it is not about simply bashing inadequate neoclassical assumptions and predictions. Rather, it offers a constructive way forward by highlighting developments in behavioral economic theory and suggesting a research program in this direction. My personal hope is that behavioral economics ceases to exist as a separate field within economics, and this becomes the normal way in which we do economics.

A distinction is sometimes drawn between experimental economics and behavioral economics.² However, the activity of behavioral economists and experimental economists is complementary and collaborative. It is often difficult to spot the dividing line between their work. For instance, experimental economists not only test the predictions of economic models, but their results have often been critical in suggesting further developments in behavioral models. Behavioral theorists on the other hand, often suggest experiments that could test their proposed theories.

¹ For a non-technical treatment of behavioral economics, the reader can consult the extremely readable and witty account by Thaler (2015) that offers a much more detailed historical account of developments in behavioral economics from the 1970s onwards from a personal perspective.

² Loewenstein (1999) gives a nice discussion of the methods in each of these areas and offers the following definition (p. F25): “BEs [behavioral economists] are methodological eclectics. They define themselves, not on the basis of the research methods that they employ, but rather their application of psychological insights to economics. In recent published research, BEs are as likely to use field research as experimentation . . . EE [experimental economists] on the other hand, define themselves on the basis of their endorsement and use of experimentation as a research tool.”

The introduction is intended to be a substantial stand-alone chapter in its own right that is integral to the book. Its purpose is to provide essential material and insights that sets the stage for the rest of the book. Perhaps, it ought also to be assigned as essential background reading in any advanced microeconomics course. Section 1 traces some of the historical developments that led to modern behavioral economics. Section 2 considers a descriptive and prescriptive approach to how economists practice their craft. Section 3 considers the role of the experimental method in behavioral economics. Section 4 considers the approach adopted by the book, and offers brief comments about the organization of the book. Section 5 outlines five theoretical ideas in behavioral economics, locating them within the larger literature, and evaluating them against the empirical evidence. Section 6 considers the empirical evidence on five interesting questions asked by, or of, behavioral economics. There are two appendices. Appendix A outlines the random lottery incentive mechanism that lies at the heart of the modern experimental method in economics. Appendix B asks you to think of 50 questions as a problem set, but I deliberately give you very little structure at this stage in order to enable a free-spirited approach to the answers. Rigorous answers to these questions can be found in the book.

1 The antecedents of behavioral economics

While Adam Smith's justly celebrated book, *The Wealth of Nations*, is widely cited, his other book, *The Theory of Moral Sentiments*, has received less attention. *The Theory of Moral Sentiments* reads like an agenda for modern behavioral economics; it recognizes many behavioral phenomena such as loss aversion, altruism, emotions, willpower, and the planner–doer framework (Ashraf et al., 2005). Classical economists such as Jeremy Bentham wrote about the psychological underpinnings of utility and Francis Edgeworth wrote about social preferences (Camerer and Loewenstein, 2004). Bardsley et al. (2010) trace the beginnings of experimental economics to the classical economists such as David Hume, Stanley Jevons, and Francis Edgeworth; Jevon's marginal utility analysis derived its motivation from experimental observations about the relation between stimuli and sensations.

Two factors contributed to the gradual elimination of psychology from economics. First, around the turn of the twentieth century, there was “a distaste for the psychology of their period, as well as the hedonistic assumptions of Benthamite utility” (Camerer and Loewenstein, 2004). The second was the revealed preference approach popularized by Paul Samuelson that emphasized the observation of *choice behavior* rather than the psychological foundations for choice behavior (Bruni and Sugden, 2007). Glimcher and Fehr (2014, p. xviii) write: “It cannot be emphasized enough how much the revealed-preference view suppressed interest in the psychological nature of preferences, because clever axiomatic systems could be used to infer properties of unobservable preference from choice.”

Important, and path-breaking, developments in behavioral economics took place in the 1950s and 1960s that included: violations of the independence axiom of expected utility theory (Allais, 1953); violations of subjective expected utility (Ellsberg, 1961; Markowitz, 1952); demonstration of the importance of bounded rationality (Simon, 1978; Selten, 1998);³ and early work on quasi hyperbolic discounting (Phelps and Pollak, 1968). However, at that time, this work struggled to get the attention that it deserved.

³ Simon (1978) refers to Herbert Simon's Nobel lecture that traces the historical development of bounded rationality through the 1950s and 1960s. Selten (1998) is an English language version of a paper that appeared initially in German in 1962.

An important catalyst for the development of behavioral economics was the decline of the behavioralist school in psychology, and the emergence of cognitive psychology. Cognitive psychology emphasized the role of mental processes in the understanding of tasks involving decision making, perception, attention, memory, and problem solving. Some cognitive psychologists naturally turned their attention to testing their models against the neoclassical framework. The two most important cognitive psychologists in this category were Daniel Kahneman and Amos Tversky, whose work in the 1970s helped kick-start modern behavioral economics. Along with Richard Thaler, who was an economist by training, and was struggling to make sense of several anomalies in neoclassical economics from the mid 1970s onwards, they are some of the earliest modern behavioral economists.

Before I discuss some of the seminal ideas and insights of modern behavioral economics,⁴ in Sections 5 and 6, I take a detour into two topics without which it could be difficult to fully appreciate the behavioral framework.

The first digression is on the *role of methodology in economics* that I consider in Section 2. In my defense, I cannot offer a better justification for this digression than the following quote from Gintis (2009, p. xvi) that nicely captures the essence of the problem:

Economic theory has been particularly compromised by its neglect of the facts concerning human behavior. . . . I happened to be reading a popular introductory graduate text on quantum mechanics, as well as a leading graduate text in microeconomics. The physics text began with the anomaly of blackbody radiation, . . . The text continued, page after page, with new anomalies . . . and new, partially successful models explaining the anomalies. In about 1925, this culminated with Heisenberg's wave mechanics and Schrödinger's equation, which fully unified the field. By contrast, the microeconomics text, despite its beauty, did not contain a single fact in the whole thousand-page volume. Rather the authors built economic theory in axiomatic fashion, making assumptions on the basis of their intuitive plausibility, their incorporation of the "stylized facts" of everyday life, or their appeal to the principles of rational thought. . . . We will see that empirical evidence challenges some of the core assumptions in classical game theory and neoclassical economics.

The second topic is the *role of experimental evidence in economics* that I consider in Section 3. The justification for this section is the continued skepticism of many economists about experimental economics, which constitutes an important part of the evidence base for behavioral economics. The following quote attributed to the Nobel Prize winner Gary Becker from a magazine interview (Camerer, 2015, p. 250) is probably not unrepresentative: "One can get excellent suggestions from experiments, but economic theory is not about how people act in experiments, but how they act in markets. And those are very different things. That may be useful to get suggestions, but it is not a test of the theory. The theory is not about how people answer questions. It is a theory about how people actually choose in market situations."

What follows is a somewhat long introduction, but this is a somewhat long book too. In mitigation, the first one third of the introduction largely deals with background material that reflects the somewhat unsettled nature of economics. My hope is that if a second edition of this book is ever written, then there would be enough convergence of views on this material, so that I can safely omit it.

⁴ I must recommend to the reader two must-read non-technical, but intellectually rich and deep, accounts of some of the central ideas in behavioral economics and the modern history of the subject. The first is Kahneman (2011) that focuses mainly on judgment and decision making and the second is an incredibly entertaining personal account by Thaler (2015) that covers a wide range of topics such as fairness, mental accounting, and behavioral finance.

2 On methodology in economics

The actual practice of behavioral economics is influenced, directly or indirectly, by Popperian views on methodology (Popper, 1934, 1963). Popper begins by distinguishing between science and non-science. A scientific hypothesis must be falsifiable in the sense that it must specify the conditions under which the hypothesis can be rejected. Further, one can only refute theories but never prove that they are true. For instance, the observation of a million white swans is consistent with the hypothesis that “all swans are white” but does not prove that the hypothesis is true; for the very next observation could be a non-white swan.

The best recipe for the advancement of science, in the Popperian view, is to subject scientific hypotheses to stringent testing, i.e., expose the hypotheses to tests that are most likely to reject them. In the strict Popperian view, one observation that is contrary to a hypothesis rejects it. For instance, a single observation of a black swan rejects the hypothesis that all swans are white. Science progresses by advancing a new hypothesis that explains everything that a rejected hypothesis explained, but, in addition, it explains some new phenomenon that the rejected hypothesis could not. For an application of the Popperian position to economic contexts, see Blaug (1992), Hausman (1992), and Hands (2001).

One concern with the Popperian approach is that a test of a hypothesis is a joint test of the hypothesis and several auxiliary assumptions. Thus, a rejection may arise because the hypothesis is incorrect, or the auxiliary assumptions might have been rejected, or both; this is known as the *Duhem–Quine thesis* (DQT). For instance, in an experimental test that rejects mixed strategy Nash equilibrium, one might wonder if the rejection was caused by one of several confounding factors, such as an inappropriate subject pool, unclear experimental instructions, and inadequate incentives.

While the Popperian position is *prescriptive* (how should we best do science?), a *descriptive* view (how is science actually done?) was offered by Kuhn (1962). Kuhn noted that knowledge in science does not accumulate in a linear manner. He highlighted, instead, the role of periodic revolutions in science, or an abrupt transformation in the existing worldview, a *paradigm shift*. He distinguishes between three phases in the development of any science. In Prescience, there is no central paradigm, but there is an attempt to focus on a set of problems. In normal science, the longest of the three phases, there is the establishment of a central paradigm, great progress is made in answering many of the questions posed during Prescience, and much success is achieved in answering new questions. In a departure from the Popperian prescriptive position, in this phase, rejections of the paradigm are robustly challenged or ignored, and belief in the paradigm is unshakable. However, as anomalies gradually begin to accumulate, and reach a tipping point, a crises takes place in the paradigm. There is a sudden paradigm shift and a new paradigm that subsumes the old paradigm takes its place.

One prescriptive response to the DQT and to Kuhn’s descriptive ideas, while retaining a Popperian approach, was proposed by Lakatos (1970) under the name: *The methodology of scientific research programs* (MSRP). Lakatos distinguished between a set of non-expendable statements or assumptions, which is the *hard core of a research program*, and a set of expendable auxiliary assumptions. In a distinctly non-Popperian recommendation, but reminiscent of the normal science phase of Kuhn, the hard core is insulated from refutation; this also addresses the DQT. For instance, Newtonian physics has a hard core that comprises of the three laws of dynamics and a law of gravitation. Any refutation of the research program, in this phase, is then ascribed to a failure of the auxiliary assumptions, which are modified to explain the refutation.

One potential defense of this approach is that it allows for a period of time for the development of a new research program that can take account of the emerging refutations. However, a practical downside could be that proponents of a research program might engage in defensive methodology for far too long, and resist the development of a new research program that has a different hard core. To take account of this possibility, Lakatos termed a research program as *theoretically progressive*, if refinements that take place by altering auxiliary assumptions but not the hard-core, lead to the explanation of existing anomalies and to novel predictions. A research program is *empirically progressive*, if the novel predictions are not refuted. Adherence to a hard core is only admissible if research programs are theoretically and empirically progressive.

Eventually anomalies play the most important part in giving rise to new research programs; Lakatos noted that all theories are born into and die in a sea of anomalies.⁵ The reader may find below that the actual practice in behavioral/experimental economics appears to be closer to the Lakatosian view than the Popperian view.⁶ For instance, in decision theory, the hard core may be thought to comprise of completeness, transitivity, and first order stochastic dominance (Bardsley et al., 2010, p. 129). Indeed, neither expected utility theory nor the main behavioral alternatives such as rank dependent utility, theory of disappointment aversion, or prospect theory, are willing to relax the assumption of well-behaved preferences. This makes it difficult for most decision theories to explain framing effects, although prospect theory is potentially able to capture framing effects through changes in the reference point.

In light of this brief discussion on methodology, let us return to the “neglect of the facts concerning human behavior in economics” that Herbert Gintis highlights above. Why should such a situation have arisen? In order to understand this, consider the following three representative views, written by some of the leaders in neoclassical economics.

Dekel and Lipman (2010, p. 264) write: “Hence the choice of a model will depend on the purpose for which the model is used, the modeler’s intuition, and the modeler’s subjective judgment of plausibility One economist may reject another’s intuition, and, ultimately, the marketplace of ideas will make some judgments.”

Gilboa et al. (2014, p. F. 516) write: “In particular, we agree that: economic models are often viewed differently than models in the other sciences; economic theory seems to value generality and simplicity at the cost of accuracy; models are expected to convey a message much more than to describe a well-defined reality; these models are often akin to observations, or to gedankenexperiments; and the economic theorist is typically not required to clearly specify where his model might be applicable and how.”

Rubinstein (2006, p. 882) writes: “As in the case of fables, models in economic theory are derived from observations of the real world, but are not meant to be testable. As in the case of fables, models have limited scope. As in the case of a good fable, a good model can have an enormous influence on the real world, not by providing advice or by predicting the future, but rather by influencing culture. Yes, I do think we are simply the tellers of fables, but is that not wonderful?”

Modern economics has been heavily influenced by the *instrumental position* taken by Friedman (1953). Friedman argued that we should not judge economic theories by the realism of its assumptions but rather, by the accuracy of its predictions. He writes (p. 14): “Truly important and

⁵ Closer to home, economists would remember the influential *anomalies feature* that Richard Thaler wrote for the *Journal of Economic Perspectives* from 1987 to 2006. Indeed, in the very first piece, Thaler, keenly aware of methodological issues, quoted from Thomas Kuhn.

⁶ For a critique of the Lakatosian approach as applied to economics, see Hands (1991) and De Marchi and Blaug (1991).

significant hypotheses will be found to have ‘assumptions’ that are wildly inaccurate descriptive representations of reality, and, in general, the more significant the theory, the more unrealistic the assumptions To be important, therefore, a hypothesis must be descriptively false in its assumptions” And shortly thereafter (p. 15) he writes: “To put this point less paradoxically, the relevant question to ask about the ‘assumptions’ of a theory is not whether they are descriptively ‘realistic,’ for they never are, but whether they are sufficiently good approximations for the purpose in hand.”

A natural progression of Friedman’s position can be found in Gilboa et al. (2014, F. 514): “Why does economic theory engage in relatively heavy technical analysis, when its basic premises are so inaccurate? Given the various violations of fundamental economic assumptions in psychological experiments, what is the point in deriving elaborate and carefully proved deductions from these assumptions? Why do economists believe that they learn something useful from analyzing models that are based on wrong assumptions?” Their answer to these question is based on an identification of economic models with *case-based reasoning* rather than *rule-based reasoning*. Rule-based reasoning requires the formulation of general rules or theories. In contrast, case-based reasoning requires one to draw inferences based on similar past cases. The purpose of economic models, in this view, is to add to the bucket list of cases and analogies that can be used to draw inferences now, or at some point in the future.

These views give a fair bit of insight into contemporary thinking in economics about how we should go about practicing our craft. I also believe that acceptance of these views is widespread in the economics profession and many economists challenged on these views are outrightly dismissive. Initial intuition about economic models, whether motivated by existing empirical evidence, or a desire to make novel predictions, must begin from somewhere. Here, the role of initial conjectures as parables, useful stories, or fables to inform one’s intuition about better and more complete models is surely important. But this cannot be the justification for continued reliance on a set of models that have faced persistent refutation, or to wish to shield them from refutation by seeking a special status for them.

Indeed, many of the contemporary methodological views in economics are retrogressive and a license to engage in defensive methodology to protect the status quo. Friedman’s approach has been much misused in economics. Consider the following entirely reasonable description of Friedman’s approach to *model building* (as distinct from evaluating theories) in Gintis (2015, p. 223) that this book concurs with: “The goal of model-building [is] to create a tractable analytical structure, analyze the behavior of this structure, and test the fruitfulness of the results by comparing them with empirical data.”⁷

Consider “normal” practice in physics; I encourage the reader not to judge natural sciences by a few well-publicized outliers. In a letter to the *London Times*, dated November 28, 1919, Albert Einstein described his *theory of relativity* in comparison to *Newtonian physics*, to a lay audience. Einstein mentioned two predictions of his theory that had been confirmed (both in domains where his theory was most likely to fail, hence, these are “stringent tests”): (1) Revolution of the ellipses of the planetary orbits round the sun, which was confirmed for Mercury. (2) The curving of light rays by the action of gravitational fields. He mentioned one prediction that had not yet been confirmed (displacement of the spectral lines toward the red end of the spectrum in the case of light transmitted to us from stars of considerable magnitude); indeed at the time Einstein published the theory of relativity, it was not even clear how to test this prediction. Einstein then

⁷ Readers interested in pursuing this approach further can consult Godfrey-Smith (2006, 2009) and Wimsatt (2007).

wrote (p. 4): “The chief attraction of the theory lies in its logical completeness. If a single one of the conclusions drawn from it proves wrong, it must be given up.”

I invite the reader to pause for a moment to compare Einstein’s approach with the “mainstream” views in economics that I have outlined above. Indeed, as Bardsley et al. (2010, p. 8) note: “But it is surprisingly common for economists to claim that the core theories of their subject are useful despite being disconfirmed by the evidence.”

The tendency to discount experimental evidence in economics, despite its growing importance and prominence, is probably an important factor in ignoring “uncomfortable” evidence in economics; see Section 3 below. Another important factor is that Friedman’s instrumental position has been used as a license by some to make ad-hoc auxiliary assumptions, and others to genuinely believe that their assumptions are literally true in an “as if” sense. Any empirical rejection of the “as if” assumptions is often rejected on the grounds that the evidence is flawed, untrustworthy, based on dubious experimental methods, or lacks external validity. This is a form of defensive methodology that is inimical to the progress of economics, and I urge the reader to resist it.

Behavioral economics offers an easier resolution of the “as if” approach. There is now compelling evidence (see Sections 5, 6) which shows that some of the central tenets of neoclassical economics are neither true in an “as if” sense, nor are their predictions always satisfactory when subject to stringent tests.

Schotter (2015) offers the following critique of Friedman’s position. Suppose that assumptions x , y , and z lead to some theory T . Suppose also that one or more assumptions are violated by the empirical evidence, yet T makes a successful prediction. Then there are three possibilities. (1) The violated assumptions are superfluous for the theory, at least in the context where the theory was tested. (2) The violated assumptions counteract each other perfectly, so they do not affect the prediction. (3) The successful prediction is a fluke. Conversely, if the assumptions are correct and the model is complete then we expect T to make successful predictions anyway. Thus, it is difficult to justify a theory based on patently false assumptions. Schotter (2015, p. 63) observes, correctly: “after all, the assumptions are the theory.”

My colleague, Ali al-Nowaihi, likes to give the following example that applies to birds who cannot swim (e.g., gannets can swim, so they are excluded). Birds fly, so one may theorize that they behave “as if” they understand the laws of aerodynamics. This is an admissible hypothesis, but then one must test the “as if” assumption. Given that air is basically a fluid, so birds might also be assumed to know the laws of hydrodynamics. If the “as if” presumption were true in this case, then birds released under water should try to swim, but they actually try to fly, and drown. Thus, the original “as if” supposition is false. If the “as if” assumptions are not tested properly, then we can never have any degree of confidence in the models based on these assumptions.

A common view in economics (shared unfortunately by some behavioral/experimental economists, I must add) appears to be that there is something rather difficult and unique about testing economic theories, relative to the natural sciences. So, at least implicitly, the argument goes, one needs to accord a “special status” to economic theories. Consider the following representative quote from Richard Lipsey’s wonderful introduction to economics [Lipsey, 1979, p. 8] cited in Bardsley et al. (2010, p. 6–7) that, I suspect, many economists would agree with: “Experimental sciences, such as chemistry and some branches of psychology, have an advantage because it is possible to produce relevant evidence through controlled laboratory experiments. Other sciences, such as astronomy and economics, cannot do this.”⁸ This mainstream view is contestable

⁸ And here is a similar view from a celebrated text in economics (Samuelson and Nordhaus, 1985, p. 8): “Economists (unfortunately) . . . cannot perform the controlled experiments of chemists or biologists because they

and there appears to be a misunderstanding about the relative difficulty of testing theories in the natural sciences and in economics.

The view that testing of theories is somehow easy or easier in the natural sciences, as compared to economics, must surely be deeply offensive and insulting to experimenters in the natural sciences. The Higgs boson or Higgs particle was proposed by British physicist Peter Higgs in the early 1960s, and it took 50 years of incredibly hard efforts to confirm the particle in 2013. Particle physicists did not seek a *special status* for this theory that could insulate it from rejection. The enormously high energies required to test for the Higgs particle required the construction of a very expensive and complex experimental facility, CERN's Large Hadron Collider, that eventually confirmed the theory. Note also that Peter Higgs was made to wait 50 odd years and given the Nobel Prize in physics only after his theory was confirmed. He was not given the Nobel on any of the following criteria: elegant and beautiful theory, useful model that helped the intuition of particle physicists, or a fable or useful story that aids in the understanding of how the universe began.

Astronomers who dealt with the question of the distance of earth from distant objects, or the chemical composition of stars that are millions of light years away, did not also seek a special status for their subject. They got on with the difficult job of seeking the relevant measurements, often using indirect evidence and clever implications of theory. They were eventually successful after several decades of work. Are economists seriously arguing that their measurement problems are more difficult than the problems in the natural sciences? Cosmic microwave background radiation was first proposed in 1948, but experimentally confirmed due to an accidental discovery in 1964. DNA was first isolated in 1869, but it took the most part of a century to find the double-helix structure of DNA, and confirm it by experimental evidence in 1953. The germ theory of disease was proposed in the mid sixteenth century, yet confirmation of the theory occurred in the seventeenth century. The pool of such examples is very large. The process of discovery, measurement, and of testing the theory, can be a long and arduous one; seeking a special status for the subject is defeatist and put bluntly, lazy.

Economists opposed to lab/field data are likely to argue that the behavior of humans is too noisy, heterogenous, and fickle, which is not a problem in the natural sciences (e.g., atoms are, after all, not subject to mood swings). This overstates the degree of difficulty in testing economic theories, relative to those in the natural sciences on at least two grounds.

1. Experimental economics has discovered systematic human behavior in many of the most important domains in economics. A small sample includes reference dependence, loss aversion, non-linear probability weighting, conditional cooperation, intention-based reciprocity, present-biased preferences, and importance of emotions such as regret, guilt, and disappointment. These behaviors are also underpinned by neuroeconomic evidence. Replication of experimental results is routine, and if similar subject pools and protocols are used, experiments produce replicable data. Examples are results from double auction experiments, and a range of games that demonstrate human prosociality, such as the ultimatum game, the gift exchange game, the trust game, and the public goods game; these examples can be multiplied many fold, as the results in this book attest.
2. If indeed human behavior is inherently too noisy and heterogenous, then economic theory needs to focus more efforts in this direction. When Brownian motion was discovered in 1827 by Robert Brown, in the behavior of pollen grains, physicists did not throw up their arms in despair. Important work in the late part of the nineteenth century, and by

cannot easily control other important factors. Like astronomers or meteorologists, they generally must be content largely to observe."

Einstein in the early 20th century, paved the way for describing not only the mathematics of Brownian motion, but also predicting the probability distribution of particles in Brownian motion. Perhaps, in an analogous manner, economic theories need to predict the probability distribution of economic behavior, which can then be tested in experiments.

Experimental economics in the lab, and in the field, has made enormous progress in developing new econometric techniques for small samples, and in novel experimental methods. It has also deeply enhanced our understanding of human behavior and allowed for stringent testing of economic theory. This progress is inconsistent with the view that we should grant a special status to economic theories that exempts them from careful and stringent testing. The differences in experiments in economics and the natural sciences are much smaller relative to the differences in attitudes and institutions in the two fields of study. Progress in economics will be substantially enhanced if we learn from best practice, and give up our implicit demand for special status.

3 The experimental method in economics

Work on experiments in behavioral economics gained particular momentum following the seminal work of Daniel Kahneman and Amos Tversky in the 1970s. However, a number of important experiments in economics were also conducted in the late 1940s, the 1950s, and the 1960s. These include Richard Chamberlain's testing of general competitive equilibrium (Chamberlain, 1948); Maurice Allais's work on demonstrating violations of the independence axiom in expected utility theory (Allais, 1953); Vernon Smith's work on induced value elicitation and double auction experiments in competitive settings (Smith, 1962); and Sidney Siegel's experiments on bargaining (Siegel and Fouraker, 1960). Other prominent figures who were either involved in experimental economics, or expressed an interest in it during the 1950s and 1960s included Ward Edwards, Reinhard Selten, Martin Schubik, Herbert Simon, Charles Plott, Donald Davidson, and Pat Suppes; for a brief historical sketch see Guala (2008) and Bardsley et al. (2010).

Experimental economics is now mainstream by most yardsticks, particularly in terms of its presence in peer reviewed journals in economics. In his early surveys on experimental economics, Roth (1987, 1988) hoped that experimental economics would perform three kinds of functions. Speaking to theorists (testing economic theory), searching for facts (generating novel empirical regularities that could be modeled by subsequent theory), and whispering in the ears of princes (offering reliable policy advice). Roth (2015) takes stock of experimental economics on these criteria and finds that it is thriving. One of his case studies, on bargaining behavior, is outlined in detail in Part IV of the book.

At one level, there has been a complete denial of the usefulness of experiments in economics. Friedman (1953, p. 10) views the domain of empirical testing in economics to be naturally occurring field data: "Unfortunately, we can seldom test particular predictions in the social sciences by experiments explicitly designed to eliminate what are judged to be the most important disturbing influences. Generally, we must rely on evidence cast up by the 'experiments' that happen to occur." A modern critique of the experimental method in economics is offered by Levitt and List (2007). They list several objections to experimental results that I address in subsequent sections.

(1) Participants in experiments are subjected to unprecedented experimental scrutiny. Since subjects may perceive that they are being watched over by the experimenter, they may give responses that the experimenter really desires (*experimenter demand effects*; see Zizzo, 2010) or

they may not reveal their true underlying preferences. For instance, they worry that participants may engage in more prosocial behavior than they really intend to.

Whilst I reserve my detailed responses to later sections, I find it somewhat curious that if subjects are accused of being influenced by experimenter demand effects, say out of guilt or shame, then they appear to exhibit social preferences (or beliefs may directly enter their utility functions, as in psychological game theory), which is precisely what is being disputed by the critics.

(2) In actual practice, human decisions are context-dependent and influenced by cues, social norms, and past experiences. It is not clear that experiments can capture these factors. For instance, participants in experiments may import an inappropriate “outside context” into their responses in experiments.

(3) Actual human behavior is strongly affected by stake sizes in experiments. Experiments are typically conducted with small stakes, so they might not capture the richness of human behavior that arises from varying stakes.

(4) There could be self-selection biases caused by student volunteers who might be particularly prosocial, younger, more educated, and have a higher need for approval, as compared to the average human population. In contrast, people who self-select themselves into real market situations, might be particularly suitable to do well in real markets.

(5) Choice sets in experiments might be particularly restrictive relative to the real world. For instance, there could be more prosocial options in experiments relative to the real world.

(6) The results of lab experiments may generalize poorly to real-world behavior for all of the reasons mentioned in (1) through (5), above. This issue of *external validity* of lab experiments is the main concern raised by the authors who write (p. 170): “Perhaps the most fundamental question in experimental economics is whether findings from the lab are likely to provide reliable inferences outside of the laboratory.”

This discussion briefly encapsulates the modern case against experimental economics. Let us now briefly examine these claims.

3.1 Experiments and internal validity

Experiments allow for unprecedented control over the economic environment, hence, they have high *internal validity*, which is critical for stringent tests of economic theories. Internal validity is reduced when there are, for instance, selection issues, confounds in treatments, and unclear experimental instructions, all of which are carefully addressed in modern experimental work. Thus, in well-conducted experiments, the complicated identification strategies of field studies can be replaced by clever and much simpler experimental design.

For instance, suppose that a researcher is interested in testing if higher wages elicit higher effort in a firm; this is known as a *gift exchange game*. A field experiment is likely to be influenced by strategic behavior and reputational concerns of the workers and firms; field experiments in general, are likely to have lower internal validity. However, in a lab experiment, these factors are easily controlled, allowing one to cleanly separate the relation between a fair-wage and effort. The high degree of experimental control in lab experiments allows for replication of lab results. For the converse reason, the results of field experiments are more difficult, and sometimes impossible to replicate when one is given access to a unique field environment.

Experiments can also test the predictions of theory in a parameter space that might be difficult to observe in the field. This is similar to extreme stress tests of aircraft frames under conditions that are not normally encountered in the actual operation of the aircraft, or the exposure of bridge designs to extreme environmental conditions. In a nutshell, all this allows for more stringent tests

of economic theory. Experiments are sometimes criticized on the grounds that the sample sizes are small. Falk and Heckman (2009) term this issue as a “red herring” on the grounds that there have been important developments in small sample econometrics, and many experiments do use large subject pools.

Camerer (2015) argues that there is no evidence of experimenter demand effects, despite the suspicion that there might be such effects; see also his discussion of the alternative interpretations of experimenter demand effects in Hoffman et al. (1998). There are several reasons why experimenter demand effects may be weak or non-existent. Such demand effects require two conditions. First, subjects must know the experimenter’s preferred hypothesis. Second, they should be willing to sacrifice their own experimental earnings in order to favor the experimenter’s preferred hypothesis.

On a-priori grounds, arguably, it is often quite hard for subjects to know the experimenter’s preferred hypothesis. This arises particularly when (i) experimental instructions are carefully worded to prevent any such inference, and (ii) the experimenter might not be sure which of the competing hypotheses actually hold. However, if subjects can somehow guess the preferred hypothesis, then stakes can be raised to levels where they are too difficult to sacrifice for the sake of pleasing the experimenter. However, in most cases, the results with high stakes are not dramatically different from those with modest stakes (Camerer and Hogarth, 1999).⁹ In three preference reversal experiments, Lambdin and Shaffer (2009) find that the percentage of subjects who were successfully able to guess the preferred hypothesis of the experimenter was 7%, 32%, and 3%.

The degree of anonymity in lab experiments can be varied, so it is an ideal environment to test for the effects of variation in the degree of anonymity (Bolton et al., 1998). One’s actions are often observed by others in real-world situations, and in many field situations, where controlling for such scrutiny, and varying its level is typically even more difficult. The criticism of lab experiments on grounds of scrutiny (by the experimenter and other participants), also applies to field experiments, insofar as field subjects realize that they are in an experiment. Such experimenter demand effects may arguably, in many cases, be even stronger in field experiments, which are typically run in collaboration with governmental and semi-governmental bodies, and NGOs.

It is indeed the case that when subjects are observed in dictator game experiments in the lab, they give higher amounts (Dana et al., 2007; Haley and Fessler, 2005). In many real-world giving situations, one is also observed by others; for instance, church collections that take the form of passing along a collection plate/basket, or having to declare one’s charitable contributions for tax purposes. However, the effect of being observed disappears if one introduces a minimal element of strategic interaction as, say, in an ultimatum game (Barmettler et al., 2012). A more important determinant of giving in dictator games is whether income is earned or not. Giving in dictator game experiments falls to about 4.3% of an endowment of \$10, when income is earned, relative to about 15% of the endowment in the case of unearned income (Cherry et al., 2002); the figure of 4.3% is closer to the corresponding field benchmark of charitable giving in the US, which stands at about 1% of income (Camerer, 2015).

A commonly heard critique of behavioral models of social preferences is that if experimentally observed social preferences are so important, then, putting it rather starkly, why do we not observe people giving envelopes stuffed with money to others (Bardsley et al., 2010, p. 53)? When

⁹ Andersen et al. (2011) consider extremely high stakes ultimatum game experiments; the stakes vary from the equivalent of 1.6 hours of work to 1600 hours of work. The median offer by the proposer is to give 20% of the share to the respondent, but the rejection rate falls with the increase in the stake. In real life, we rarely make decisions involving 1600 hours of work, yet social preferences were not eliminated in the experiment.

dictators in experiments give out of earned income, then the extent of giving is not too far off from the rate of charitable giving (4.3% versus 1% for the case of US; see above). In the real world, subjects give charity out of after-tax income, which is not the case in the lab. So imagine that in dictator games in the lab with earned income, the dictator was told: “Here is your endowment of \$10, which you have earned. We are taking 30% off as taxes, which we will partly use for redistributive purposes to the recipient in the experiment. How much of the rest will you offer to the recipient?” I will be surprised if the 4.3% giving in lab dictator games does not get closer to 1% figure for charitable giving in the field. Similar observations apply to proposer offers and responder rejections in lab experiments that do not include a tax redistributive component. If this is the case, then giving in experiments may be tapping into the innate human desire to redistribute to others, that is, at least partly, codified institutionally in the social welfare state.

3.2 Subject pools used in lab experiments

It is not unusual in many quarters to dismiss experiments conducted on students, the typical lab subject pool, as having limited or no relevance to testing economic theories. There are several objections to this claim that we now outline.

Economic theory does not specify the subject pool on which its predictions are to be tested. Gilboa et al. (2014, p. F516) write “the economic theorist is typically not required to clearly specify where his model might be applicable and how.” Clearly, you cannot have it both ways by not specifying a subject pool and then objecting to a particular subject pool. This view has been popularized in Vernon Smith’s *blame the theory argument*. Writing in the context of incentives in experiments, Smith (2001) writes in his abstract: “The rhetoric of hypothesis testing implies that game theory is not testable if a negative result is blamed on any auxiliary hypothesis such as ‘rewards are inadequate.’ This is because either the theory is not falsifiable (since a larger payoff can be imagined, one can always conclude that payoffs were inadequate) or it has no predictive content (the appropriate payoff cannot be prespecified).”

One concern with the student subject population is that students might not have the necessary and relevant experience to conform to the predictions of the theory. However, one can allow lab subjects to gain experience in the lab by repeatedly making decisions; indeed, many lab experiments examine such learning effects and the effects of experience. We postpone a fuller discussion of these issues to Section 3.4, where we consider the external validity of lab experiments.

Students possess higher than average education and intelligence, which should be rather favorable to tests of neoclassical economic theory that requires economic agents to possess high levels of cognitive ability. It often comes as a surprise to the critics, but student subjects are much less prosocial relative to non-student subject pools (Falk et al., 2013; Carpenter and Seki, 2011; Anderson et al., 2013).¹⁰ In a review of 13 studies that satisfy stringent tests of comparability, Fréchette (2015) finds that either there was very little difference between the behavior of students and professionals, or students were actually closer to the predictions of neoclassical theory. CEOs are often more trusting as compared to the student population (Fehr and List, 2004). More prosocial students do not self-select themselves as subjects in experiment (Cleave et al., 2012). Students who self-select themselves into experiments are motivated by monetary rewards (Abeler and Nosenzo, 2015), or interest in experimental lab tasks (Slonim et al., 2013). This evidence stands in contrast to their characterization in Levitt and List (2007) (based on two studies conducted in the 1960s) as scientific do-gooders who cooperate with experimenters to seek social approval.

¹⁰ However, student subjects might be more prosocial when it comes to volunteering time (Slonim et al., 2013).

3.3 Stake sizes in experiments

Economic theory does not specify the size of the stakes for which its predictions hold. Experimental economics is typically criticized for its low stakes. The evidence on stake size effects is mixed. However, many experimental results continue to hold, at least qualitatively, even with higher stakes (Slonim and Roth, 1998; Cameron, 1999). The most prominent effect of stakes arises when one moves from hypothetical payoffs to some strictly positive incentives. However, there is much less difference between moderate and high stakes; in particular, the main effect is a reduction in the variance of responses (Camerer and Hogarth, 1999).

There are two issues with high stakes, which are understated in many critiques of experimental economics. First, the vast majority of decisions that we make in real life are low stake decisions. How many times do we buy a car, a house, or a consumer durable such as a TV/laptop? Second, the main evidence for stake effects comes from experiments themselves. Third, as Thaler (2015) notes, the insistence on high stakes arises presumably because we are supposed to pay greater attention to economic decisions involving high stakes. But our success and expertise in making economic decisions is as much a matter of practice and learning. Since high stakes decisions are rare, we get limited opportunities to learn and make optimal decisions; the converse is true of low stakes decisions. Hence, there is no supposition that high stakes decisions should be closer to the predicted outcomes in neoclassical economics. So, he argues, correctly, that economists need to make up their minds whether they wish to insist on high stakes or low stakes as the appropriate test of their theories. Either way, experiments still offer the most natural environment to test the effect of stakes, which is an argument for more, not fewer, experiments.

3.4 The issue of the external validity of lab findings

Camerer (2015) distinguishes between the *policy view* and the *scientific view*. In the policy view, generalizability of lab findings to the field, or *external validity*, is essential. In the scientific view, all properly gathered evidence, including lab and field evidence, serves to enhance our understanding of human behavior. In this view, there is no hierarchical relation between lab and field evidence, and it is a mistake to pose the issue as if one had to make a choice between the two kinds of evidence. Camerer (2015, p. 251) explains cogently: “In this view, since the goal is to understand general principles, whether the ‘lab generalizes to the field’ (sometimes called ‘external validity’ of an experiment) is distracting, difficult to know (since there is no single ‘external’ target setting), and is no more useful than asking whether ‘the field generalizes to the lab.’”

To understand Camerer’s argument more fully, consider the following simple formalization in Falk and Heckman (2009). Suppose that we are interested in some variable Y that can be explained fully by the variables $X_1, X_2, \dots, X_n$ and the “true” functional relation between them is given by $Y = g(X_1, X_2, \dots, X_n)$, which is sometimes known as an *all causes model*. A researcher may be interested in examining the causal effect of X_1 on Y , holding fixed all other variables $\hat{X} = (X_2, X_3, \dots, X_n)$. For instance, in gift exchange experiments, Y is the level of effort of a worker and X_1 is the level of wage paid by the firm. The all causes model will typically include many factors in the vector $\hat{X}$, such as the number of firms and workers, choice sets, payoff functions, incentives, demographic characteristics, regulatory environment, and moral and social characteristics of the parties involved.

When the relevant hypothesis is tested in the lab, the researcher estimates a model of the form $Y = f(X_1, X^L)$, rather than the all causes model $Y = f(X_1, \hat{X})$, where $X^L \neq \hat{X}$; X^L includes

variables such as incentives given in the experiment, the endowments of subjects, the subject pool, context, and the structure of payoffs. One may also conduct field experiments in which one estimates a model of the form $Y = f(X_1, X^{F_1})$, where $X^{F_1} \neq \widehat{X}$, and typically $X^{F_1} \neq X^L$. Field experiments are conducted with a particular subject pool, such as sports card traders in List (2006).

The typical claim by critics of the experimental method is that $f(X_1, X^L)$ does not satisfy external validity, but $f(X_1, X^{F_1})$ does satisfy it. Now suppose that we are interested in examining the gift exchange relation in yet another population of subjects in the field, say, part time employees at General Motors. This gives rise to yet another estimated relation $Y = f(X_1, X^{F_2})$, where X^{F_2} reflects the set of variables and their characteristics in this field experiment. Is there any particular reason why the results based on the model $Y = f(X_1, X^{F_1})$ are more relevant, as compared to $Y = f(X_1, X^L)$, for predicting the causal effects of X_1 in the relation $Y = f(X_1, X^{F_2})$? Camerer (2015, p. 256) offers his assessment (expressed in our notation): “If the litmus test of ‘external validity’ is accurate extrapolation to X^{F_2} , is the lab X^L necessarily less externally valid than the field setting X^{F_1} ? How should this even be judged?” Falk and Heckman (2009, p. 536) go slightly further: “The general quest for running experiments in the field to obtain more realistic data is therefore misguided. In fact, the key issue is what is the best way to isolate the effect of X_1 while holding constant $\widehat{X}$.”

Since the criterion for external validity is unclear, it is best to treat lab and field evidence as complementary. Lab evidence allows for much tighter control of the variables in $\widehat{X}$. Field experiments allow for a larger variation in some aspects of $\widehat{X}$ (e.g., different subject pools with different demographic and social characteristics) while lab experiments allow for larger variation in other aspects of $\widehat{X}$ (e.g., exploration of the parameter space for values that can be hard or rare to find in the field). Lab experiments allow for greater replication because they are less costly and the economic environment in the lab can be more tightly controlled, while any specific field environment could be fairly unique.

We review the evidence for the generalizability of lab evidence to the field in many parts of this book. We end this section with the following bold claim from Camerer (2015, p. 277) made from studies where the lab and field evidence can be well matched: “There is no replicated evidence that experimental economics lab data fail to generalize to central empirical features of field data (when the lab features are deliberately closely matched to field features).” Readers interested in these issues can further consult Camerer (2015, pp. 281–5) for a list of studies that show a good association of lab behavior with field behavior in studies where it is more difficult to match the lab and the field evidence due to differences in the design or subject population.

Not everyone within the experimental economics community is willing to dismiss the importance of external validity. For instance, Kessler and Vesterlund (2015) believe that aiming for external validity is important, that qualitative experimental results have high degree of external validity, and that the concerns about external validity pertain only to quantitative experimental results. However, using a relatively large number of studies, Herbst and Mas (2015) show that peer effects on worker output in lab experiments and field studies from naturally occurring environments are quantitatively very similar. Hence, experiments appear to have external validity, even for quantitative estimates.

In light of the discussion above, the reader may perhaps appreciate better the view taken in this book that all sources of evidence, lab experiments, field experiments, and field data are equally valid and complementary in nature.

3.5 The role of incentives in economics

The norm in experimental economics is that all decisions made by subjects, or any elicitation of their underlying preferences in experiments, should be incentive compatible. It would currently be near impossible to get an experimental paper published in an economics journal if it did not respect incentive compatibility, preferably by using monetary rewards. In contrast, psychology does not require similar adherence to incentives. Camerer and Hogarth (1999) perform a meta-study of 74 studies, over the period 1990–98, in the leading economics journals: *American Economic Review*, *Econometrica*, *Journal of Political Economy*, and *Quarterly Journal of Economics*. Not a single experimental study in this sample was published without the use of incentives. In a meta-study over the period 1988–1997, Hertwig and Ortmann (2001) found that only 26% of the articles published in a leading journal in psychology, the *Journal of Behavioral Decision Making*, used monetary task related incentives.

Economists have traditionally viewed effort as aversive and requiring scarce cognitive resources. Hence, they believe that people will exert effort only if the marginal disutility of effort is exceeded by the marginal utility of monetary incentives (*extrinsic motivation*). By contrast, psychologists have stressed the *intrinsic motivation* of subjects in experiments that does not require task related monetary incentives. Psychologists do pay subjects a show-up fee and/or course credit because it may be unethical to pay less than a minimum wage for student's time and also because the fixed fee may elicit a reciprocal response by priming intrinsic motivation. Another difference between experiments in economics and psychology is that in the former, experimental practice is much more standardized and regulated (Hertwig and Ortmann, 2001). For instance, deception is taboo in economics experiments, but its practice is variable in psychology experiments.

Smith (1976) made an early recommendation for the use of incentives, based on his experience in double auction experiments. Employing monetary incentives in experiments is also a common recommendation by some of the pioneers in the field (Davis and Holt, 1993; Roth, 1995; Smith, 1991; Smith and Walker, 1993). The effectiveness of incentives, particularly in settings outside double auction experiments, is an empirical question. Several meta studies of the effect of incentives are now available, which show that the effect of monetary incentives on effort and performance in experiments is quite subtle. Neither of the following two extreme positions is supported by the evidence: Incentives make no difference and incentives remove all behavioral anomalies.

However, there is a caveat to these meta studies. Since the underlying preferences are unobserved, in experiments, task performance and incentive compatibility are measured by compliance with the predictions of the underlying theory. However, the underlying theory might itself be refuted by the evidence. One might then fall back on measuring the effect of incentives on the effort undertaken by the subjects (an input), rather than the performance in the task (the output); for a brief survey of these studies, see Bardsley et al. (2010, Ch. 6). However, in many tasks, effort might not improve performance. For instance, consider subjects in experiments engaged in non-trivial strategic interaction. In most games, it would be hard for the players to hit upon the Nash equilibrium purely by deduction, even if incentives were high.

The results reported in the careful meta-study by Camerer and Hogarth (1999) are particularly instructive. In many economic environments, such as choosing among risky gambles, market trading, and bargaining, the weight of the evidence (and the modal result) shows that increasing incentives does not change the average behavior. However, incentives often reduce the variance of results. Incentives may even harm the performance of subjects in experiments, for instance, subjects may choke under pressure (Ariely et al., 2009); their intrinsic motivation may be crowded out, and they may engage in too much payoff-reducing experimentation to avoid

negative incentives such as punishments (Hogarth et al., 1991);¹¹ they may place too great a reliance on personal judgment, when relying on public information would have improved pay-offs (Arkes et al., 1986); they may experience motivational crowding-out, e.g., in the presence of incentives, individuals do not feel responsible for their own behavior (Gneezy and Rustichini, 2000b); individuals might be insulted by the low level of incentives (Gneezy and Rustichini, 2000a). However, for another set of problems, mostly in judgment tasks, financial incentives affect average performance. Typically, the nature of these tasks is such that increased effort improves performance. Examples include memory retrieval tasks, tasks where recalling the play in previous rounds improves predictions, or mundane tasks such as piece rate clerical work where one might be easily bored, e.g., counting the number of occurrences of a particular alphabet on a page of English text.

The meta-study by Bonner et al. (2000) supports the results of the Camerer–Hogarth study. They find that incentives have little effect in problem solving tasks, highest positive effects in tasks where effort improves performance (e.g., clerical tasks, pain endurance, or detecting typos on a page), and weak positive effects in judgment tasks. Hertwig and Ortmann (2001) find moderately positive effect of incentives. However, their sample size is small. Only 48 out of 186 studies (26%) that they considered used financial incentives. Of these, only 10 explored the effect of monetary payments. One of their suggestions is to use different treatments that do use and do not use monetary incentives to build a better picture of the effect of incentives.

Clearly, a reduction in the variance of responses in the presence of incentives, in some experiments, is desirable on the grounds that it improves the statistical power of tests. However, economics advocates a cost–benefit approach, and research funding for experiments is a scarce resource. Hence, one has to trade off the reduced variance against performing more experiments with bigger subject pools in the absence of monetary incentives. Greater variance of responses produces more outliers, but as Camerer and Hogarth (1999, p. 31) point out, there are alternative solutions: “Of course, other methods might work the same magic more cheaply. Trimmed means and robust statistical methods also reduce the influence of outliers.”

So what explains the absolute adherence of experimental economists to incentives as a matter of norm? Bardsley et al. (2010, pp. 249–50) conjecture a cynical explanation: “A reason often given to psychologist’s opposition to them is that incentives present an obstacle to less-experienced researchers who find it harder to secure research funding. It may be that economists are less concerned by the presence of such obstacles, or even that some actively promote the use of incentives as a barrier to entry.” Many psychologists remain unconvinced of the arguments that experimenters in economics propose in favor of using incentives. For instance, Read (2005, p. 265) concludes his paper as follows: “. . . there is no basis for requiring the use of real incentives to do experimental economics.”

The decision to employ incentives is a part of the experimental design. But as a practical matter, experimenters interested in publishing their work in economics journals have little choice in this matter. A second issue in the design of experiments is the level of incentives and the context. Gneezy and Rustichini (2000a) use four different levels of incentives, zero, low, medium, and high, to check for the level effect and conduct two different experiments to check for context effects. In one experiment, the IQ experiment, they find that incentives improve performance when one compares the levels low and high; but there was no difference between medium and high incentives. In the second experiment, the donations experiment, donations were highest

¹¹ For a formal model that shows the trade-off between intrinsic and extrinsic motivation, see Bénabou and Tirole (2003).

when no incentives were given; in this case, intrinsic motivation is superior to extrinsic motivation. Using the same dataset, Rydval and Ortmann (2004) find that ability levels of individuals explained greater variation in performance relative to incentives. The assessment offered by Bardsley et al. (2010, p. 253) on the level of incentives is this: “The message seems to be that in terms of the impact on cognitive effort allocation the presence of task related incentives matters more than their level.”

How can an experimental economist who has decided to run experiments using incentives ensure that the responses by the subjects are incentive compatible? Typically, incentive compatibility in experiments has been defined with respect to expected utility theory; however, the behavior of the majority of people is not consistent with expected utility theory. Hence, judging incentive compatibility is a vexed task. For instance, the leading method of ensuring incentive compatible choices, the *random lottery incentive scheme* (RLI), that we outline in Appendix A, depends crucially on the *independence axiom* of expected utility theory. However, if the decision maker does not follow expected utility but follows, say, rank dependent utility or prospect theory, then the independence axiom does not hold. Thus, choices are not guaranteed to be incentive compatible.

The evidence against expected utility is now overwhelming (see Part I) and the independence axiom has been rejected in many empirical tests (e.g., *Allais paradox*). Bardsley et al. (2010) argue, however, that despite the rejection of the independence axiom, empirical evidence shows that the random lottery mechanism does not bias results. They write (p. 270): “it may simply be a happy coincidence that the RLI works, by engaging a particular mental heuristic that promotes unbiased task responses.” Some readers will wish to seek further clarification of the underlying mechanism that makes RLI an empirically attractive option.

Another popular incentive compatible mechanism in experiments that rely on an expected utility formulation is the *Becker–DeGroot–Marshak mechanism* (BDM) (Becker et al., 1964). This is typically employed in eliciting the willingness to pay and the willingness to accept for an object. Subjects in their roles as sellers are asked to state their valuation, v , for an object. A random price, p , is then drawn. If $p \leq v$, then a seller is not allowed to sell but if $p > v$, then the seller must sell. Subjects who follow expected utility should report their true valuations. To see this, suppose that the seller’s valuation for an object is believed to be distributed randomly over the interval $[\underline{v}, \bar{v}]$, the true valuation is v , and the price is drawn randomly from the interval $[\underline{v}, \bar{v}]$, using the distribution F . Suppose that the seller chooses to declare a low valuation, $v_L < v$. In this case, the seller chooses to forgo a profitable opportunity to sell if the price turns out to be in the interval $(v_L, v]$ and the expected forgone profits are $\int_{v_L}^v (v - p) dF(p) > 0$. Thus, the seller never declares a low valuation. Now suppose that the seller declares a high valuation, $v_H > v$. In this case, the seller risks the potential expected loss $\int_v^{v_H} (v - p) dF(p) < 0$, so he never overstates his valuation. In short, the BDM is incentive compatible under expected utility. A direct implementation of the BDM has been found not to be incentive compatible (Bohm et al., 1997). However, suppose decision makers are presented with ascending or descending prices and must choose to trade or not at these prices. In the end, one of the trades is picked at random and paid-off. There is some evidence that this version of the BDM may be incentive compatible (Braga and Starmer, 2005).

Similar calculations as employed in the BDM show that the *second price auction* (bidders bid simultaneously, and the winner pays the second highest bid) is also incentive compatible under expected utility. Bardsley et al. (2010, Chapter 6) review evidence which shows that the responses in BDM and the second price auction are sensitive to experience and, in later rounds, valuations are likely to converge to the true values. But the evidence on the incentive compatibility of variants of the *Vickery auctions* (which is a more general form of second price auctions) is mixed. They

write (p. 274): “the efficacy of particular elicitation mechanisms can vary across different types of tasks. Indeed, whether an elicitation mechanism works may depend on the kind of research question that motivates its use.”

To summarize, the discussion on incentive compatible elicitation mechanisms in experiments raises uncomfortable questions for the practice of experimental economics. First, predicted incentive compatibility relies on theories such as expected utility theory that have inadequate empirical support. Second, there are no universally agreed on mechanisms that will guarantee incentive compatibility in experiments and it very much comes down to a matter of judgment of the experimenter. Third, despite the firm insistence of experimental economists to use task related incentives, the theoretical response to these problems (e.g., the development of incentive compatibility under behavioral theories) appears to be inadequate.

3.6 Is survey data of any use?

Section 3.5 shows that there is often merit in the use of incentives, e.g., usefulness in double auction experiments, judgment tasks, and effort related responses as in clerical tasks, and reduction in variation of responses. However, it is fair to say that the empirical case for the use of incentives in experiments is not as strong as is typically made out within the experimental economics community. Hence, one needs to consider other sources of data too. Most economists mistrust *survey data* and data based on *hypothetical questions* on the grounds that subjects are not incentivized to reveal their true preferences. This is due to the traditional belief in economics that people mainly have *extrinsic* rather than *intrinsic* motivation.

In the history of behavioral economics, the reliance on hypothetical questions and survey data often gave rise to deep insights that allowed for major advances. Two prominent examples include the work of Daniel Kahneman and Amos Tversky on prospect theory (Kahneman and Tversky, 1979) based on hypothetical questions in lab experiments, and the work of Daniel Kahneman, Richard Thaler, and Jack Knetsch on fairness motivations in humans (Kahneman et al., 1986) based on hypothetical questions posed in telephone surveys. Kahneman and Tversky (1979) is the second most cited paper in all of economics, the foundation for the Nobel prize to Kahneman, and the source of prospect theory, which is currently the most satisfactory decision theory under risk, uncertainty, and ambiguity.¹² Yet the paper is based on hypothetical, non-incentivized, lab experiments. Any guesses if it would have been published in an economics journal today?

Another merit of studies based on hypothetical, non-incentivized, questions is that they can complement lab experiments in certain areas. We give an example from fairness concerns in Section 6.1. Here, we consider two examples from the work of Daniel Kahneman and Amos Tversky.

Example I.1 *Consider the identification of loss aversion (losses bite more than equivalent gains) in Kahneman and Tversky (1979). In lab experiments, it is not always easy to induce loss aversion over “large losses” because it is considered unethical in experimental economics to leave subjects out-of-pocket. The main alternative in lab experiments is to give subjects money upfront to ensure they are never out-of-pocket. However, this may contaminate their responses by the “house money effect” (gamblers who win money in a casino are more likely to gamble with it; as they say, easy come easy go).*

Example I.2 *Consider the following hypothetical, non-incentivized, lab questions from experiments conducted in a seminal paper by Kahneman and Tversky (1984). The percentage of subjects choosing each response is given in brackets.*

¹² The source for the “second most cited paper” claim is Table 2 in Kim et al. (2006).

Imagine that the US is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows:

Positive Framing: If program A is adopted, 200 people will be saved. If program B is adopted, there is a one-third probability that 600 people will be saved and a two-thirds probability that no people will be saved. Which of the two programs would you favor? (72% chose A, 28% chose B).

Negative Framing: If program C is adopted, 400 people will die. If program D is adopted, there is a one-third probability that nobody will die and a two-thirds probability that 600 people will die. Which of the two programs would you favor? (22% chose C, 78% chose D).

Relative to the status-quo, positive framing presents data in terms of “lives saved”, while negative framing presents the same data in terms of “lives lost”. Options A and C are identical, and options B and D are also identical. Under frame-invariance, the typical assumption in neoclassical economics, if A is chosen over B then C must be chosen over D (and vice versa). However, in the domain of gains (lives saved relative to the status quo), the majority (72%) chose the safe option (A) over the risky option (B). In the domain of losses (lives lost relative to the status quo) the majority (78%) chose the risky option (D) over the safe option (C). This establishes several results. First, behavior is not frame-invariant. Second, the results are not consistent with expected utility. Third, subjects are risk averse in gains and risk seeking in losses; this is one of the important insights of prospect theory.

These results have survived several challenges (e.g., choices over incentivized lotteries) and even professional physicians and World Bank staff behave in the same manner as lab subjects; see Part I for more details. Clearly this experiment cannot be run in the lab because it would be unethical to take a life.

Thaler (2015, p. 47) writes on the aversion to survey data: “This disdain [for survey data] is simply unscientific. Polling data, which just comes from asking people whether they are planning to vote and for whom, when carefully used by skilled statisticians . . . yield remarkably accurate predictions of elections. The most amusing aspect of this anti-survey attitude is that many important macroeconomic variables are produced by surveys! . . . “jobs” data . . . come from surveys conducted by the Census Bureau. The unemployment rate, . . . is also determined from a survey that asks people whether they are looking for work. Yet using published survey data is not considered a faux pas in macroeconomics. Apparently economists don’t mind survey data as long as someone other than the researcher collected it.”

Happiness economics, which we consider in Part 6 is based almost entirely on survey data. Policymakers appear to take serious interest in this area and survey measures of well-being and happiness are highly correlated, which is consistent with the standard expected of incentivized responses. Furthermore, firms often use information gleaned from market surveys to introduce new products about which consumers have no prior experience, and alter the characteristics of existing products.

Consider an example where incentives make the problem even worse. Using hypothetical, non-incentivized questions, Lichtenstein and Slovic (1973) asked people to choose between a less risky P -bet (high probability of winning a low prize) and a more risky $\$$ -bet (a low probability of winning a high prize). When asked to choose directly between the two bets, most people chose the low risk option, the P -bet. Yet, most people assigned a higher certainty equivalent to the $\$$ -bet as compared to the P -bet. Thus, we have a case of *preference reversals* that cannot be explained by any model of consistent preferences. Grether and Plott (1979) suspected that the

problem was caused by hypothetical choices. However, when they re-ran the experiments using incentivized subjects, the incidence of preference reversals worsened (see Part I of the book for details).

In sum, there are no grounds to outrightly reject survey data. Survey data has pitfalls, for instance, poll data sometimes gives misleading results, however the benefits of survey data outstrip the potential pitfalls. But other data sources also have limitations; hence, it is important to use all sources of data, surveys, experiments, and field evidence, to build a more complete picture of human behavior.

4 Approach and organization of the book

This book is an attempt to take stock of behavioral economics and is aimed to serve several purposes: A course text for advanced students in economics and other social sciences, a research handbook for behavioral economists, and an invitation to economists and other social scientists of all persuasions to explore this exciting new field. In its teaching role, the book would ideally be taught in a year long course in behavioral economics, supplemented by readings that reflect the interests of the instructor. A good example is a typical two semester North American style course that has 13 weeks of teaching in each semester; students meet each week for a two hour lecture and a one hour problem solving class. This book tries to standardize the material in behavioral economics so that students can see behavioral economics as a coherent and widely applicable body of theory, much as they might see any other established area in economics. It is also intended to ‘nudge’ many idiosyncratic course outlines, that pass for behavioral economics at the moment, to adopt a more balanced approach.

Given the scope of the book, one can also construct a large number of coherent and interesting single semester courses not just in behavioral economics but also in behavioral decision theory, behavioral macroeconomics, behavioral industrial organization, behavioral contract theory, topics in behavioral economics, and the like. I believe that the book should also be essential background reading for any advanced course in microeconomics in order to address Herbert Gintis’s (2009, p. xvi) concern raised above, till the time that microeconomics books respond to his suggestion.

Despite the size of the book, it is, I believe, the “minimum” amount of material that any academic who declares behavioral economics or experimental economics as their research interest, must have deep, rather than passing, familiarity with.

As the reader may have guessed from Sections 2 and 3, my main criterion for including models in this book is their consistency with the evidence, unless there is significant merit in using a model for pedagogical or other reasons. Most of the models that I use can typically explain at least as much as neoclassical models, but can also better explain data from other domains of human behavior. It is entirely possible, of course, to append auxiliary assumptions to standard neoclassical models to explain almost any set of stylized facts. However, I try to stay away from models in which these auxiliary assumptions are ad-hoc fixes.

I encourage the reader to keep an open mind about behavioral economics models and judge models by the relevant empirical evidence. Models in behavioral economics are as theoretically rigorous as models in neoclassical economics, if rigor is an important criteria for the reader. Gilboa (2009, Section 7.1) may well be right that all models are ultimately wrong. Even if this statement were true, we must consistently strive to improve our models in the light of rejections, in order to make better predictions and improve our understanding of human behavior. The

sequence of these improved models may or may not ever converge to the “true model.” Yet, each time we reject a model and put in its place a new one that makes better predictions, we make progress.

The level of honesty that we need as a profession is captured in the words of the Nobel Prize winning physicist Richard Feynman (1965, p. 158) that economists would do well to embrace: “But experimenters search most diligently, and with the greatest effort, in exactly those places where it seems most likely that we can prove our theories wrong. In other words, we are trying to prove ourselves wrong as quickly as possible, because only in that way can we find progress.” The “all models are wrong critique” is unhelpful at best and, if used inappropriately, it is likely to hinder progress in the subject.

For many of the topics, the book is organized in the following general style. A neoclassical theory is outlined, followed by a review of the evidence for it. If the weight of the evidence is inconsistent with the theory, then the behavioral alternatives and the evidence for or against them is described. There is a range of applications in the book for most of the behavioral theories that the reader/instructor can choose from. In order to enable readers who might not be familiar with the full range of topics in behavioral economics, I err on the side of longer introductions to most of the chapters. As a first pass, readers may wish to skim through the introductions to the various parts/chapters, in order to get a birds-eye view of the material. This should enable readers to draw up a priority list of topics that they would wish to read or teach in their courses. I deliberately shy away from offering such a list of topics to the reader, and like a good restaurant, prefer to fall back on offering a wide menu of tempting choices, hoping that you, the reader, will keep coming back, and spread the word.

Some readers may feel that it is presumptuous to include the word “foundations” in the title of this book. However, in justification, I believe that there is now a sufficiently rich body of lab and field evidence that is well described by models of behavioral economic theory. The richness of human behavior that we can account for with these models is unprecedented in modern economics. A few of the areas in behavioral economics, notably *neuroeconomics*, are very young and I have some hesitation in bringing this material under the rubric of a book that claims to describe the foundations of a subject. Yet, omitting this material is not an attractive option, and I have erred on the side of inclusion.

I also try to flag up material that is speculative, yet promising, or where the evidence base is not sufficiently established at this point in time. Behavioral economics continues to be work in progress and despite the huge increase in understanding attained over the last several decades, a lot needs to be done. Writing this introduction upon completion of the book, and reflecting on the material, I must confess that I have never personally felt so enriched, yet so ignorant, in my life. I hope that the serious, and just the plain curious, among you, come away with a similar sentiment after reading this book.

The book is organized into nine parts and many parts have multiple chapters; there are problems at the end of each part, except for Part 9 on neuroeconomics. The order of chapters reflects, at least partially, the historical development of the subject, and also bears some similarity with the organization of a typical course in microeconomics. Each part begins with an introduction to the material in all the constituent chapters in the part, and each chapter has a separate, but more detailed, introduction.

The table of contents give a bird’s eye view of what is inside the book and I will not bore you with a verbatim description; anyone bold enough to read so far, probably has enough on their plate to think about. I should make a few broad comments though, about my organization of the material. I focus mainly on topics that readers may find to be in an unexpected location within the book.

The book opens with Part 1 on *behavioral decision theory* because playing a game against nature under risk, uncertainty, and ambiguity, in a static setting, is one of the simplest economic problems; this abstracts from temporal and strategic concerns. However, there is an important overlap between risk preferences and time preferences, which is split between Part 1 and Part 3 on time preferences. Many readers might have wished to see a more thorough treatment of ambiguity. However, most of the modern developments in ambiguity are within the confines of the neoclassical models, although an important behavioral literature on source-dependent preferences, that we describe in Part 1, is now beginning to develop that highlights the role of prospect theory.

Microeconomics texts typically begin with a discussion of the properties of human preferences, which are regarded as the primitives of the model. Most evidence indicates that there is a mixture of individuals with purely *self-regarding preferences*, as in neoclassical economics, and those with *other-regarding preferences*. Part 2 considers the evidence on *human sociality* and behavioral models that take account of this evidence. There is also a discussion of the implications of social preferences for competitive general equilibrium in this part, which typically comes much later in a microeconomics course. Two important topics that lie at the heart of human motivation in economics, *social identity* and *human virtues*, appear in a stand-alone chapter in Part 2. The inclusion of these major topics should be less surprising than the fact that most microeconomics texts have somehow contrived to exclude them.

An explicit time dimension is not fundamental to the material in Parts 1 and 2. In Part 3, we consider the evidence on time preferences and *behavioral models of time discounting*. The treatment of time preferences is excessively narrow in neoclassical microeconomics texts. This is because the entire psychology of time preferences is captured by a single parameter, the discount rate, in the exponential discounted utility model—the main model of time preferences in neoclassical economics. This is not just unsatisfactory in light of the richness in observed time preferences, but exponential discounting is strongly rejected by the evidence, perhaps even more so than expected utility theory.

There will be much that is new and unfamiliar to the reader in Part 3 that will require investment in learning new machinery such as *subadditivity*, *attribute-based models* of time preferences, and *models of reference time preferences*. I advise the serious reader to persevere with Part 3. It is worth telling an anecdote that the reader may wish to keep in mind when an unfamiliar topic (and there will be many) is encountered in Part 3. When George Loewenstein, one of the leaders in time discounting, first saw Part 3, he particularly commended me for including *subadditivity* (i.e., discounting depends on how one partitions a given interval of time). However, when another group of non-specialists read Part 3 as part of a group reading seminar in a leading university, they were put off by the “unusual and new” concept of subadditivity. The reason subadditivity is there in the book is because it is currently supported by the evidence; its current popularity/aesthetic appeal (or lack of it) are criteria that, for this book, are not relevant.

Part 4, the longest part of the book, is on *behavioral game theory*. Classical game theory revolutionized economics by forcing it to specify explicitly the economic environment, set of players, sequence of moves, and the mapping of histories to payoffs. Anyone comparing industrial organization theory before the advent of game theory with modern industrial organization theory will immediately notice the much greater clarity achieved by modern game theoretic models (think, e.g., of models of entry deterrence). Gintis (2009) advocates keeping game theory as the common toolkit for all social sciences despite pointing out serious shortcomings in classical game theory, for instance, the assumption of common priors and the justification for a Nash equilibrium. The approach in this book concurs with this sentiment. Despite widespread belief to the contrary, the evidence has not been too kind to classical models of game theory. This is particularly the

case for observed behavior in the early rounds of a game, and for equilibrium refinements that require high cognitive requirements. In particular, it stretches the imagination to believe that players could arrive at a Nash equilibrium purely by a deductive process. For instance, the cooperation rate in many static prisoner's dilemma game experiments is about 60%; cooperation here is a dominated strategy, which in classical game theory, ought never to have been played.¹³

Part 4 considers at length the evidence for classical models of game theory and the leading behavioral alternatives. Many of the main behavioral alternatives, such as *level-k models*, the *cognitive hierarchy model*, and the *quantal response equilibrium*, relax the “equilibrium in beliefs” assumption, or the assumption that players play a best response. There are several other behavioral models of strategic interaction that are in the fray. While the empirical evidence is not always consistent with these models, the most heartening aspect of the discourse in behavioral game theory is that we are actually using empirical evidence to choose among the models. You cannot convince the leaders in this field, say, Vincent Crawford or Colin Camerer, about your proposal for a new solution concept in game theory by simply appealing to the aesthetic appeal of your proposed model, or its ability to tell a useful story, or a fable, if it is not supported by the evidence. I have decided to include the topic of *psychological game theory* in Part 4 but some instructors may have wished to place this topic in Part 6 on emotions, because it also deals with *anger* and *guilt*, and others in Part 2, because it also deals with intentions-based reciprocity. My relatively detailed treatment of this material reflects my preference to see this material closer to the centre stage of modern behavioral economics.

Part 5 outlines the evidence on human learning and traditional as well as *behavioral models of learning*. I also give chapter length treatments of *evolutionary game theory* and *stochastic social dynamics*. An appendix briefly introduces the reader to the necessary technical machinery on deterministic and stochastic dynamical systems. Some instructors would have wished to see the chapter on evolutionary game theory in Part 4. However, one way of looking at evolutionary game theory is that it deals with learning at the level of the gene. One aim of this chapter is to provide evolutionary foundations for human sociality that we covered in Part 2, and also introduce some newer and interesting topics, such as *gene-culture coevolution*. Part 5 is particularly instructive in evaluating the common claim that a Nash equilibrium arises if sufficient learning opportunities are provided to the subjects. A separate chapter-length treatment on stochastic social dynamics in Part 5 might be unexpected, even for many behavioral economists who do not typically include this topic in their courses. However, I believe that this material needs to be taken more seriously, and all students of behavioral economics should have at least a basic familiarity with it.

Neoclassical economics typically focuses on cold and emotionless deliberation. Part 6 considers the role of emotions in explaining economic phenomena. Instructors interested in teaching a course that focuses on emotions will need to combine the material here with that from other parts of the book, such as psychological game theory (Part 4), models of regret and disappointment aversion (Part 1), and issues of self-control and present-biased preferences (Part 3). Part 6 also considers the Gul–Pesendorfer model of temptation that some readers might have preferred to situate in Part 3, where issues of present-biased preferences are discussed. I have also placed the important policy relevant topic of *happiness economics* in Part 6, insofar as happiness may be considered as a type of emotion. The evidence base in happiness economics is typically constructed using survey data that not all economists agree with (see Section 3.6 above), which has hampered its acceptability within academic economists. I urge economists to take this material

¹³ Social preferences alone cannot explain behavior of the players in the prisoner's dilemma game; see al-Nowaihi and Dhami (2015).

more seriously, particularly given the correlations between various measures of well-being and happiness. Some readers may find *models of dual selves* to be somewhat out of place in this part; I partly share this concern but it was not immediately clear where better to situate this important topic.

Part 7 considers *models of bounded rationality*, and it is split into three chapters. The chapter on *judgment heuristics*, a topic that owes its origin and importance to Tversky and Kahneman (1974), brings into sharp focus the debate about the relative suitability of the *optimization approach*, and the *heuristic-based approach* to economic models.¹⁴ The chapter on *mental accounting* considers work that Richard Thaler almost single-handedly pioneered. It deserves to see much more development and interest among theorists working in behavioral economics. The reader may not have expected a chapter on *behavioral finance* in Part 7 but there is no better place to illustrate bounded rationality and the inefficiency of markets in the very market that is typically held up as a model of efficiency in neoclassical economics.

Part 8 considers issues in *behavioral welfare economics*, which is an area that is likely to experience more development in the future. If people have behavioral biases relative to the neoclassical model, then should we respect those biases or not? The debate is not just about *libertarianism* and *paternalism*, but also about: what exactly do these terms mean in the presence of behavioral biases?

Part 9 gives a very brief tour of *neuroeconomics* that highlights the neuroeconomic foundations of just a few selected aspects of human behavior from the first four parts of the book. In particular, I make no attempt at completeness, or balance, in the treatment of Part 9.

There are some notable omissions from the book that are partly dictated by technological considerations such as the physical size of the book, the current importance of these topics in behavioral economics, and last but not least, by my own lack of competence in these areas. *Complexity theory* and its implications for public policy do not figure in this book; readers can pursue Mitchell (2009) for an introduction, followed by Colander and Kupers (2014) for policy issues. I have also omitted a discussion of *agent-based computational models*; readers can begin with Tesfatsion and Judd (2006) and Farmer and Foley (2009). I also give insufficient attention to the *epistemic foundations of equilibrium concepts* in classical and behavioral game theory; see Dekel and Siniscalchi (2015) for a recent review and Gintis (2009) for a critique of the epistemic foundations of classical game theory. My discussion of neuroeconomics is highly incomplete and selective; for an authoritative survey, see Glimcher et al. (2009) and Glimcher and Fehr (2014).

5 Five theoretical approaches in behavioral economics

I would now like to pick up the story of behavioral economics where I left off at the end of Section 1. I shall consider five case studies of theoretical models in behavioral economics, chosen from five different parts of this book.¹⁵ In each case, I also briefly comment on some/all of the following: the historical context of these models, reactions to these models in the profession, evidence on the models, applications, and lessons learnt. The reader should not construe that I

¹⁴ For a discussion of alternative views on the optimization versus heuristics debate, the reader may consult the June 2013 issue of the *Journal of Economic Literature*, Volume 51, No. 2.

¹⁵ An idea whose development I wished to trace out in this section, since Gary Bolton pointed it out to me a few years ago, was the development of models of relative concerns for others that arose surprisingly from experiments on bargaining games conducted by Alvin Roth with others (see Part 4 of the book). However, Roth (2015) has recently described this story very lucidly, so I have omitted it (see Part 4 of the book for details).

consider the behavioral models not mentioned in this section as hierarchically inferior. An identical observation holds for the material in Section 6 below, where I consider five examples of behavioral evidence.

5.1 A case study of prospect theory

Two papers in the 1970s by Daniel Kahneman and Amos Tversky may be identified with the beginning of modern behavioral economics. In the first, Tversky and Kahneman (1974) proposed a radical, non-optimization approach to decision making in economics in which people use heuristics or simple rules of thumb; we discuss this work in Part 8 and Section 5.5 below. In the second, Kahneman and Tversky (1979) outlined a new theory of decision making under risk, uncertainty, and ambiguity that distilled in a simple, conservative, extension of expected utility theory, the main experimental insights from their own work and that of others. They called it *prospect theory* (PT), which is not a particularly illuminating name for the theory.¹⁶

Consider a lottery that describes outcome, probability pairs in n states of the world,

$$L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n), \quad (1)$$

where $x_1 < x_2 < \dots < x_n$ are monetary prizes (positive or negative) and $p_i \geq 0$ is the objective probability with which the prize x_i occurs, such that $\sum_{i=1}^n p_i = 1$. In the dominant decision theory in neoclassical economics, *expected utility theory* (EU), lottery L is evaluated by the function $EU(L) = \sum_{i=1}^n p_i u(x_i)$, where u is a utility function for monetary prizes. When well-defined subjective probabilities replace objective probabilities (uncertainty) then EU is referred to as *subjective expected utility*. Two features stand out in this formulation. First, utility derives from the final outcomes in each of the n states. Second, the objective is linear in probabilities. EU is underpinned by a compelling and plausible set of preference axioms (von Neumann and Morgenstern, 1944). However, a very large body of evidence rejects the hypothesis that all humans follow expected utility theory (Kahneman and Tversky, 2000; Starmer, 2000; Wakker, 2010). Axiomatic plausibility on its own cannot be used as a criterion for the continued acceptability of a theory if the evidence rejects it. Indeed, the independence axiom, which appears eminently sensible is often rejected by the evidence; the Allais paradox is one of the earliest violations.

PT is a *descriptive* theory of choice that strives to explain actual human behavior not just for risk, but also for uncertainty and ambiguity. Like many behavioral theories, it also has rigorous axiomatic foundations. PT not only accounted for the known violations of EU, it helped to successfully predict and explain a range of new phenomena. In this sense, it satisfies the criteria of theoretical and empirical progress in the Lakatosian framework. A key idea in PT is *reference dependence*. This implies that humans derive utility from changes in outcomes relative to some reference outcome; if the outcome is equal to or greater than the reference outcome it is in the *domain of gains*, otherwise it is in the *domain of losses*.

One could renormalize all outcomes relative to a reference outcome under EU but this is hardly enlightening, because EU has little to offer towards an understanding of human behavior in the domain of gains and losses. In contrast, PT gives a rich account of the difference in human behavior in the domain of losses. A key idea that drives many results in behavioral economics is *loss aversion*, i.e., losses bite more than equivalent gains. Kahneman and Tversky (1979) report a

¹⁶ If you are mystified by the name, prospect theory, as I was once, then you can seek a resolution to this mystery by reading p. 25 in Thaler (2015).

Figure 1 The power form of the utility function under prospect theory.

median figure of loss aversion of 2.25. So, for instance, assuming linear utility, a monetary gain of 100 feels like a utility gain of 100, while a monetary loss of 100 feels like a utility loss of 225 under PT; under EU, a loss of 100 would just feel like a utility loss of 100. Loss aversion is empirically very robust, and it may help some of us to understand our own past behavior.¹⁷

Furthermore, evidence shows that the utility function, v , under PT is concave in the domain of gains and convex in losses. This is shown in Figure 1 for the case of the following power form of utility

$$v(y) = \begin{cases} y^{\gamma^+} & \text{if } y \geq 0 \\ -\lambda (-y)^{\gamma^-} & \text{if } y < 0 \end{cases}, \gamma^+ > 0, \gamma^- > 0, \lambda > 1, \quad (2)$$

plotted for the case of the empirically observed values of $\gamma^+ = \gamma^- = 0.88$ and $\lambda = 2.25$ in Kahneman and Tversky (1979). Notice the kink at the reference point of zero and a sudden increase in slope as we enter into the domain of losses. This captures loss aversion, as reflected in the parameter λ in (2). Given the different shapes of the utility function in gains and losses (concave in gains, so risk averse, and convex in losses, so risk loving),¹⁸ the reader should now readily make sense of the results in Example I.2.

A third component of prospect theory is *non-linear probability weighting*; recall that under EU, probabilities are weighted linearly. In particular, at least for probabilities bounded away from the endpoints of the interval $[0, 1]$, evidence suggests that low probabilities are subjectively over-weighted, while high probabilities are subjectively underweighted. This is captured by a continuous, strictly increasing, *probability weighting function*, $w(p) : [0, 1] \rightarrow [0, 1]$ such that $w(0) = 0$ and $w(1) = 1$. Figure 2 shows a plot of the Prelec probability weighting function due to Prelec (1998); this is given by $w(p) = e^{-\beta(-\ln p)^\alpha}$, where $\alpha > 0$, $\beta > 0$. Arguably, Figures 1 and 2 are the two most important diagrams in Part I of the book.

¹⁷ I undoubtedly received many gifts as a child that I only have a dim memory of, but I can never forget the 5 rupee note that I lost at age 5, or the toy car given to me by an uncle from the US that was stolen on the very first day in school. Losing the toy car was certainly a far more painful and long-lasting experience as compared to the joy that I felt at receiving it. Loss aversion may be one explanation behind these feelings.

¹⁸ We have not, so far, said anything about non-linear probability weights, which, with the shape of the utility function, jointly determine attitudes to risk under PT (see below).

Figure 2 A plot of the Prelec function for $\beta = 1$ and $\alpha = 0.5$.

Suppose that an individual faces the following lottery in *incremental form*

$$\tilde{L} = (y_{-m}, p_{-m}; \dots; y_0, p_0; \dots; y_n, p_n), \quad (3)$$

where $y_{-m} \leq y_{-m+1} \leq \dots \leq y_{-1} \leq y_0 = 0 \leq y_1 \leq y_2 \leq \dots \leq y_n$ are monetary outcomes, each expressed as an increment relative to a reference point r ; so if the monetary outcome is x_i , then $y_i = x_i - r$. Here, we have m outcomes in the domain of losses and n outcomes in the domain of gains. Kahneman and Tversky (1979) proposed that a decision maker who follows PT, evaluates lottery $\tilde{L}$ as: $PT(\tilde{L}) = \sum_{i=-m}^n w(p_i) v(y_i)$.¹⁹ However, it was soon realized that this could lead to stochastically dominated options being chosen.

Quiggin (1982) suggested a way out of this problem with his proposal of *rank dependent utility* (RDU) that alters EU in a minimal, but important way. A decision maker who follows rank dependent utility evaluates the lottery L in (1) as: $RDU(L) = \sum_{i=1}^n \pi_i u(x_i)$; π_i , known as the *decision weight* corresponding to outcome x_i , is simply a cumulative transformation of the probability weighting function given in Figure 2.²⁰ Crucially, the utility function, u , stays as it is under EU. RDU can explain everything that EU can (because for $\alpha = \beta = 1$, the Prelec function is $w(p) = p$), disallows stochastically dominated choices, and can explain the celebrated Allais paradoxes.

Tversky and Kahneman (1992) incorporated insights from RDU into their 1979 version of prospect theory and came up with *cumulative prospect theory*.²¹ Following convention, we call the 1979 version *original prospect theory* and the 1992 version, simply, *prospect theory* (PT), which we focus on below. Under PT, a decision maker evaluates the lottery in (3) as $PT(\tilde{L}) = \sum_{i=-m}^n \pi_i v(y_i)$, where the decision weights, π_i , are constructed as under RDU but computed separately for gains and losses relative to the reference point. Decision makers who follow PT do not choose stochastically dominated options.

¹⁹ In the main, Kahneman and Tversky (1979) were interested in two-outcome lotteries but their model is generalizable to more than two outcomes.

²⁰ For readers who are itching for more information at this stage, before they get to Part I, $\pi_i = w\left(\sum_{j=i}^n p_j\right) - w\left(\sum_{j=i+1}^n p_j\right)$ for $i = 1, 2, \dots, n$.

²¹ The work of Starmer and Sugden (1989) in introducing non-linear probability weights in a prospect theoretic framework ought also to be mentioned here.

PT has been incredibly successful in understanding human behavior under risk, uncertainty and ambiguity; for a book length treatment, see Wakker (2010). Arguably, no other decision theory in economics has been so successful in explaining such a wide range of phenomena. Part 1 gives the details, but a small sample of these applications is as follows. Why does the equity premium puzzle (too high a return on equities relative to bonds) exist (Benartzi and Thaler, 1995)? Why is it so hard to find a taxi on a rainy day in New York (Camerer et al. 1997)? Why do people pay taxes (Dhami and al-Nowaihi, 2007, 2010a)? Why is there a disparity between willingness to pay and willingness to accept (Thaler, 1980)? How does ex-ante competition serve as a reference point in the formation of ex-post contracts (Fehr et al. 2011). Why are stabilizations delayed (Weyland, 1996)? Why are price elasticities asymmetric (Camerer, 2000)? Why do people hold on to loss making stock for too long and sell winners too early (Odean, 1998)? Why are people influenced by goals (Locke and Latham, 1990)? Why do people simultaneously gamble and insure (Kahneman and Tversky, 1979)? Why are incentives low-powered (de Meza and Webb, 2007)? Why do markets price skewness in asset returns (Barberis, 2013)? Furthermore, most of what economists think of as *risk aversion* might well be just *loss aversion* (Novemsky and Kahneman, 2005). It is hard to think of an area in economics that has not been touched directly or indirectly by prospect theory.

EU is a special case of RDU, which in turn, is a special case of PT. Thus, PT can explain everything that the other theories can explain, but the converse is false. For the purists, PT has axiomatic foundations (Chateauneuf and Wakker, 1999) and the individual components of prospect theory have axiomatic foundations, such as the utility function in Figure 1 (al-Nowaihi et al., 2008) and the Prelec probability function in Figure 2 (Prelec, 1998; al-Nowaihi and Dhami, 2006a). There is strong empirical support for the individual components of PT in choice data (Wakker, 2010), and in neural data (De Martino et al., 2006; Roiser et al., 2009; Tom et al., 2007). When a two-horse race is run between EU and PT, the predictions of EU are qualitatively and quantitatively unsatisfactory, while those of PT fit well the evidence (Dhami and al-Nowaihi, 2007). Mixture models indicate that there is possibly a 80%–20% split of people who follow PT and EU (Bruhin et al., 2010). Field evidence also supports PT, even among experienced subjects (Pope and Schweitzer, 2011; Fryer et al., 2012; Camerer, 2015).²² Close primate relatives, such as capuchin monkeys, also exhibit loss aversion, suggesting that loss aversion already existed prior to the separation of the human line from other primate relatives, and is hardwired in us (Chen et al., 2006).

A non-economist reading this introduction would think that surely PT must be the main decision theory taught in microeconomics courses. Wrong! Most of the standard texts in microeconomics either omit any mention of PT, or refer to it only in passing (Varian, 1992; Mas-Collel et al., 1995; Jehle and Reny, 2011). Such a situation is unlikely to have arisen in the natural sciences, at least in modern times. Incredibly, it is still possible to get a degree in economics in many universities without having undertaken a study of prospect theory, or even a course in behavioral economics. So why this relative neglect of PT, despite its growing usefulness and importance, and the continued reliance on EU? One can conjecture several reasons.

²² The List (2003) findings are commonly cited as showing that lab evidence on loss aversion does not generalize to the market; indeed, the title of the paper is: Does market experience eliminate market anomalies? However, the data in the paper shows that experience, whether in the lab or in the market, reduces loss aversion and the magnitudes of reduction are comparable. Significantly loss aversion still remains despite market experience, as is established by many other empirical studies.

1. The institutional structure in economics has a strong status-quo bias, partly because of homespun and self-serving methodological positions that do not recognize the primary role of evidence and of refutability (see discussion in Section 2 above). So, for instance, EU is often justified as telling a useful story of human behavior under risk and uncertainty or justified on the grounds that people behave “as if” they follow EU. An EU analysis also underpins many important results such as the existence of a Nash equilibrium and problems in mechanism design, thus, refutations of EU could be alarming for many economists. These defences of EU are untenable on scientific grounds.
2. Many economists appear to believe that EU is successful in making qualitative predictions, which justifies its use, while PT impinges mainly on quantitative results. However, a-priori, it is often not clear which qualitative predictions made under an EU analysis will be empirically supported. Within the same model, EU may make predictions that are qualitatively and quantitatively incorrect, while PT makes the correct predictions in each case (Dhami and al-Nowaihi, 2007, 2010a).
3. Economists critical of PT often argue that an exogenous reference point in PT is an unacceptable auxiliary assumption. In contrast, Kahneman and Tversky (1979) identified an endogenous reference point, the *status quo*, which is eminently sensible in most applications. As they also recognize, one’s entitlement or bargaining power, historical norms, or the expected value of a lottery, may also prove to be compelling reference points. Every falsifiable theory makes auxiliary assumptions, which can and should be tested. Evidence shows that people do indeed have reference points. It is well known that rationality, by itself, has very little predictive power in the neoclassical model in the absence of auxiliary assumptions; see a nice discussion in Thaler (2015, Ch. 17). The current state of the art in neoclassical economics is not even remotely close to the position that “all auxiliary assumptions must be endogenized.” Indeed it might not be sensible to aspire to do so.

One response to this criticism has been the development of a theory of *endogenous reference points*; roughly this is similar to imposing rational expectations on the formation of reference points (Kőszegi and Rabin, 2006). This solution has served to satisfy many neoclassical theorists although it sits uneasily with the evidence on cognitive limitations that we review at length in this book. Whether endogenous reference points in the sense of Kőszegi–Rabin is a step in the right direction is entirely an empirical question that its authors are aware of. Initial empirical evidence (see Part I) is consistent with the model, but we must await more stringent tests of the theory before we can be more confident.

4. It is not uncommon to hear the following view from some quarters: “PT has more parameters than the other decision theories, so it is not surprising that it explains better?” Incidentally, it is conveniently glossed over that exactly the same a-priori argument applies to the use of EU over expected value theory that it replaced.

There are two main statistical methods of addressing this criticism. First, estimate the model for a subset of the sample and use the estimated parameters to test the predictions on the remaining data. Second, use statistical criteria that allow one to test the trade-off between a greater number of parameters and better explanatory power, even among non-nested models, such as the Akaike information criteria (AIC), or the Bayesian information criteria (BIC). One may then run a horse race between the alternative theories.

I am unaware of completed studies in the first category, but there are some in the second. In a horse race between eight theories including EU and RDU (but not PT), Hey and Orme (1994) conclude (p. 1321): “Expected utility (and its special case, risk neutrality) emerges from this analysis fairly intact . . . However, we should emphasize once more

that this interpretation of our results needs to be taken with caution—since our sample of 80 subjects was in no sense representative.” The overriding feeling from these results (see also the survey by Hey, 2014), is that victories for one decision theory over another are rather messy and require one to buy into functional restrictions, assumptions on the error processes, and data limitations that one is never entirely comfortable with.

It is not commonly realized that PT also applies to situations of ambiguity; this is shown explicitly in Tversky and Kahneman (1992). In a comprehensive and careful study, Kothiyal et al. (2014) run a horse race between 11 competing theories of ambiguity that include subjective expected utility, PT, and several theories that are natural extensions of expected utility to ambiguity; PT emerges as the clear winner in this competition. Erev et al. (2010) run an unusual choice prediction competition pitting several decision theories against each other, many of which are more popular in psychology. In choice tasks that involved predictions from actual decisions, a stochastic version of PT outperformed the other theories. In contrast, in choice tasks involving predictions from experience, models that relied on small samples (see Section 5.5 below) performed best.

Under EU, attitudes to risk are captured entirely by the shape of the utility function. However, if we make any departure from linearity in probabilities in an EU type functional, as e.g., in RDU or PT, then attitudes to risk are *jointly* determined by the shapes of the probability weighting function and the utility function. In particular, the *four fold classification of risk* is one of the central insights of PT (Tversky and Kahneman, 1992), and despite subsequent empirical criticisms, it remains a robust finding (Fehr-Duda and Epper, 2012). Thus, under PT, one needs to elicit the probability weighting function and the utility functions separately. This can be accomplished by the trade-off method (Wakker and Deneffe, 1996; see Part 1).

Using a cleverly designed elicitation domain, the trade-off method is valid for EU and RDU. Employing this procedure, Abdellaoui (2000) checked if people transform probabilities; in particular, this test is not subject to the criticism that RDU does better because it has a higher number of parameters. The test showed that people transformed probabilities, which is inconsistent with EU but consistent with RDU. Abdellaoui then conducted a stringent test of the difference between RDU and PT and found that the probability weighting function was different for gains and losses, which is consistent with PT but not RDU. He then checked for simple lotteries, a condition (the duality of probability weighting functions) that would have established that RDU and PT coincide, but this condition was rejected.²³

A greater challenge to PT is posed by the following developments that appear to be lost in the rather narrow and confused mainstream critique of PT.

1. Michael Birnbaum has done a series of experiments whose results are not consistent with PT (Birnbaum, 2008). However, these results are not consistent with any of the other mainstream decision theories. His own proposals (e.g., *configural weights models*) are likely to appear ad hoc to many economists in the manner in which they allocate decision weights to outcomes. Further, there are no preference foundations of his proposed theory (see Part 1). For simple lotteries, the predictions of configural weights models are identical to PT.

²³ In personal communication, Mohammed Abdellaoui shared some findings of ongoing research that compares PT with alternative theories based on a comparison that takes account of the extra parameters under PT. These results are consistent with those reported above for Abdellaoui (2000).

2. There could be potential interaction between probability weights and the size of outcomes (Fehr-Duda et al., 2010). These results hit at the very foundation of models where the relevant objective functions are separable in probabilities and outcomes, such as EU, RDU, PT, and most other known decision models.
3. As Kahneman and Tversky (1979) so presciently realized, human behavior near the end-points of the probability interval is variable. Some people treat very low probabilities as very salient (notice the steep slope of the Prelec function in Figure 2 as $p \rightarrow 0$). However, others simply ignore very low probabilities (but this cannot be captured in Figure 2). Since the probability weighting functions, such as the Prelec function, underlie many behavioral theories, such as RDU, PT, and configural weights models, this evidence is troublesome for all of them. The neglect of low probability events, at least for a sizeable fraction of the population, impinges on a wide range of phenomena, such as buying inadequate insurance for low probability natural hazards, running red traffic lights, deterrence effects of capital punishment, and driving and talking on mobile phones (see Part I for details). One way of accounting for these phenomena is the proposal by Dhami and al-Nowaihi (2010b) to modify the Prelec function to a richer, axiomatically founded, probability weighting function that allows both overweighting and underweighting of very tiny probabilities. Whether this proposal will work is an open empirical question.

The rather detailed case study of PT in this section is not only useful for those seeking insights into behavioral theories of decision making, but also to illustrate the approach that I take in this book. I shall ask uncomfortable questions of both neoclassical and behavioral models, highlight the progress that has been made, and, whenever possible, use empirical evidence to judge between alternative theories.

5.2 Human sociality and inequity averse preferences

The exclusive pursuit of self-interest and the lack of any consideration of character virtues in neoclassical economics, is at variance with the evidence. Gintis (2009, p. 49) captures the heart of the issue: “Self-regarding agents are in common parlance called *sociopaths* . . . We conclude from behavioral game theory that one must treat individuals’ objectives as a matter of *fact*, not *logic*.” Evidence indicates that humans: exhibit *altruism* and *envy*; have an inherent tendency to cooperate yet display *conditional reciprocity* (respond to kindness with kindness and unkindness with unkindness); judge the kindness or otherwise of the *intentions* of others; and value human virtues such as “promises” for their own sake. Despite a great amount of evidence for *human sociality*, the acceptance of these forms of other-regarding behaviors is relatively slow among mainstream economics.

Many economists will probably dispute this criticism on the grounds that neoclassical economics allows people to have *other-regarding preferences*, and cite the rich tradition for this work (Veblen, 1899; Duesenberry, 1949). While this is certainly true, however, neoclassical economics has not generated models that can explain the richness of modern experimental findings on social preferences and human virtues, which is a minimum standard for aspiring contenders (Fehr and Schmidt, 2006). By contrast, behavioral economic theory has provided a rich range of models that are consistent with the evidence. Behavioral economics does not argue that human virtues, such as honesty and keeping one’s promises, are absolutes. Human adherence to virtues also depends on the cost of being virtuous and on the behavior (virtuous or otherwise) of others, e.g., tax evaders feel less guilty, if there is greater incidence of tax evasion in society.

Some of the earliest experiments on fairness concerns were conducted in the mid 1980s by Daniel Kahneman, Jack Knetsch, and Richard Thaler, based on telephone surveys in Canada.²⁴ Consider the following survey questions from Kahneman et al. (1991):

Question 1a. “A shortage has developed for a popular model of automobile, and customers must now wait two months for delivery. A dealer has been selling these cars at list price. Now the dealer prices this model at \$200 above list price.” Out of 130 respondents, 29% found the behavior of dealers acceptable, while 71% found it unacceptable.

Question 1b. “A shortage has developed for a popular model of automobile, and customers must now wait two months for delivery. A dealer has been selling these cars at a discount of \$200 below list price. Now the dealer sells this model only at list price.” Out of 123 respondents, 58% found the behavior of dealers acceptable while 42% found it unacceptable.

This example illustrates a number of interesting points.

1. Under self-regarding preferences, the responses to the two questions should be similar, but they are different.
2. The two different economic environments in Q1a and Q1b may generate ‘entitlements’ or status-quo reference points, such that receiving less than the entitlement is considered unfair. The entitlement is not necessarily mutually agreed upon. In other contexts, this can give rise to a *self-serving bias* in negotiations, which can potentially account for strikes, wars, and bargaining failures (Babcock and Loewenstein, 1997).
3. This example highlights some issues that play no role in neoclassical economics: For instance, forgoing a discount is less aversive relative to a surcharge. This leads to a better understanding of many business practices. Consider, for instance, charging for credit card usage in the early days of credit cards (Thaler, 2015). Initially, there was a 3% *surcharge* on the use of credit card payments in retail stores, which a consumer could avoid by paying cash. The credit card companies successfully lobbied the retail price of a \$1 item to be raised to \$1.03. So cash buyers could pay a *discounted price* of \$1, while card users could pay the *full price* of \$1.03. Card users thus do not pay a surcharge for their purchase. As Thaler puts it (p. 18): “Paying a surcharge is out-of-pocket, whereas not receiving a discount is a ‘mere’ opportunity cost.” Clearly direct out-of-pocket costs are more aversive relative to the more indirect concept of opportunity costs that is less well understood by many.

There is now overwhelming evidence of social preferences from lab and field data that has been widely replicated around the world with small and large stakes. Experimental games that have been used to build up the evidence base for social preferences include the *dictator game*, the *ultimatum game*, the *gift exchange game*, the *trust game*, and the *public goods game with and without punishment*.

Of the experimental games on human sociality, the *ultimatum game* (Güth et al., 1982) is the most replicated. In the ultimatum game, a proposer is given a fixed sum of money to split with the responder. The responder can then accept or reject. The backward induction outcome using classical game theory is that the proposer will offer the minimum divisible unit of money (e.g., 1 cent out of a dollar) to the responder; after all, something is better than nothing for the responder, so he accepts. By contrast, the average offer made by the proposer is 30–40 percent of the pie. Low offers are rejected by the responders who often invoke the “unfairness of low offers” as their justification for rejection; in neoclassical economics, people are amoral, so these considerations

²⁴ See the interesting background to these surveys in Thaler (2015, Ch. 14) and a discussion of the other experiments that they conducted.

do not arise. The results survive with sensibly high stakes, but rejection rates fall with extremely high stakes, although proposers still offer 20% of the pie (see Part 2 for details). These results have been replicated across the globe (Henrich et al., 2001) and reveal large cross-cultural differences in fairness norms.

The evidence from these experimental games shows that self-regarding preferences are not insignificant. However, a majority of the subjects also exhibit other-regarding preferences. A critical insight of this literature is that introducing a minority of individuals with other-regarding preferences in a pool of self-regarding individuals can potentially produce large changes (Fehr and Schmidt, 1999; Fehr and Gächter, 2000b). Empirical success in many areas that traditionally focused exclusively on self-regarding preferences, e.g., contract theory and political economy, has been considerably enhanced by incorporating other-regarding preferences. Over many years, Herbert Gintis and Samuel Bowles have made a compelling case for incorporating reciprocity into economic models, based on its evolutionary foundations (Gintis, 2009; Bowles and Gintis, 2011).

How should one proceed in light of this empirical evidence? Economists have traditionally been justifiably worried about preference-manipulation to explain economic phenomena. However, these concerns do not, and should not, apply to the modern literature on other-regarding preferences. The main models of other-regarding preferences have been subjected to extensive and stringent empirical testing, and fit well the evidence from a range of experimental games. Yet, it is not unusual to hear the comments that the incorporation of other-regarding preferences will “compromise the hard-won discipline encapsulated in the neoclassical framework with self-regarding preferences,” or that “other-regarding preferences are ad-hoc,” or that “they take the easy way out.” There is no empirical basis for these arguments; and we seek to demonstrate this in Part 2. Anyone who has been following the publications in the leading journals in economics in the last few years would have noticed that this state of affairs is fortunately changing.

Inequity aversion is an important human motivation. People chose to live in a welfare state with democratically elected governments where taxes finance redistribution to the poor and socially disadvantaged, and provide social insurance. Most of us will find it morally repugnant to live in a system without these features, even if we disagree on the exact levels of social redistribution. People also give their money and time to charitable causes; in the US, charitable donations alone account for 1% of GDP over and above redistributive taxes paid by people. Clearly, we are also driven by altruistic concerns. At the same time, we are envious of others who might be better-off than us. This is particularly the case when we believe that the higher income of others is not deserved; there is often a public outcry over high salaries and bonuses to top management in the financial sector especially at a time when they might be perceived as being responsible for a financial crises.

Fehr and Schmidt (1999) propose a simple, tractable, yet powerful model to capture these concerns. Suppose that n individuals are ordered in such a way that they have incomes $y_1 < y_2 < \dots < y_n$. Then, the Fehr–Schmidt utility function of any individual i is given by

$$U_i = y_i - \frac{\alpha_i}{n-1} \sum_{j>i} (y_j - y_i) - \frac{\beta_i}{n-1} \sum_{j<i} (y_i - y_j), \alpha_i \geq 0, 0 \leq \beta_i < 1. \quad (4)$$

An individual is said to have *inequity averse preferences*, a form of other-regarding preferences, if at least one of β_i and α_i is non-zero. In contrast, the neoclassical model with self-regarding preferences requires $\beta_i = \alpha_i = 0$ for all i . The first term in (4) captures self-regarding preferences and the next two terms capture, respectively, disadvantageous and advantageous inequity. Most experiments find that $\beta_i < \alpha_i$, so individuals suffer relatively more from disadvantageous

inequity; Eckel and Gintis (2010) review empirical estimates of the parameters from various studies. Empirically, $\beta_i < 1$ because we do not observe individuals throwing away their own incomes to reduce disutility from advantageous inequity. As with most other leading models in behavioral economics, this model has axiomatic foundations (Neilson, 2006). The Fehr–Schmidt model can be extended to a non-linear version, and this avenue has been fruitfully explored in several applications of the model.

Another popular model of inequity aversion is a model of *equity, reciprocity, and competition* (ERC), due to Bolton and Ockenfels (2000). Suppose that there are n players, $i = 1, 2, \dots, n$. The monetary payoff of player i is $y_i > 0$, and the sum of the total monetary payoffs is $S = \sum_{i=1}^n y_i$. The relative monetary payoff of player i is given by $r_i = y_i/S$. Then, the utility function of player i is given by

$$u^i(y_i, r_i). \quad (5)$$

u^i is twice continuously differentiable in y_i, r_i , and increasing and concave in y_i . For any given monetary payoff, u^i is maximized at $r_i = 1/n$ and is strictly decreasing and strictly concave in r_i around this point. Thus, individuals prefer to increase their monetary payoffs, yet for any monetary payoff, the individual prefers equal division; different individuals may view this trade-off differently, hence, the index i on the utility function. In the ERC model, individuals compare their payoff with the total payoff of others, but they do not care about interpersonal comparisons of their own payoffs with others (i.e., there is no notion of advantageous or disadvantageous inequity). In this sense, ERC has a less nuanced notion of inequality relative to the Fehr–Schmidt model.

The Fehr–Schmidt model is a bold one. It sticks its neck out and proposes a particular functional form that is eminently testable; this is quite distinct from the neoclassical approach, which argues that its underlying framework can potentially account for other-regarding preferences, yet does not specify how. The Fehr–Schmidt model has two eminently attractive features. First, it is able to explain the results from the key experimental games on human sociality such as the dictator game, ultimatum game, trust game, and public goods game with punishment; Part 2 gives the details. Thus, it meets the minimum standard for any aspiring theory of other-regarding preferences. Second, it predicts cooperation and sharing in bilateral/small group encounters and self-regarding outcomes under market competition. For instance, in ultimatum games, the proposer offers the responder a share of the pie because advantageous inequity is aversive and the responder rejects low offers because disadvantageous inequity is aversive. Ex-post punishment of non-contributors by contributors in public goods games can also be explained by disadvantageous inequity suffered by contributors. By contrast, under self-regarding preferences, we should never observe such punishments because bygones are bygones; see Section 6.2 below for more details. However, in an ultimatum game with responder competition, low offers are not rejected by any responder, because another responder may accept the offer, removing the opportunity to punish the proposer for an unfair offer. Anticipating this, the proposer makes a low offer. In this case, the outcome is as if individuals had self-regarding preferences although they really have other-regarding preferences.

The ERC model is also able to explain several important experimental results such as those from ultimatum games (including those under proposer competition), differences in the relative amounts given by proposers in ultimatum and dictator games, and the positive association between effort and rents in the gift exchange game. The ERC model also allows for asymmetric information, which gives it a wider domain of applicability. It can also explain better the data

in three player ultimatum games where a passive third party appears less cared-for relative to the predictions of the Fehr–Schmidt model (Bolton and Ockenfels, 1998). In other domains, it is less successful. Mean preserving spreads of payoffs leave a player’s utility unaffected but this is not supported by the experimental results (Charness and Rabin, 2002). In public goods games with punishments, players with ERC utility will not punish non-contributors because they are not concerned with a comparison of individual payoffs. Anticipating this, non-contributors will not contribute. Hence, the ERC model predicts that the outcome of the public goods games with and without punishments should be identical, a finding that is rejected by the evidence (Fehr and Gächter, 2000a,b). The ERC model may perhaps give even more realistic predictions in cognitively challenging situations where players might not know the precise income distribution of others but still have a rough idea of their relative income.

Clearly, the Fehr–Schmidt model and the ERC model cannot explain all aspects of social preferences because they are not designed to do so. In many situations, inferring intentions is important. Most people would punish others for intentional unkindness, but not for unintentional unkindness. Even the law makes a distinction between murder and manslaughter. However, inferring intentions of others requires a specification of belief hierarchies and a rigorous analysis requires the use of *psychological game theory*, which, in contrast to classical game theory, allows beliefs to directly enter the utility function (Geanakoplos et al., 1989; Rabin, 1993; Dufwenberg and Kirchsteiger, 2004; Battigalli and Dufwenberg, 2009); see Part 4 for the details. For instance, we may offer a tip to a taxi driver if we believe that he expects a tip. Indeed, the insights offered by Fehr–Schmidt preferences have been successfully combined with endogenous beliefs in the framework of psychological game theory (Falk and Fischbacher, 2006). In other domains, such as equal splits in ultimatum games, it appears that people follow certain *fairness norms* that are not directly captured either by the Fehr–Schmidt model or the ERC model (Rotemberg, 2008; Andreoni and Bernheim, 2009). The interested reader can pursue an empirical critique of both models in Cooper and Kagel (2015).

The Fehr–Schmidt model has led to several important theoretical advances in the literature on human sociality. For instance, it has played an important role in contract theory in the understanding of long-term contracts (Brown et al., 2004, 2012), and the choice of contracts in the presence of contractual incompleteness, such as the choice of bonus contracts over incentive contracts (Fehr et al., 2007). In each of these cases, the experimental evidence is consistent with the predictions of the underlying model.

Redistributive concerns are often center stage in national and local elections. In experimental games, people often prefer a smaller more equitably distributed cake to a larger less equitably distributed cake; these results fit well the Fehr–Schmidt model (Tyran and Sausgruber, 2006; Ackert et al., 2007). These empirical insights have led to new theoretical results in *behavioral political economy*, such as the existence of a Condorcet winner with inequity averse preferences, and the equilibrium redistributive tax when there is a mixture of voters who have self-regarding and Fehr–Schmidt preferences (Dhami and al-Nowaihi, 2010c,d). There has been progress in establishing key results on the effects of other-regarding preferences in a Walrasian competitive equilibrium (Dufwenberg et al., 2011); Fehr–Schmidt preferences provide an important example of a key separability assumption in this framework (Dhami and al-Nowaihi, 2010d). The standard machinery of stochastic dominance for self-regarding preferences (e.g., first and second order stochastic dominance and Lorenz dominance) does not apply when people have other-regarding preferences. However, the analogues of all these concepts for inequity averse preferences have been developed rigorously (Dhami and al-Nowaihi, 2013). Part 2 describes the details of these developments.

5.3 The quasi-hyperbolic model and self-control problems

Temporal analyses of economic models, for descriptive and normative purposes, almost exclusively rely on the *exponential discounted utility* (EDU) model. The EDU model arose purely in response to technical considerations. Samuelson (1937) proposed the EDU model and it turned out to be the unique method of discounting among delay-discounting models that leads to *time consistent choices* (Strotz, 1956). Let $\mathbf{c}_0 = (c_0, c_1, \dots, c_T)$ denote the real-valued *temporal consumption profile* of an individual at time $t = 0$. Under EDU, this consumption profile is evaluated by the following utility function,

$$U(\mathbf{c}_0) = \sum_{t=0}^T \delta^t u(c_t); \delta = \frac{1}{1+\theta}, \theta > 0. \quad (6)$$

The EDU model captures the key idea of impatience in a simple and parsimonious manner. However, a single parameter, the constant *discount rate*, θ , captures all relevant psychological considerations. In contrast to many who followed him, Samuelson was very careful in introducing his proposal. On the descriptive validity of his model he writes (p. 159) “It is completely arbitrary to assume that the individual behaves so as to maximize an integral of the form envisaged in (2) [i.e., the EDU model in (6)].” On the normative implications of EDU he writes (p. 161): “. . . any connection between utility as discussed here and any welfare concept is disavowed.”

The evidence does not support the EDU model. Arguably, the EDU model is rejected even more strongly than expected utility theory. The evidence can be gleaned from many sources (Loewenstein and Prelec, 1992; Frederick et al., 2002). There are several anomalies of the EDU model that make it a poor candidate of choice on empirical grounds. For instance, empirical evidence shows that losses are discounted less than gains (*the sign effect*), greater magnitudes are discounted relatively less (*the magnitude effect*), discounting over an interval depends on how that interval is subdivided (*subadditive discounting*), temporal choices can be cyclical (*apparent intransitivity of preferences*), and choices may depend on the *shape of the consumption profile*, despite no changes in discounted utility. Furthermore, the discount rate depends on age (younger people are more impatient), intelligence (higher IQ is correlated with lower impatience), and addictions (gamblers, smokers, drug users, and heavy alcohol drinkers are more impatient).

In this section, we concentrate on an important anomaly of the EDU, namely, the rejection of the constant discount rate, sometimes known as the *common difference effect*. Consider the following example from Thaler (1981): “Most people prefer one apple today to two apples tomorrow but they prefer two apples in 51 days to one apple in 50 days.” This *temporal preference reversal* violates constant discounting. A range of other examples highlight an increase in impatience when a future reward is shifted in date towards the present. For instance, short-lived New Year resolutions on smoking or drinking alcohol made with perfect sincerity at an earlier date, procrastination in undertaking various tasks or activities, splurging too much on consumption now, and saving inadequately for the future.

The sort of preferences exhibited in Thaler’s apples problem are known as *present-biased preferences*. Consider outcome–time pairs of the form (z, t) , where z is an outcome (possibly but not necessarily monetary), and t is time. Consider two possible outcomes z, z' and three time periods t, τ, t' , all strictly positive. The decision maker considers alternative outcome–time pairs at time 0. Let $\succsim$ be a preference relation between outcome–time pairs (e.g., if $(8, 3) \succsim (10, 4)$, the 8 units

Figure 3 A plot of the discount rate for the one-parameter hyperbolic discounting function with varying time delay.

received 3 periods from now are “at least as good as” 10 units received 4 periods from now). A great deal of evidence indicates *preference reversals* of the following form.

$$(z, t) \succsim (z', t') \text{ but } (z', t' + \tau) \succsim (z, t + \tau); \tau > 0, t' > t, z' > z. \quad (7)$$

One may fix z, t, t' in an experiment and ask subjects to state a value of z' such that they are indifferent between (z, t) and (z', t') . A straightforward calculation can then be used to infer the implied discount rate. Early experiments by Thaler (1981) showed that the implied discount rates for a one month, one year, and ten year horizon, were, respectively, 3.45, 1.2, and 0.19. Thus, individuals are more impatient, the closer the reward is to the present.

Fundamental work was done by George Ainslie in fitting discount functions to human and non-human temporal choice data that is summarized in Ainslie (1992). Figure 3 plots the implied per-period discount rate when the future reward is received with various time delays, for one of his functional forms that fitted his data well; see Part 3 for the details. As in Thaler’s experiments, the discount rate is higher when the reward is more proximate to the present and the discount rate is hyperbolically declining, hence, the term *hyperbolic discounting*.

One behavioral response to the empirical data has been to suggest a two-parameter *general hyperbolic discount function* that nests EDU as a special case (Loewenstein and Prelec, 1992).²⁵ However, a much simpler version, *quasi hyperbolic discounting* or the (β, δ) form, based on initial work by Phelps and Pollak (1968), but popularized by Laibson (1994, 1997), has paved the way for major applications of present-biased preferences. Under quasi-hyperbolic discounting, the consumption profile $c_0 = (c_0, c_1, \dots, c_T)$ is evaluated in the following manner.

$$U^0(c_0) = u(c_0) + \beta \sum_{t=1}^T \delta^t u(c_t), \quad 0 < \beta < 1, \delta = \frac{1}{1 + \theta}, \theta > 0. \quad (8)$$

²⁵ See also al-Nowaihi and Dhami (2006b) for a simple axiomatic derivation of the general hyperbolic discount function that corrects some errors in the seminal work of Loewenstein and Prelec (1992).

Here, δ plays the same role that it plays in the EDU model. The real bite comes from the term β that shrinks the utility from future consumption levels, relative to the present. This creates an additional *present bias for current consumption* over and above impatience that is captured in the discount factor δ . This feature explains preference reversals such as in Thaler's apples example, which the reader can readily verify. Unlike the general form of hyperbolic discounting, under quasi-hyperbolic discounting, the discount rate jumps up discontinuously just as one approaches the current date; the reader can do a few quick plots to check this.

Empirical evidence typically shows declining discount rates as in Figure 3, which implies *present-biased preferences*. However, there is somewhat less agreement about whether discount rates just decline, or if they decline in a hyperbolic manner. A great deal of empirical evidence from the lab and the field is consistent with quasi-hyperbolic discounting (Viscusi et al., 2008; Fang and Silverman, 2009; Tanaka et al., 2010).

Quasi-hyperbolic discounting has given rise to a wide range of applications of behavioral time discounting and a real improvement in our understanding of temporal decisions; an entire chapter is devoted to these applications in Part 3. Do individuals with present-biased preferences have adequate awareness that they might also exhibit a present bias in the future? This turns out to be a rather critical question whose consequences have been well explored (O'Donoghue and Rabin, 2001). In this context, it is best to think of individuals as a collection of *multiple selves*, each self coinciding with a distinct time period (e.g., a morning-self who presses the snooze button, overriding the decision to wake up early made by a night-self). Empirical evidence suggests that individuals lie somewhere between the two extremes of full awareness of future self-control problems, and no awareness of such problems; thus, they may be termed as *partial-naifs*.

Partial-naivety about future self-control problems, in conjunction with quasi-hyperbolic preferences, makes interesting predictions in a range of problems (see Part 3). There are important applications to macroeconomics, where one can derive the behavioral analogue of the Euler equation and explain several critical puzzles, for instance (Laibson, 1997, 1998): Why does consumption track income so closely? Why do individuals undersave for retirement? Why is there a sharp drop in consumption at retirement? Why do individuals hold illiquid assets and credit card debt simultaneously? Why is high consumption variability not associated with high consumption growth? What is the appropriate relation between intertemporal substitution and risk?

But there is also an equally important range of microeconomic questions that can be addressed with this framework: Why do many people procrastinate (O'Donoghue and Rabin, 2001)? Why do many people retire early (Diamond and Köszegi, 2003)? What are appropriate sin taxes (taxes on harmful addictions) in the presence of present bias (O'Donoghue and Rabin, 2006)? Why do smokers sometimes welcome an increase in the retail tax on cigarettes (Gruber and Mullainathan, 2005)? Why might some people buy expensive annual gym memberships, when a pay-per-visit contract would have saved them money (DellaVigna and Malmendier, 2004)? Why might farmers use fertilizers suboptimally (Duflo et al., 2011)? Hopefully these questions may whet your appetite to read Part 3 in more detail.

Given the evidence, the rigorous axiomatic developments, and wide-ranging applications of present-biased preferences, the dominance of EDU might well be an interesting topic for a student of economic thought writing a dissertation in 2030. But I would be lying if I said that the current generation of behavioral economists do not find this state of affairs to be frustrating. There have been several criticisms of hyperbolic discounting. But whether time preferences are exactly

hyperbolic or not will be eventually less important than whether they are present-biased.²⁶ Ultimately, a more complete picture of choice over temporal sequences might also need to relax the high degree of cognitive requirement that is embodied in all delay-discounting models. *Attribute-based models* that invoke choice heuristics may well outperform existing delay-discounting models (Ericson et al., 2015).

5.4 Level-k and CH models: disequilibrium in beliefs in strategic interaction

Non-cooperative game theory represents one of the most significant advances in economic theory. It has enabled economists to make very precise and testable predictions in strategic situations. In the economics profession there is widespread acceptance and use of the main solution concept, *Nash equilibrium*. In a Nash equilibrium and its extensions, players play a best response to their beliefs, and the beliefs and actions of the players are mutually consistent. Furthermore, Bayes' rule is used to update beliefs, whenever possible.

How do the actions and beliefs of players come to be mutually consistent? The most common justifications are an appeal to an unmodeled, underlying, process of learning, or that a Nash equilibrium is simply a social norm. None of these arguments is satisfactory. First, as we show in Part 5, the outcomes of experiments on learning do not necessarily converge to a Nash equilibrium. Second, many norms are not Nash equilibria, particularly in the domain of cooperative human outcomes. Furthermore, realistic epistemic conditions that justify Nash equilibrium play are not easily satisfied (e.g., common knowledge of rationality only implies the weaker notion of rationalizability); see Gintis (2009, p. 83) for related commentary.

Whether people do play a Nash equilibrium is an empirical matter. Let me cull out, very briefly, some interesting aspects of the evidence that is reviewed over several hundred pages in Parts 4 and 5; I suppress the very large number of references.²⁷ In many games, the experimental evidence, particularly in the early rounds of a game, is not consistent with a Nash equilibrium. In many others, the outcomes do not converge to a Nash equilibrium, even when the experiments are repeated over a large number of rounds. Even in relatively simple games that involve more than two to three steps of iterated deletion of dominated strategies, the outcome is often not a Nash equilibrium. However, it is also the case that in more complicated games, experimental evidence is sometimes surprisingly consistent with a Nash equilibrium, such as in signaling game experiments. In other games where complexity and cognitive requirements are quite high, such as bargaining under one-sided asymmetric information, the evidence is inconsistent with a Nash equilibrium. Yet, rather miraculously, when the degree of complexity is raised even further, as in bargaining under two-sided asymmetric information, the evidence fits well with a Nash equilibrium. In some games, where the Nash equilibrium is incredibly difficult to compute, such as in traffic network games, one sometimes observes relatively quick convergence to the Nash equilibrium; see, for instance, Mak et al. (2015). In this game, there are 3.3 billion pure-strategy equilibria, yet, incredibly, all players coordinate to converge on one of these equilibria! In other fairly complex games, the outcome is not even close to a Nash equilibrium, e.g., players might be subject to a winner's curse in common value auctions.

²⁶ In this book we also consider several other theories of present-biased preferences. These include the *planner-doer model* (Shefrin and Thaler, 1981), *models of dual-selves* (Fudenberg and Levine, 2006) and the Gul-Pesendorfer model of *temptation preferences* (Gul and Pesendorfer, 2001).

²⁷ For an excellent, but slightly dated review of the evidence, see Camerer (2003a).

In other cases, such as *market entry games*,²⁸ the number of entrants exactly matches that predicted by a Nash equilibrium. Kahneman (1988), who ran these experiments, exclaimed that “it looks like magic.” However, it is now well known that behavioral theories, such as the *cognitive hierarchy model*, discussed in Part 4, explain the evidence on market entry games equally well.

In sum, the case for focusing exclusive attention on a Nash equilibrium in economics is difficult to justify. In far too many cases, the behavioral alternatives provide a much superior explanation of the relevant evidence. One approach to relaxing the cognitive requirements embodied in a Nash equilibrium is to allow players to play noisy best replies, rather than strict best replies. This is the approach taken in *quantal response equilibrium* (QRE). A second approach, that we focus on briefly in this section, is *level- k models* (Nagel, 1995; Stahl and Wilson, 1995) and the closely related *cognitive hierarchy model* (Camerer et al., 2004).

The classic game that is used to illustrate the level- k model is the *p -beauty contest*. Suppose that in a winner-take-all contest, each of n participants chooses a number, x_i , from the interval $[0, 100]$. The winning guess is the number closest to $p\bar{x}$, where $p > 0$, and $\bar{x}$ is the mean guess. Let us assume that $p = \frac{2}{3}$. In a symmetric Nash equilibrium, all participants should choose the guess 0. This is easily checked. Conditional on the equilibrium guess of the other players, any player who chooses $0 + \varepsilon$, where $\varepsilon \in \{0, 1, \dots, 100\}$, moves the target ($\frac{2}{3}\bar{x}$) upwards from 0 to $\frac{2}{3n}\varepsilon$. But for $n \geq 2$, the new target is still closer to 0 than to ε , so no profitable deviations are possible. Likewise, the reader can check that there is no symmetric pure strategy Nash equilibrium in guesses that is strictly positive, because it would be destroyed if one individual chooses a lower guess.²⁹

In what follows, we shall, on empirical grounds, ignore Breitmoser’s effect that was raised in the last footnote. The typical findings in p -beauty game experiments are shown in Figure 4 for $p = \frac{2}{3}$ and for a diverse subject pool, comprising high ability Caltech students, economics Ph.D. students, portfolio managers, and high school students. The results are in stark contrast to the Nash equilibrium prediction. The original experimental findings are due to Nagel (1995), the first replication was by Ho et al. (1998), and since then, the experiment has been replicated many times. In particular, a peculiar feature of the data is that there are spikes around guesses of 33, 22, 14, . . . This is inconsistent with a Nash equilibrium.

Level- k models offer a parsimonious way of explaining these findings. In a level- k model, players have types Lk , $k = 0, 1, \dots, K$. Each type, except type $L0$, plays a best response, assuming that all other players are of type $Lk - 1$. The specification of type $L0$ depends on the problem and in some applications, this type is assumed to be simply randomizing equally among the available actions. In other domains, uniform randomization by type $L0$ players is behaviorally implausible, and one may have to modify it. For instance, in Crawford and Iriberri (2007b), type $L0$ players prefer the label-salient action in games where labels convey salience. The theory does not require type $L0$ players to physically exist; this type may simply represent a model of other players that type $L1$ players have in mind. The frequencies of the various types of players can be estimated

²⁸ In a market entry game, a set of firms with unit supply must simultaneously enter into a market with a fixed demand of $d > 0$ integer units. If just d firms enter, all make profits. If more than d firms enter, all firms earn zero, and if less than d firms enter, then the entrants earn a low but positive level of profits.

²⁹ Breitmoser (2012) questions the suitability of a level- k approach for the p -beauty contest. His main point is that by ignoring the effect of one’s own guess on the average guess, the predictions of level- k models are misspecified. However, it appears to be the case, in most experiments, that subjects ignore the effects of their own actions on the average and the guesses of subjects in experiments are in conformity with the predictions of level- k models; see Part 4 for the details.

Figure 4 Distribution of choices by different subject pools in a p-beauty contest game.

from the data. Empirical studies show that the largest percentage of players is of types L_0 , L_1 , and L_2 . Players of type L_3 or beyond, are rare.

Level- k models directly speak to the cognitive limitations of players and truncate the “infinite regress in beliefs” feature of classical game theory at some low, cognitively plausible, level. In particular, the solution concept that is proposed here is non-circular in the following sense that is well described by Selten (1998): “Basic concepts in game theory are often circular in the sense that they are based on definitions by implicit properties . . . Boundedly rational strategic reasoning seems to avoid circular concepts. It directly results in a procedure by which a problem solution is found.”

Let us apply level- k models to the p-beauty contest game. Type L_0 players simply randomize equally among the various guesses so their average guess is 50. Type L_1 players play a best response to a guess of 50, which is $\frac{2}{3}50 = 33.3$. Type L_2 players play a best response to a guess of 33.3, which is $\frac{2}{3}33.3 = 22.2$. Similarly, type L_3 players choose $\frac{2}{3}22.2 = 14.8$. The level- k model predicts spikes at 33.3, 22.2, and 14.8, which matches well with the data in Figure 4. If we accept that type L_0 players randomize equally among their choices, then this is an incredibly precise prediction that is confirmed by the data. This model is a “disequilibrium in beliefs” model so that, ex-post, many players will be surprised at the outcome, because their initial beliefs about other players are not confirmed.

A perseverant classical game theorist may not accept these results, arguing that a Nash equilibrium is about learning through repeated play; so, if you played the p-beauty game several times, the Nash equilibrium prediction will hold. This argument does not hold for several reasons. First, even if subjects use simple rules of thumb in a repeated p-beauty contest, and play a best response to the observed mean in the last period, then under reasonable assumptions the outcomes can be shown to converge to a guess of zero. Second, unlike the repeated p-beauty contest, real-world environments are not stationary, so a repeated p-beauty contest is not a stringent

Figure 5 Choices of game theorist subjects in a p-beauty contest game.

test of the theory. Third, a Nash equilibrium does not explain the temporal pattern of guesses. In a 10 round repeated p-beauty contest where groups of 3 subjects are matched by cognitive ability, a level- k model describes well the temporal pattern of guesses (Gill and Prowse, 2015). In the final two rounds, the high cognitive ability group reaches the Nash equilibrium prediction 29% of the time; the corresponding figure for the mixed and low cognitive ability groups is, respectively, only 15% and 13%.

A particularly simple version of the p-beauty contest occurs when there are two players, $n = 2$. For $p = \frac{2}{3}$, the winning guess is simply the lower of the two guesses. Thus, the cognitive requirements in guessing a Nash equilibrium are substantially reduced. Yet, before the p-beauty contest was part of the common folklore, when the experiments were run with professionals at conferences, the Nash outcome was not achieved for the vast majority of subjects. Four of these five conferences were economics conferences that included game theorists (Grosskopf and Nagel, 2008). 36.2% of professionals and 9.85% of students chose the Nash outcome. However, any choice greater than zero is a weakly dominated strategy, which is chosen by 62.8% of professionals and 91.15% of students. There is no statistical difference between the cumulative distribution of choices in the cases $n = 2$ and $n > 2$ for both pools of player. The results from game theorist subjects in Figure 5 show that their behavior is similar to other humans, although 22% of the choices in this group conformed to the Nash outcome, the highest among the six groups considered (Bosch-Domènech et al., 2002).

The *cognitive hierarchy* (CH) model is similar to the level- k model. However, in the CH model, each type, Lk , $k = 1, 2, \dots$, assumes that there is a distribution, typically Poisson, of players of all lower types, $Lk - 1$, $Lk - 2$, $\dots$, $L0$. The predictions of the level- k model and the CH model are similar for a large class of games and it is very difficult to put one ahead of the other on empirical grounds (Crawford et al., 2013). When the early-round results of a large class of 55 games are pitted against the predictions of the CH model and the Nash equilibrium, then there are two findings (Camerer et al., 2004). Whenever the Nash equilibrium predicts well, CH predicts well too, and when the Nash equilibrium predicts poorly, CH predictions are more accurate. Field data supports the superior predictions of the CH model relative to a Nash equilibrium (Goldfarb and Yang, 2009; Goldfarb and Xiao, 2011). Level- k models are supported by a great deal of other evidence (Costa-Gomes et al., 2001; Costa-Gomes and Crawford, 2006).

The applications of level- k and CH models have grown enormously. These range from testing the significance of focal points when they come into conflict with label salience in symmetric and asymmetric games (Crawford et al., 2008); the role of preplay communication in enhancing coordination (Crawford, 2007); the explanation of the “magical” results in the market entry game

that were originally thought of as a remarkable confirmation of Nash equilibrium (Camerer et al., 2004); and the explanation of the winner's curse in common-value auctions (Crawford et al., 2009; Crawford and Iriberri, 2007a).

Level- k models do not have a theory of level-0 players and the behavior of these players needs to be inferred from the data. So, a critic might argue, is it legitimate to use the same data to infer parameters of the behavior of level-0 players, and then use these estimated parameters to estimate the remaining parameters of interest? Crawford and Iriberri (2007b) solve this problem by first using a part of the sample to estimate the behavior of level-0 players. They then successfully make predictions for out-of-sample data (which in this case is a set of closely related games) that are confirmed.

Hargreaves Heap et al. (2014) question the issue of portability of level- k behavior across a wider range of games than are considered in Crawford and Iriberri (2007b). They do assume, however, that the specification of the level 0 players is identical across these games. In some games, particularly coordination games, *team reasoning* (see Part 4) rather than level- k models appear to better describe the evidence. This should alert us to the importance of different contexts that may trigger different behavioral responses—in some kinds of games, level- k reasoning may be invoked, while in others, team reasoning may be invoked. Perhaps a hybrid of level- k and team reasoning models, provided team reasoning can be formally defined in a satisfactory manner, may explain the data even better; similar conclusions are reached by Crawford et al. (2008, p. 1448).

5.5 *The heuristics and biases program: radical behavioral economics*

The neoclassical approach views economic agents as Bayesian, subjective expected utility maximizing decision makers who have unlimited cognitive abilities and follow the rules of classical statistics. These economic agents also routinely engage in mathematical optimization, using the latest developments in mathematics, statistics, engineering, and computer science. This is one possible hypothesis of human behavior to start with. However, as always, its descriptive validity hinges on the empirical evidence. Following Milton Friedman's approach (see Section 2 above), and some may argue, its misuse, it is not an uncommon response in economics to handwave away the evidence and argue that real humans behave "as if" they were textbook economic agents in neoclassical theory.

The crucial significance of the *heuristics and biases program* of Daniel Kahneman and Amos Tversky was that they showed systematically that this "as if" view is inconsistent with the evidence (Tversky and Kahneman, 1974). *Heuristics* are any rules of thumb that individuals actually use, as distinct from normative recommendations. Heuristics are *fast*, in terms of the computation time required, and *frugal*, in terms of information requirements. The term *biases* in the program refers to the difference between actual human behavior and the predictions of neoclassical theory.

The heuristics and biases program, one of the most important advances in all of social science, created great disagreement among psychologists. Some of the attacks on Tversky and Kahneman were vicious, and even personal (see Part 7 and Stanovich and West, 2000, p. 649).³⁰ Most economists ignored this work, and continue to do so, despite its ubiquitous presence around us in the media, public debates, and in behavioral finance. Luckily for behavioral economics, a young

³⁰ Here are some quotes from published journal articles (references in Part 7). 1. "it is Kahneman & Tversky, not their subjects, who have failed to grasp the logic of the problem." 2. "If a 'fallacy' is involved, it is probably more attributable to the researchers than to the subjects." 3. "In the examples of alleged base rate fallacy considered by Kahneman and Tversky, they, and not their experimental subjects, commit the fallacies."

economist, reading this work in 1976 did not ignore it; he wrote about it recently (Thaler, 2015, p. 22): “As I read, my heart started pounding the way it might during the final minutes of a close game. The paper took me thirty minutes to read from start to finish, but my life had changed forever.”

Tversky and Kahneman identified a range of judgment heuristics, which are underpinned by a great deal of evidence. Part 7 gives the details. Here, we consider some aspects of this research program. Let us call a textbook neoclassical economic agent who follows the rules of classical statistics a *Bayesian*.

People are often asked to answer questions of the form: How likely is that event A was generated by category/class/process B? In answering this question, people often use the *representativeness heuristic*, i.e., they give an answer based on how much event A looks like B.³¹ Relative to a Bayesian, people often assign too high a probability that small samples share the properties of large samples. Such individuals behave as if they obeyed a *law of small numbers*, rather than the statistically correct, *law of large numbers*. This has important implications. For instance, individuals find it difficult to produce hypothetical sequences of random numbers; these sequences exhibit too much *negative autocorrelation* (Tversky and Kahneman, 1974; Bar-Hillel and Wagenaar, 1991; Rapoport and Budescu, 1997). This behavior produces the *gambler's fallacy*, i.e., avoiding bets on recent winning numbers in gambling or recent winners in the stock market (Clotfelter and Cook, 1993; Terrell, 1994; Odean, 1998).

People may often observe many consecutive, identical, outcomes. In this case, they may use the representativeness heuristic to infer that the sample is drawn from a population that contains a disproportionate share of such outcomes. Thus, they may expect more of these outcomes in the future; this *positive autocorrelation* in outcomes is known as the *hot hands fallacy*. Clearly, a Bayesian would also update in the same direction, however, under representativeness, individuals react more strongly. The hot hands phenomenon has been documented in sports, such as basketball or baseball, where players who score heavily in a game may be believed to be on a hot streak. Lotto stores that sell winning lotto tickets experience unusually high sales for up to 40 weeks following the lotto win, although the probability of purchasing a winning ticket from that store is unchanged (Guryan and Kearney, 2008). For an “animate” stochastic process that relies on human skills (e.g., basketball and baseball), one is more likely to observe a hot hands fallacy relative to an “inanimate” process (e.g., casino betting), where a gambler's fallacy is more likely to be observed (Ayton and Fischer, 2004). The law of small numbers can also explain the existence of overconfidence (Rabin, 2002).

Individuals use the *availability heuristic* when they judge the probability of an event by the ease with which similar events are accessible or “available” to the mind. Accessibility is easier for salient and vivid events, which highlights the importance of media coverage of events. There is a close link between the perceived frequency of deaths by various causes and proxies for the availability of such events in memory (Lichtenstein et al., 1978).

The *affect heuristic* identifies the role of emotions in human decisions (Slovic et al., 2002; Loewenstein et al., 2001). People often classify and tag events by their *affect*. For instance, a holiday in New York may leave a positive affect, if it was enjoyable but, *ceteris paribus*, a negative affect, if one was mugged during the holiday. The affect heuristic argues that the pool of these positive and

³¹ For instance, suppose that three successive balls are drawn with replacement from either urn A that has 1 red and 2 black balls or urn B, which has 2 red and 1 black balls; it is common knowledge that urn A is chosen with probability 0.6. The three sampled balls turn out to be 1 red and 2 black. What is the probability that the balls came from urn A? The statistically correct answer is 0.75, but an individual subject to the representativeness heuristics gives an answer greater than 0.75 and, in the extreme case, an answer of 1.

negative affects determines our choices, rather than objective statistical probabilities of events, e.g., do I go to New York for my next holiday? The affect heuristic may economize on cognitive efforts in making a decision and quicken decision making, because it is easier to think “what do I feel about it?” rather than “what do I think about it?” (Kahneman, 2011). Even experts rate the risk of hazardous substances by the feeling of dread that these substances invoke (Fischhoff et al., 1978; Slovic et al., 1999). Loewenstein et al. (2001) make a powerful case for understanding choices among risky options in terms of their emotional impact.

Anchoring, the influence of initial suggestions as anchors on subsequent judgments, is one of the most robust and important heuristics. When anchors are self-generated, people adjust insufficiently towards the correct response, but when they are provided by others (e.g., the experimenter), people are often biased towards finding confirmatory evidence for them. In a famous experiment, the response of subjects to the question “how many African countries are there in the United Nations?” is influenced by the prior observed outcome of a random wheel of fortune that is rigged to come up with the numbers 10 or 65 (Tversky and Kahneman, 1974); clearly irrelevant information influences choice in this case. In field studies, experienced judges and estate agents are influenced by anchors (Englich and Mussweiler, 2001; Northcraft and Neale, 1987). Implausible and irrelevant anchors can have a significant effect on subjects’ choices (Strack and Mussweiler, 1997). Regulation, such as caps on damages awarded to litigants, serves an anchoring role and influences the rate of pretrial settlements and the level of damages (Babcock and Pogarsky, 1999; Pogarsky and Babcock, 2001).

Anchoring has been documented in a wide range of contexts, such as poetry reading sessions (Ariely et al., 2006); violation of a basic implication of efficient markets (Mussweiler and Schneller, 2003), and first offers in price negotiation (Galinsky and Mussweiler, 2001). Anchoring has also been used to explain a range of other behavioral phenomena, such as hindsight bias, non-linear probability weighting, and preference reversals.

Bayes’ rule fundamentally underpins modern economic theory. However, most people do not employ Bayes’ rule when the relevant information is presented in a probability format. In particular, individuals routinely exhibit *base rate neglect*, i.e., give insufficient attention to the prevalence of a particular trait or feature in the overall population (Kahneman and Tversky, 1972; Bar-Hillel, 1980; Tversky and Kahneman, 1980). Consider the following problem, adapted from Casscells et al. (1978) that was given to students at Harvard Medical School. Suppose that a police Breathalyzer test discovers false drunkenness in 5% of the cases when the driver is sober. However, the Breathalyzers are always able to detect a truly drunk person with complete certainty. In the general population, 1/1000 of drivers engage in driving while drunk. Suppose that a driver is checked at random, and takes a Breathalyzer test, which shows that the driver is drunk. How high is the probability he or she really is drunk? The modal response was 95%, the mean response was 56%, and only a sixth of the students gave the correct answer, which is approximately 2%. Most people ignore the low base rate of 1/1000 of drivers who drink and drive.

Hindsight bias occurs when individuals make a prediction about some future event, but after they observe the actual outcome, their postdictive judgment (i.e., recall of their initial prediction) is too close to the actual outcome (Fischhoff, 1975). Thus, people give the impression as if “they knew it all along.” This bias is extremely important in legal cases where the judge and jurors must infer if the defendant took enough preventive care in the past, having already observed the outcome of the defendant’s decision. A meta-study finds that experts also exhibit the hindsight bias (Guilbault et al., 2004). In finance, hindsight bias reduces estimates of volatility, and people engage in less corrective activity of incorrect models (Biais and Weber, 2009).

Confirmation bias is an important heuristic in which people interpret the evidence in a self-serving manner so as to confirm their initially held views (Lord et al. 1979). Higher cognitive ability does not reduce this bias (Stanovich and West 2007). As one may expect, since confirmation bias vindicates initially held views, it can also explain the prevalence of overconfidence and underconfidence (Rabin and Schrag, 1999).

As with many other great works, some of the initial charges against the heuristics and biases approach could be easily refuted. These included the charge that subject errors and misperceptions caused the biases, or that Kahneman and Tversky did not understand probability theory well enough. Other charges took longer to refute, some were already actually answered by Tversky and Kahneman in their published work, others helped to modify the theory without serious changes in the message. A prime example is the belief that if individuals are presented with information in *frequency format* rather than in a *probability format*, then human biases disappear (Cosmides and Tooby, 1996; Gigerenzer and Hoffrage, 1995). Empirical evidence, examined in some detail in Part 7, supports two kinds of conclusions. (1) Natural frequency format reduces the extent of biases only for a few heuristics. For instance, in the best case scenario for the frequency format, for base rate neglect, less than half the subjects conform to Bayes' rule. (2) For the vast majority of heuristics, results for the probability format and the frequency format are comparable. Most real-world data of interest to economists are presented in a probability format, e.g., interest rate increases announced by central banks, interest rates quoted by mortgage providers, percentage changes in unemployment, crime, and GDP changes announced by various government agencies. Thus, the debate between the proponents of the natural frequency format and the probability format might be of more academic than substantive interest.

In his seminal work on bounded rationality, Herbert Simon argued that cognitive limitations preclude individuals from engaging in neoclassical optimization exercises. As Simon (1978, p. 347) famously put it: "But there are no direct observations that individuals or firms do actually equate marginal costs and revenues." Reinhard Selten has often argued that many economic problems are hard in the sense that they are *NP-Complete*. This means that the number of steps needed to solve a problem in any algorithm of the solution, grows exponentially with the size of the problem, as in the well-known travelling salesman problem. Moderately difficult problems in this class require very high computation time. It is a leap of faith to assume that humans can routinely solve these problems or act "as if" they could.

Herbert Simon's solution was to replace *optimization behavior* with *satisficing behavior*, i.e., individuals have an *aspiration level* and adjust gradually towards it (Simon, 1978, 2000; Selten, 2001); for supportive empirical evidence see Caplin et al. (2011). A second line in the literature is associated with the work of Gerd Gigerenzer and colleagues (Gigerenzer et al., 1999; Gigerenzer and Selten, 2001). The main thrust of this approach is that heuristics are not mistakes, but a rational response to bounded rationality, and heuristics often outperform selected optimization methods. However, the superiority of fast and frugal heuristics is often demonstrated in domains where the relevant optimization benchmark is unclear. In contrast, Tversky–Kahneman were interested in domains where the relevant benchmark is completely clear. Furthermore, in the fast and frugal heuristics approach, the heuristics are typically experimenter provided; by contrast, in more complicated situations, it is not always clear what the relevant heuristics should be. Tversky–Kahneman are able, in contrast, to typically specify the environments in which their heuristics apply.

Gigerenzer's work, in particular, has led to a heated debate with the Tversky–Kahneman approach with most commentators treating the positions as adversarial. This has come to be known as the *great rationality debate* in psychology that is outlined in Part 7 (Stanovich and

West, 2000; Stanovich, 2012). My own reading is that this debate is extremely muddled; the two approaches are complementary and deal with quite different domains. Both approaches need to be encouraged by social scientists, but for entirely different reasons. Kahneman and Tversky's (1996, p. 584) frustration is well captured in this quote: "The position described by Gigerenzer is indeed easy to refute but it bears little resemblance to ours. It is useful to remember that the refutation of a caricature can be no more than a caricature of a refutation."

How would you feel about economics, and particularly about economists, if you were Daniel Kahneman? (1) Prospect theory, the most empirically satisfactory decision theory for risk, uncertainty, and ambiguity, has not yet made it into the mainstream economics curriculum, 36 years after it was published. (2) The heuristics and biases approach was initially viciously attacked, continues to be ignored by most economists despite having the greatest relevance for their work, and then pitted unfairly and unnecessarily against Gerd Gigerenzer's approach. One can sense the underlying disappointment if one reads Kahneman (2011) between the lines. However, the literature on behavioral finance, and a new generation of economists, most notably led by Matthew Rabin, have rekindled interest in this approach. Part 7 reports this work in detail.

6 Five examples of behavioral evidence

In this section, I consider five examples of behavioral evidence. This evidence often challenges some of the assumptions or implications of neoclassical models that are taken to be true on a-priori grounds. A more detailed account can be found later in the book.

6.1 *Does competitive market equilibrium survive fairness considerations?*

The development of the theory of competitive market equilibrium (CE) is one of the great intellectual achievements of modern economics. Empirical tests of a CE require a specification of the hypothetical Walrasian auctioneer that is a central part of the theory. Chamberlin (1948) ran some of the first CE experiments with Harvard students. He allowed students to interact freely in their roles as buyers and sellers in a market, and strike voluntary and mutually agreeable deals. This experimental protocol accords well with the intuition of many people about how competitive markets function. He found that prices did not converge to a CE. Modern experimentalists will disagree with many features of Chamberlin's experiments, despite their intuitive appeal. For instance, subjects were not incentivized and did not play the game anonymously without face to face interaction. I suspect strongly that Chamberlin's results will go through even if the subjects were incentivized; the main drivers of his result are the other elements of his experimental design. However, Chamberlin's results have not had a fundamental impact on modern economics.

Vernon Smith (1962) used a novel method of inducing demands and supplies among subjects in experiments. This is known as *induced value methodology*, and is now a standard technique to induce preferences in experiments. Each buyer is given a card with a valuation on it that is privately known to the buyer only. The buyers cannot pay a price above their valuation. Similarly, sellers are given a card with a cost on it, and they are not permitted to sell below it. In a *double auction setting*, in each round, buyers place 'bids' and sellers post 'asks.' Buyer-seller pairs voluntarily trade within a given period; successful matches drop out for the remainder of the period. Subjects keep playing within the period until they strike no more voluntary deals, or the

period ends. Within this setting, there is relatively quick convergence to a CE, a result that has been replicated many times (Davis and Holt, 1993; Kagel and Roth, 1995). This result also holds with zero intelligence robots (Gode and Sunder, 1993), which suggests that it is the underlying induced value methodology and the institution of double auctions that lead to a CE.

Vernon Smith's findings were readily accepted into economics, unlike Chamberlin's and Kahneman and Tversky's findings. However, Smith's results leave open the question whether we get the CE outcome in the absence of (i) the double auction setting, which is not a particularly pervasive institution, (ii) the induced value methodology, and (iii) in richer competitive market settings. Regarding (ii), Thaler (2015, p. 40) writes: "But I had some worries about this methodology [induced value methodology]. When you go to the store and decide whether to buy a jacket for \$49, no one is telling you how much you are willing to pay for it. You have to decide that for yourself, and that value might depend on all sorts of issues." Indeed, in Thaler's own experiments on exchange asymmetries, when subjects had to assign a value to an owned object and an unowned but identical object, owners assigned higher values to owned items. In this section, we focus on (iii).

Fehr et al. (1998) tested for a CE by enriching the market environment to include issues of endogenous quality. In this case, the outcomes did not converge to a CE. It is worth exploring these findings and the subsequent literature. Suppose that risk-neutral sellers have some fixed cost, f , of producing a single unit of a good and they must choose the quality of the good from some interval $[q_0, q_1]$. The variable cost of producing alternative quality levels is $c(q)$ such that $c' > 0$, so higher quality is more costly to produce. Risk-neutral buyers have unit demands, know the seller's cost, and make price offers to the sellers. Hence, this is a one-sided oral auction with many buyers. Buyers prefer higher quality, and their valuation for one unit of the good is $v(q)$, such that $v' > 0$. Sellers observe the auction price, p , and then decide on non-enforceable quality that they will supply to the buyer. There are more sellers than buyers.

Since higher quality is costly to produce, if all parties have self-regarding preferences, then we should expect sellers to act opportunistically and supply the lowest quality, q_0 . Anticipating this, buyers will offer the lowest price $p = v(q_0)$. Thus, in a competitive equilibrium, sellers make a profit equal to $v(q_0) - f - c(q_0)$, the utility of the buyer who wins the auction is $v(q_0) - p = 0$, and the utility of non-winning buyers is also zero. The parameters of the experiment are chosen so that $v(q_0) > f + c(q_0)$, where $f + c(q_0)$ is the minimum cost to the seller of supplying a unit of the good at the lowest price, hence, it is the *reservation price* in the experiments.

The outcome will be very different if market participants have other-regarding preferences. In particular, if sellers are known to exhibit reciprocity, then buyers will offer prices in excess of the seller's reservation price, and the seller will reciprocate with higher quality. It is likely that in equilibrium, buyers and sellers derive, respectively, higher utility and higher profits relative to the predictions of a CE (with self-regarding preferences). This may be termed as the reciprocity treatment (RT). The parameters in the experiments were chosen so that reciprocal quality increases were associated with Pareto improvements. In order to check if reciprocity is the driving motive, a control treatment (CT) was also implemented in which the quality was publicly known to be exogenously fixed and the seller had no control over it.

There was intra-group homogeneity among the sellers and the buyers. The matched parties did not know each other's identities; price messages were transmitted by telephone to hide the identities of players. While prices were publicly announced, the information on quality was revealed only to the two contracting parties. These features ensured that there were no reputational effects across different rounds of the game. For the RT, Figure 6 shows the response of quality (vertical axis, $[q_0, q_1] = [0, 0.7]$) to various levels of price (horizontal axis, in blocks of 10s, and ranging

Figure 6 Response of quality to price in a competitive equilibrium.

from 30 to 110). Numbers over the bars indicate the number of observations in each category. The main finding is that higher prices offered by buyers elicit higher quality by the sellers. Furthermore, in the RT, the average price offered by the buyers was twice the level of the reservation price. However, in the CT, where the quality was fixed exogenously, the prices go down to the sellers' reservation price, hence, sellers' reciprocal behavior is the main driver of departures from the CE outcome. When sellers were offered low prices, they reacted by offering the minimum quality, which is also consistent with the reciprocity hypothesis.

There is experimental evidence of correlation between competition, market institutions, and trust/reciprocity. In their seminal cross-cultural study of the ultimatum game, Henrich et al. (2001) found that the rejection rates of lower offers are higher in societies where there is predominance of buying/selling, working for a wage, and production is carried out on a cooperative basis (as in modern firms). However, causality can run both ways. In societies with greater trust and reciprocity, markets may tend to work well because it is easier to engage in information contracts. Conversely, markets may have an impact on sociality and, therefore, affect the willingness to trust and reciprocate. Given the current evidence, we cannot establish the direction of causality. Evidence shows that in the trust game, competition improves human sociality (Huck et al., 2012); this line of research needs to be developed further.

List (2006) seeks to address the issue of sellers' quality differences between lab and field experiments, based on data gathered from sports card dealers. In the typical marketplace for sports cards, dealers display their sports cards and buyers mill around, requesting cards of a particular quality and offering a price for that quality. In the field data, quality can often be hard to verify and sellers do not know if buyers will later engage in costly quality verification from a third party. Buyers and sellers are recruited by monitors from a sports card market to participate in an hour long experiment. Buyers can offer either a low price, \$20, or a high price, \$65. In contrast to the field study, sellers in the lab know that the quality will be subsequently measured, a factor that may influence their quality supplied in the lab relative to the field.

The lab experiments were conducted in close proximity to the sports card market, hence, these experiments offer an unusually clean comparison of lab and field results. There were two kinds of subjects under study, local dealers (70% of the sample), and non-local dealers (30% of the sample).

Figure 7 Response of quality to price for local and non-local dealers in the lab and in the field.

Source: Camerer, Colin F. (2015). "The promise and success of lab-field generalizability in experimental economics: a critical reply to Levitt and List." In G. R. Fréchette and A. Schotter (eds.), *Handbook of Experimental Economic Methodology*, pp. 249–96. Adapted from List, J. A. (2006). "The behavioralist meets the market: measuring social preferences and reputation effects in actual transactions." *Journal of Political Economy* 114(1) 1–37.

List (2006, p. 5–6) used the results of this data to conclude that “even though the data collected from one-shot laboratory experiments suggest that social preferences are quite important among these agents, parallel treatments in the field suggest that such effects have minimal influence in naturally occurring transactions. In this sense, dealer behavior in the marketplace approaches what is predicted by self-interest theory.”

Following Camerer (2015), let us re-examine the data arising from a within-subjects analysis, i.e., from instances where the same sports card seller or buyer generated data in the lab and in the field; clearly, this is the most meaningful comparison between the lab and the field. This also ties in nicely with the discussion on lab-field generalizability in Section 3, above. The results are shown in Figure 7; some of this data is based on analysis that was not reported in List (2006). When data are pooled for local and non-local dealers, the quality level supplied (on a 1 to 5 scale) is lower in the field setting, relative to the lab, for each price level: 2.3 versus 3.1 when the price is \$20, and 3.1 versus 4.1 when the price is \$65. However, the response of quality to changes in price is similar in the lab and the field.

Interpreting the results of List (2006), Levitt and List (2008) argue that sports card dealers in the field behave more selfishly, and (p. 10) “increase quality little in response to a generous offer from the buyer.” In their abstract, they say: “Economic models can benefit from incorporating insights from psychology, but behavior in the lab might be a poor guide to real-world behavior.” Is this a reasonable conclusion for the more relevant case of within-subjects design? Using Figure 8, for field data, non-local dealers increase their quality in response to higher prices by just 0.13, but the corresponding figure for local dealers (who constitute 70% of the sample) is 1.40, which is significant. Levitt and List draw their strong conclusion because they only report the data for non-local dealers in their 2008 paper. Local dealers do offer higher quality in response to higher prices, hence, their behavior could be the outcome of social preferences.

Camerer (2015) conducts tests of statistical significance of the difference in quality between the lab and the field, for the within-subjects design, but the results are inconclusive. He notes: “To be crystal clear, I am not sure whether dealers behave differently in the lab and the field.” List

(2006) also gives data on the difference between actual quality supplied by sellers and the seller's claimed quality, a measure of the sellers' mendacity. Mendacious behavior is more common in the field, yet the statistical tests lack power to differentiate lab and field data.

6.2 Why do we not let bygones be bygones?

An important insight of neoclassical economics is that if self-regarding preferences are combined with classical game theory, then we should not observe costly ex-post punishments. This is because, such punishments only reduce the size of an individual's payoff, so why punish? In other words, *let bygones be bygones*.

Consider a typical public goods game experiment. A group of n risk-neutral individuals are given an initial endowment of money, $y > 0$. They simultaneously decide on their respective contributions, $g_i \geq 0$, $i = 1, \dots, n$, to a public good, giving rise to $G = \sum_{i=1}^n g_i$ units of the public good (the production technology for the public good is linear). The public good gives a return $r > 0$ per unit, to each individual. Thus, the utility of the i th individual is given by $y - g_i + rG$; typically $\frac{1}{n} < r < 1$, so that it is privately optimal to free-ride (i.e., $g_i = 0$), although the efficient solution is that everyone should contribute their entire endowment (i.e., $g_i = y$). Now introduce a costly ex-post punishment stage in which, at the end of the game, the individuals can observe the contributions of others, and engage in costly punishment of non-contributors. An individual who desires to punish another, gives up one monetary unit and the experimenter takes away three monetary units from the intended target of the punishment.

Classical game theory predicts that the punishment stage is irrelevant, because bygones are bygones. Looking ahead, rational players will realize that the punishment stage has no bite, hence, the public goods game with and without punishment is predicted to yield identical results. Fehr and Gächter (2000a) put this to the test. They ran 10 rounds of a public goods game with punishment, followed by 10 rounds without punishment (rounds 11–20), with $y = 20$ and $r = 0.4$. There were three different treatments. In the partner treatment, the same subjects were matched over all rounds. In the stranger treatment, they were randomly rematched in groups at the start of each round. In the perfect stranger treatment, they were randomly rematched in groups at the start of each round. The perfect stranger treatment is similar to the stranger treatment, but when subjects are

Figure 8 Public good contributions in the presence and absence of punishments.

Source: Fehr and Gächter (1999).

rematched at the start of each round, the experimenter ensures that they have not been matched in any of the past rounds. The results are shown in Figure 8.³²

The prediction of classical game theory, based on self-regarding preferences, is rejected by this evidence. Contributions are high in the presence of punishment for each of the three treatments (rounds 1–10), but decline rapidly once the punishment is removed, reaching near perfect free-riding levels (rounds 11–20). Furthermore, in the presence of punishments, there is a marked difference in the contributions in the three treatments. Contributions are near first-best levels in the partner treatment, but even in the perfect stranger treatment, subjects contribute about half their endowments. Subjects seem to anticipate that they will be punished if they contribute less, particularly when they are repeatedly matched with the same partners. This induces high levels of cooperation.

Punishments, in contrast to the predictions of classical game theory, perform a prosocial role. When the punishment option is removed, subjects begin with high levels of cooperation. However, once contributors observe low contributions in their groups by opportunistic players, they respond in the next round by contributing less. This leads to successive rounds of negative reciprocity and reduced contributions. The efficiency enhancing role of punishments has also been documented in other games, such as in the gift exchange game with punishment (Fehr et al., 1997); we consider this and other evidence in Part 2.

Consider a few other related points about this analysis.

1. The fact that in the absence of punishment, we observe widespread free-riding does not save the theory with self-regarding preferences, because it cannot explain the pattern of decay in contributions. An explanation of this pattern requires a fraction of the players to exhibit reciprocity (Fischbacher et al., 2001; Fehr and Fischbacher, 2005; Fischbacher and Gächter, 2010).
2. When the experiment is repeated outside Western countries, one also observes antisocial punishment, i.e., punishment of contributors by non-contributors who react to past punishments. Antisocial punishments are more likely to be found in societies where the indices for the *norms of civic cooperation* and *rule of law* are low (Herrmann et al., 2008). Experiments possibly overstate the role of punishments because in actual practice, punishments are institutionally meted. Democratic societies do not sanction antisocial punishments. The desire for prosocial punishments, and the efficiency enhancing role of punishments (see below) in most Western societies, possibly underpins public sanctions for antisocial behavior.

In an important advance, Fehr and Williams (2015) allow subjects in experiments to voluntarily choose one of the following four institutions. (1) No punishments. (2) Fehr–Gächter type peer punishment. (3) As in (2), but with the additional opportunity for each individual to announce how much everybody should contribute. The average contributions are revealed at the end of each round. This captures the formation of social norms of contributions. (4) Centralized punishment by a democratically determined leader, plus social norms of contributions, as in (3). The main result is that virtually all subjects choose institutions (3) and (4). Furthermore, institution (4) wipes out antisocial punishment. We also review other results in Part 2, which demonstrate that antisocial punishments are eliminated if, ex-ante, individuals choose the punishment institution by a referendum.

³² One of the most versatile and sagacious social scientists of our times, Herbert Gintis, once mentioned to me that Figure 8 was one of the most important graphs that he had seen in his life.

3. The efficiency enhancing role of costly punishments has also been debated using evolutionary arguments. In experiments, the net effect of costly punishments may be to reduce overall payoffs (Page et al., 2005). However, this is not the case, if sufficiently large numbers of rounds of punishments are allowed. Gächter et al. (2008) have shown that if the credibility of the punishment threat is established, and if the punishment opportunity arises over sufficiently many rounds (10 and 50 round cooperation games are considered), then punishments are efficiency enhancing; in fact, only 5–8 rounds of punishments may suffice to increase overall payoffs. Social punishments and reciprocity are also likely to have been essential to the formation of social norms of cooperative behavior (Gintis, 2009).
4. Subjects do not let bygones be bygones, which is a puzzle under self-regarding preferences. Punishments in the public goods experiments can be explained by Fehr–Schmidt preferences in which people have a concern for inequity aversion. Neural evidence is consistent with the view that individuals derive hedonic satisfaction from the act of punishing others who they believe have wronged them. A region of the brain, the striatum, that is associated with the brain's reward circuits, shows greater activity when social punishments are carried out (De Quervain et al., 2004). This also illustrates the powerful role of neural evidence in informing us about human motivations.

6.3 Are financial markets efficient?

Let us call the neoclassically rational agents in financial market *arbitrageurs*. Most neoclassical economic analyses allow for the possibility that some economic agents could be irrational, also known as *noise traders*, relative to arbitrageurs. Yet, it is argued, we can ignore them due to two a-priori arguments.

1. The individual errors of *noise traders* will cancel in the aggregate.
2. Noise traders, if any, will lose money due to the arbitrage activity of arbitrageurs, hence, they will eventually exit the market.

Anyone who has done an introductory course in economics would have come across these plausible sounding arguments. Most, including those teaching these arguments, are likely to have been convinced. Empirical evidence shows how flawed this a-priori reasoning can be. Formulating plausible a-priori hypotheses is essential in all science, as is testing them stringently, but the stringent testing bit appears to have received less attention, possibly motivated by bogus “as if” arguments.

The first argument has been debunked by the heuristics and biases approach of Kahneman and Tversky (Section 5.5, above). Individual errors of noise traders are often systematic and not random, so they can accumulate in one direction. For instance, individuals subject to the hindsight bias consistently underestimate volatility of stock prices, and fail to update their incorrect models fully (Biais and Weber, 2009). In the formation of *bubbles*, for instance, house price bubbles, individual beliefs can systematically depart from fundamental values for a sufficient length of time. In financial markets, the *disposition effect* caused by loss aversion may prevent people from selling stock below its purchase price precisely at a time when such arbitrage activity is required to equilibrate the market. Insofar as loss aversion is hardwired in individuals, they systematically engage in the disposition effect.

The second argument also turns out to be problematic. Consider the example of house price bubbles, and let prices exceed fundamental values. Yet, suppose that investor sentiment, as

captured in the beliefs of noise traders, is that prices will continue to increase. If there are enough noise traders in the market, then arbitrageurs might be forced to bet their money in the direction of a price increase, which exacerbates the departure of price from fundamental values. The seminal work of De Long et al. (1990) shows that noise traders may make more profits than arbitrageurs, particularly if they are bullish, and they may continue to make money for a time, while arbitrageurs might not be able to hold on to loss making positions for long enough. But, there are many other reasons why financial markets might not be efficient that we discuss next.

Traditional finance has been built on the foundations of the *efficient markets hypothesis* (EMH). It requires that at any instant in time, the price of a security must equal its fundamental value, which we may take to be the present discounted value of all future income flows from the security. Several theoretical arguments can be advanced for why the EMH need not hold. The demonstration of De Long et al. (1990) for market inefficiency based on noise trader risk provided an early theoretical challenge to the EMH. The full range of substitute securities that are required to guarantee EMH might not exist. Transaction costs of arbitrage (cost of finding mispricing information and brokerage fees for taking a short position) might also impede market efficiency.

The difficulty of beating the stock market is often cited as proof of its efficiency. EMH implies that there are no arbitrage opportunities; however, the absence of arbitrage opportunities does not logically imply that EMH holds. This is simply a confusion between necessary and sufficient conditions (Barberis and Thaler, 2003). EMH relies on instantaneous flows of information. Yet, evidence shows that some kinds of information may flow only gradually through the market, leading to a relationship between momentum and trading volumes of stocks, and aggressive trading, even when price equals fundamental values (Hong and Stein, 1999, 2007).

Professional arbitrageurs, such as mutual funds managers, invest on behalf of small and dispersed investors who have little financial expertise. However, the greater financial nous of professional arbitrageurs cannot be relied on to induce market efficiency (Shleifer and Vishny, 1997). Small investors only observe indirect signals of the ability of professional arbitrageurs, such as the end of year financial performance of professionals, and their performance relative to other professionals. This forces professional arbitrageurs to (i) liquidate their positions in loss making assets too quickly before the year is out, which makes it difficult to counter the activity of noise traders, and (ii) to invest in relatively similar portfolios to avoid looking worse than the others, which is a form of *herding behavior* and can lead errors to accumulate in one direction. These distortions may even reduce the performance of professional arbitrageurs below that of passive investment strategies (Ippolito, 1989; Lakonishok et al., 1992).

A great deal of evidence from financial markets is inconsistent with the EMH. While substitute securities are essential for EMH, their prices can differ systematically, which is inconsistent with EMH. Particularly clean evidence of this effect comes from *Siamese-twin companies* that have merged in the past on an $x : y$ equity basis, yet may trade separately in different markets. If EMH holds, then their traded prices should be in the $x : y$ ratio, but they differ systematically from this ratio (Froot and Dabora, 1999). Security prices often react to no-news and many stock market crashes occur suddenly without any apparent changes in fundamental values (Cutler et al., 1991). The price of freshly inducted stocks into the S&P 500 index immediately jumps upwards, but no new information about the company has been revealed (Shleifer, 1986). The volatility in stock prices is excessive, relative to the predictions of EMH (Shiller, 1981).

Stale information can predict future prices. For instance, stocks that have done well over a long horizon give low subsequent returns and past losers give higher subsequent returns (De Bondt and Thaler, 1985). Over shorter horizons, a *momentum effect* has been observed; recent stock market performance of stocks can carry over to the future (Jegadeesh and Titman,

1993). All public information should immediately have been incorporated into stock prices, yet there is evidence of a *post-earnings-news drift* (Michaely et al., 1995). The decision to buy stocks depends on whether news about the performance of stocks is framed as *high, long-term, returns*, or a *more finely presented series of fluctuating short-term stock returns* (Benartzi and Thaler, 1995). The evidence from closed-end funds shows that there is a systematic difference between “net asset value” and the market price of shares, which is not consistent with the EMH (Lee et al., 1991).

The behavior of investors who follow prospect theory creates another reason for the inconsistency of evidence with the EMH, which assumes that investors follow expected utility theory. Recall the probability weighting function in Figure 2. This is central to the emerging topic of *psychology of tail events* (Barberis, 2013). Since individuals overweight small probabilities, the market will price skewness in the returns to assets (fat tails on the right of the returns distribution); although, the probability of these returns is low, the probability is overweighted. If there is a small probability of returns on an asset collapsing, then this can potentially explain the equity premium puzzle (De Giorgi and Legg, 2012); since the low probability downside risk is overweighted, a premium must be paid to induce investors to hold it. Other aspects of prospect theory also mitigate against the EMH. Loss aversion contributes to two phenomena already discussed above, the disposition effect (Odean, 1998), and the equity premium puzzle (Benartzi and Thaler, 1995).

6.4 Is expert behavior consistent with neoclassical economics?

A common response to the anomalies of the neoclassical model is that its predictions apply only to experienced subjects who operate in domains familiar to them. A particularly good test of this response is to examine the behavior of experts in their own field. The available empirical evidence shows that experts are not immune to biases and exhibit some biases even more than lay people (Gilovich et al., 2002; Kahneman, 2003; Kahneman, 2011; and Tetlock, 2006). Tetlock (1999, p. 351) evaluates the evidence on the predictions of experts on political events as follows: “Across all seven domains, experts were only slightly more accurate than one would expect from chance . . . Most respondents thought they knew more than they did. Across all predictions that were elicited, experts who assigned confidence estimates of 80% or higher were correct only 45% of the time . . . Expertise thus may not translate into predictive accuracy, but it does translate into the ability to generate explanations for predictions that experts themselves find so compelling that the result is massive over-confidence.”

Experts exhibit many of the biases that we outlined in Section 5.5. They exhibit greater *over-confidence* relative to lay people (Heath and Tversky, 1991; Frascara, 1999; Glaser et al., 2007a,b), and more experienced experts are even more overconfident (Kirchler and Maciejovsky, 2002). Managerial overconfidence may explain excessive merger activity, despite the fact that relatively few mergers are successful (Malmendier and Tate, 2005, 2008). Another manifestation of overconfidence is the predicted distributions of stock market returns by senior finance professionals; the predicted intervals are too narrow and realized returns are within their 80% confidence intervals, only 36% of the time (Ben-David et al., 2013). Mathematical psychologists exhibit the *law of small numbers* (Tversky and Kahneman, 1973). Experts’ perceived riskiness of various hazardous substances is determined by their *affective response* (Slovic et al., 1999). The affective response of experts also determines the likelihood of reoffending that they assign to discharged mental patients (Slovic et al., 2000). Clinical psychologists *underweight the base rate* relative to a Bayesian decision maker (Meehl and Rosen, 1955). Finance professionals exhibit the *hindsight bias* (Guilbault et al., 2004; Biais and Weber, 2009).

Estate agents *anchor* on the list price when evaluating the value of properties (Northcraft and Neale, 1987). The anchoring heuristic has also been found to influence expert legal judgment (Chapman and Bornstein, 1996; Englich and Mussweiler, 2001; Englich et al., 2006). Judges exhibit the false consensus effect (Solan et al. 2008) and there have been various legal and institutional developments to minimize the effect of such biases (Rachlinski, 1998). In imputing the risk preferences of others, finance professionals are disproportionately influenced by their own risk preferences—this is the *false consensus effect* (Roth and Voskort, 2014). When presented with identical options, the responses of physicians are influenced by *framing effects*; their responses depend on whether outcomes are framed as gains or losses relative to a reference point (McNeil et al., 1982; Kahneman and Tversky, 1984). Physicians display limited attention and cognitive overload with the addition of extra choices, even when the total number of choices is relatively small (Redelmeier and Shafir, 1995).

6.5 Do people play a mixed strategy Nash equilibrium?

The ability to play a *mixed strategy Nash equilibrium* (MSE) is critical to the theoretical foundations of neoclassical economics; many critical results, such as existence results in game theory, depend on it (Nash, 1950). We have already noted that the epistemic conditions for playing a Nash equilibrium are extremely stringent, although these results are inadequately highlighted in most game theory courses. Harsanyi (1973) interprets an MSE as the limiting behavior in a set of games that have pure strategy equilibria, but the payoffs are perturbed; this is the *purification agenda*. Yet, these results do not hold for an important range of games that economists are interested in, such as repeated games and principal–agent games, which limits the practical usefulness of this argument (Gintis, 2009; Chapter 6).

An extra layer of cognitive sophistication is required for an MSE relative to a pure strategy Nash equilibrium. Players must randomize among their pure strategies in such a manner that leaves their opponents exactly indifferent among the pure strategies in the support of their mixed strategies. It takes most undergraduates a while to internalize this breathtaking degree of sophistication, but most buy into the idea within a few weeks. However, the evidence on MSE is rarely presented in game theory courses. The history of science is replete with ideas that were ex-ante counterintuitive, yet surprisingly turned out to be true when confronted with the empirical evidence. Based on the available evidence, MSE cannot be classified into this category. The empirical argument is twofold: (i) Many people play a mixed strategy, but not an MSE. (ii) The best evidence supporting the MSE comes from professional sports, a domain that arguably is not the most suitable for reasons given below.

Consider the rather complicated choice facing a football penalty kicker. It requires choosing the height, direction, and swerve of the ball, as well as body feints and gestures. For simplicity, let us assume that the choice is either to kick to the left, or to the right of the goalkeeper. Clearly, over successive penalty shots, kickers would need to randomize somehow, otherwise, given the widespread use of video analysis of past games in modern sports, they will be ineffective. Similar comments apply to tennis serves, which are complicated by the spin, the angle, and the slice on the ball, but let us assume that the choice is to serve either to the left or to the right. In these domains, support is found for the MSE in professional soccer games (Palacios-Huerta, 2003) and in professional tennis matches (Walker and Wooders, 2001). However, in each case, there is serial dependence in the actions (penalty kicks and tennis serves) that is not detected by the opponents, thus, they are not able to exploit it. Serial dependence is not surprising, given the difficulty that humans have in generating random sequences of numbers

(see Section 5.5, above). However, leaving aside the modelling of other complexities in penalty kicks and tennis serves that are mentioned above, serial dependence is strictly not consistent with an MSE.

The results on MSE in a sports context are clearly important because they give us a concrete domain in which MSE is reasonably successful. However, the main skills employed by professional sportsmen in playing mixed strategies are motor skills and hand–eye–foot coordination. The development of these skills has an evolutionary basis in hunting, and in intergroup conflict, where they were probably critical for physical survival. Indeed, with practice, humans can achieve a high level of these skills, as evidenced by professional sportsmen. There is less basis to believe that motor skills come into play in important economic decisions such as choosing between alternative pension plans, portfolios of assets, savings decisions, choice of a University course or degree, tax evasion decisions, number of hours to work, or in dealing with self-control issues. Data from professional sports may, thus, have low external validity in establishing conclusive evidence for an MSE.

The ability to play a MSE in a sports context does not translate into an ability to play MSE in other contexts, i.e., the ability to play mixed strategies is not portable. The initial evidence was supportive of the portability of MSE (Palacios-Huerta and Volij, 2008), however, this was overturned by the results in Wooders (2010). In a carefully conducted study, Levitt et al. (2010) appear to have largely settled the debate by providing a clear negative answer to the question of the portability of MSE.

The serial dependence in football kicks and tennis serves suggests that subjects may be using some mixing heuristics that were not explicitly tested in the empirical model. This is an important consideration. In an influential experiment to test an MSE, O'Neill (1987) employed a two-player zero-sum game in which each player had four strategies (Ace, 2, 3, and Joker) and there was a unique MSE (details in Part 4). The experimental results, on the face of it, provided stunning confirmation of an MSE. The marginal frequencies of play by the row and column players appeared close to the MSE, as did the win percentages of each player. However, in an exemplary piece of empirical work, Brown and Rosenthal (1990) showed that O'Neill's findings constituted an unequivocal rejection of MSE. Indeed, several plausible heuristic-based models could account for the observed empirical results. Despite the proximity of the empirical frequencies of play with the MSE predictions, a chi-square test rejected MSE at any level of significance. Furthermore, they showed that the O'Neill design had insufficient power to distinguish between MSE and the alternative explanations.

There is some evidence that an MSE is more likely to be supported by the evidence when it predicts uniform randomization over the available pure strategies (Slonim et al., 2003). However, moving away from this special case and from sports contexts, the evidence often does not support an MSE. Using an extensive empirical analysis, Mookherjee and Sopher (1994, 1997) conclude in their 1994 paper (p. 109) that: "The rejection of the minimax theory at the aggregate level, and not just at the level of individual decision making, implies that it cannot even be treated as an acceptable as if theory."

Suppose that a game has a unique MSE and it is played repeatedly over a finite number of rounds. One expects players to draw repeatedly in each round from a multinomial distribution that reflects the MSE of the game. However, a common finding is that there is serial correlation in such play. One defence of the MSE is that although players can play an MSE in a static game, they are unable to draw randomly from the relevant multinomial distribution in repeated play. In order to test for this possibility, subjects were given a randomizing device, yet they exhibited serial correlation in play (Shachat, 2002). A reasonable interpretation is that subjects do play

mixed strategies, but not in the proportions predicted by MSE. We consider several empirical studies of MSE in Part 4.

In the *equilibrium in beliefs* interpretation of MSE, each player plays a pure strategy (but never a mixed strategy) and the proportion of players who play each pure strategy is identical to the predicted MSE. Thus, each player acts as if he faces an opponent who plays a mixed strategy (Binmore, 1991). However, the evidence that people do play mixed strategies (although typically not the MSE) also rejects the equilibrium in beliefs interpretation of MSE.

Appendix A: The random lottery incentive mechanism

Consider the *random lottery incentive mechanism* (RLI) that is widely employed to pay subjects in experiments. Suppose that expected utility maximizing subjects in an experiment perform n tasks from a set of tasks $T = \{t_1, \dots, t_n\}$. Let task t_i involve choosing from a set of lotteries, $\mathcal{L}_i$ and define $\mathcal{L} = \cup_i \mathcal{L}_i$ as the set of all lotteries considered in the n tasks. Consider a subject in the experiment whose preferences over pairs of elements in $\mathcal{L}$ are represented by $\succeq$. At the beginning of the experiment, subjects are told that one of the tasks will be picked at random once all tasks are completed, and their choice in that task will be paid off for real. Let us abstract from issues of a possible show-up fee for the experiment that we have already commented on above.

Suppose that in any task, t_i , the most preferred lottery of the subject is L_i^* . Conditional on the incentive structure described above, should the subject choose L_i^* ? An elicitation method is incentive compatible if the answer is yes. The probability that task i is chosen to be rewarded at the end of the experiment is $\frac{1}{n}$. With the complementary probability $1 - \frac{1}{n}$, any of the other $n - 1$ tasks might be chosen to be rewarded. Let the choice made by the subject on any task t_j , $j \neq i$ be L_j . Let us denote by $(L_1, \frac{1}{n}; \dots; L_i^*, \frac{1}{n}; \dots; L_n, \frac{1}{n})$ the compound lottery in which lottery L_j is played with probability p_j . From the *independence axiom* of expected utility theory that should be familiar to most undergraduates in economics (see Part I for details), we know that since $L_i^* \succeq \widehat{L}_i$ for all $\widehat{L}_i \in \mathcal{L}_i$, it follows that

$$\left(L_1, \frac{1}{n}; \dots; L_i^*, \frac{1}{n}; \dots; L_n, \frac{1}{n} \right) \succeq \left(L_1, \frac{1}{n}; \dots; \widehat{L}_i, \frac{1}{n}; \dots; L_n, \frac{1}{n} \right) \text{ for all } \widehat{L}_i \in \mathcal{L}_i. \quad (9)$$

In words, the independence axiom says that if $L_i^* \succeq \widehat{L}_i$ then the decision maker prefers any mixture of lotteries that gives L_i^* over an identical mixture that contains $\widehat{L}_i$ in its place. Thus, the subject will choose L_i^* in task t_i . We can show this to be true for all tasks $t_j \in T$. Thus, RLI is incentive compatible.

Appendix B: In lieu of a problem set

This section poses 50 problems, written in the same order as the topics in the book and tailored to the material presented in the introduction. If you are already familiar with a particular problem, just move on to the next one. The problems range from straightforward applications of the material in the introduction to slightly more challenging ones. I deliberately avoid giving too much structure to the problems, so that you can try to solve them by writing your own models in a free-spirited manner. If you wish to use the neoclassical model to solve a problem, then think carefully about the auxiliary assumptions that you might invoke. In particular, do ask yourself

if the auxiliary assumptions that you use are ad hoc or not. You will encounter the solutions to these problems, and many others, as you progress through the book; this will also give you an opportunity to check your initial responses.

1. Many taxi drivers quit too early on rainy days in New York when the effective wage rate is actually very high. In other words, why is it so hard to find a taxi on a rainy day in New York?
2. Why do owners of objects, humans or chimps, value them more than non-owners (under neoclassical economics, everyone should value objects at their opportunity cost)?
3. If people play Russian roulette, why are they likely to pay more to reduce the number of bullets from 1 to 0, as compared to from 4 to 3 (check that under expected utility these two choices should be equally attractive)?
4. From 1926 to about the mid 1980s, the annual real return on stocks has been about 7% with a standard deviation of 20%, while the annual real return on treasury bills has been less than 1%. In neoclassical economics, a coefficient of relative risk aversion of about 30 can explain these findings, but the actual coefficient is around 1. This is the equity-premium puzzle. How can you explain the equity-premium puzzle?
5. A decision maker has initial wealth, w . Suppose that at all levels of wealth, he prefers to keep his wealth rather than play the lottery L_1 : win \$11 or lose \$10 with equal chance, for any w . Then, under expected utility theory, the decision maker will prefer the lottery L_1 to the lottery L_2 : lose \$100 and win an infinite amount with equal probabilities (*Rabin's paradox*). Thus risk aversion over small stakes, under expected utility theory, implies implausible risk aversion over large stakes. Does expected utility correctly encapsulate the risk attitudes of an individual? Can you think of modifications to expected utility that will explain Rabin's paradox?
6. For an amateur tax evader, the actual probability of audit is 1–3% and the penalty for being caught is (i) return of evaded taxes, plus (ii) fine at the rate of 1–2 times evaded tax. A quick back of the envelope calculation will show that this implies a return on tax evasion of about 96–98%. If you are an expected utility maximizer and have a coefficient of relative risk aversion of about 70 or above, you will pay your taxes; but, empirically, the coefficient is about 1. Since there are very few assets with this return, why do people pay any taxes?
7. Why do most people not buy insurance against very low probability events such as natural hazards, even when insurance is better than actuarially fair and the losses of insurance firms are underwritten by the government?
8. In everyday conversations about risky decisions, people speak of *optimism*, *pessimism*, *disappointment*, and *regret* (think only of pure risk in a simple game against nature). Can neoclassical decision theory under risk account for these emotions?
9. In recessions, why do firms typically prefer to lay-off workers rather than cut wages?
10. Why do most people find a cut in the nominal wage of 5% under zero inflation to be more unfair relative to a nominal wage increase of 2% under 7% inflation? What are the implications for macroeconomics?
11. In experiments on redistributive taxes, why do people often choose a smaller, more equally distributed, cake as compared to one in which they get a larger share of a very unequally distributed cake?
12. Should we generally expect any difference in outcomes relative to the neoclassical case if a minority of players have other-regarding preferences (i.e., also care about payoffs of others in addition to their own)? You may think of optimal contracts (static and finitely repeated)

between a principal and two agents in a production task where both agents are essential. One of the agents has self-regarding preferences, but the other has other-regarding preferences; the principal does not know who's who.

13. Why are individuals often willing to punish third parties for observed norm violations between other players even when their own material payoffs have not been affected?
14. Why do workers often respond to higher wage offers of firms by working harder, even in "static games," where they could take the money and run? Why, in these static problems, may firms choose to offer high wages that exceed the opportunity cost of hiring workers? How might you distinguish the predictions of this model from the model of efficiency wages?
15. Why may firms sometimes choose to offer non-enforceable bonus contracts to workers in preference to enforceable incentive contracts, even in static problems? And why might the choice of effort by workers under bonus contracts be relatively higher as compared to that under incentive contracts?
16. Why do moral suasion, trust, and giving workers a goal/sense of purpose or a particular company identity, often outperform monetary incentives?
17. Why do people not lie maximally even when their behavior is guaranteed to remain completely anonymous? And why do we teach children not to lie, act morally rather than opportunistically, and help those who are less fortunate, rather than the neoclassical prescriptions about human behavior (maximize your payoffs/utility subject to technological constraints, but ignore any moral or ethical considerations relative to payoff maximization)?
18. Consider Akerlof and Kranton's (2005, p. 9) description of the following initiation process at the US West Point military academy. "On plebes' first day . . . they strip down to their underwear. Their hair is cut off. They are put in uniform. They then must address an older cadet, with the proper salute . . . must stand and salute and repeat, and stand and salute and repeat, until they get it exactly right, all the while being reprimanded for every tiny mistake." How would an economist brought up on the theory of incentives and organizations make sense of this initiation ceremony?
19. Why does the law make a distinction between murder and manslaughter, assigning much lower punishments for manslaughter for the same harm to the victim?
20. Most people would prefer one apple today to two apples tomorrow, but they prefer two apples in 51 days to one apple in 50 days. How can you explain this preference reversal?
21. Discounting over an entire time interval $[t, \bar{t}]$ in one go, turns out to be larger, relative to discounting over n successive sub intervals $[t, t_1], [t_1, t_2], \dots, [t_{n-1}, \bar{t}]$; this is known as subadditive discounting. Under exponential discounting, the two answers should be identical. What modifications do you think are needed to the exponential discounting model to explain this empirical finding?
22. Why does the data (e.g., for the US) show a sharp drop in consumption at retirement?
23. Why do many people simultaneously hold illiquid assets and credit card debt?
24. Why do many people procrastinate so much?
25. Why do many people pay more for an annual gym membership when they could save money on a pay-as-you-go basis?
26. In normal form games in which a Nash equilibrium can be found with more than 2–3 steps of iterated elimination of dominated strategies, the experimental evidence often shows that the outcome is not a Nash equilibrium. Does this evidence cause you to have any reservations about equilibrium concepts in classical game theory or a desire to modify them? If so, how?

27. Why do we observe far more cooperation in a one-shot prisoner's dilemma games (about 60% of the time) relative to the prediction of classical game theory that predicts no cooperation under the assumption that people have self-regarding preferences? Bear in mind that the prisoner's dilemma game is possibly the most widely used game in the social sciences as a metaphor for human cooperation (or the lack of it), so this is not an unimportant result that can be ignored.
28. Empirical evidence shows that in centipede games, the backward induction outcome (play down at the first node) is played less than 10% of the time. In 6 node centipede games, in a majority of the cases, players move across to at least the 4th node. How can you explain this finding? Does your explanation have testable implications?
29. If you are unconvinced by the experimental method, can you come up with a few "stringent" non-experimental tests of classical game theory using real-world data?
30. Why do bargaining negotiations often stall with adverse consequences for both parties (union strikes, wars, family gridlocks over issues) even when issues of asymmetric information are not salient? This is particularly the case in conditions where the classical alternating offers bargaining game predicts an immediate bargaining solution without delay.
31. You live in Italy and as most folks who live there, you never tip cab drivers. However, one week you go abroad, and take a taxi to a friend's house who lives in the countryside in a country where there is a norm for tipping taxi drivers. A 70-year-old meek looking and frail taxi driver delivers you safely to your destination. Would you honor the norm of tipping him or just walk away? Suppose you answered that you would pay the tip. Is your behavior consistent with classical game theory? If not, then which feature of classical game theory could be altered to explain your tipping behavior?
32. Why are winners of common value auctions often "cursed" in the sense that they make far less money than they anticipated?
33. Eyetracking data from a three-round, two-player bargaining game whose structure is hidden from view, but searchable by using mouse clicks, reveals the following. Most subjects search for payoffs and the size of the cake to be divided in each round, forward from the first round rather than backward from the third round. Subjects trained in backward induction do search backwards more often. Does this in any way make you uneasy about equilibrium concepts in classical game theory, or would you simply discount this evidence?
34. Why do interrogators often (successfully) conduct around-the-clock interrogation of suspects?
35. Why might many people end up marrying or proposing marriage/seeking divorce without sufficient deliberation, or buy consumer durables in haste? Can you think of any legal interventions that take such human behavior into account? Would such legal interventions be necessary for the typical individual in the neoclassical framework?
36. Why are most people happy to buy consumer durables on installments, yet prefer to prepay for a holiday?
37. Why do smokers and alcoholics often pay money at rehab clinics to get rid of their addictions? Recall that the typical model of addiction in neoclassical economics assumes that people choose to get rationally addicted, taking account of the relevant costs and benefits now, and in the future.

38. Why do many cigarette smokers report an increase in happiness following an increase in excise duty on cigarettes (based on US and Canadian data)?
39. A town is served by two hospitals. In the larger hospital, about 45 babies are born each day, and in the smaller hospital, about 15 babies are born each day. As you know, about 50% of all babies are boys. However, the exact percentage varies from day to day. For a period of 1 year, each hospital recorded the days on which more than 60% of the babies born were boys. Which hospital do you think recorded more such days? 53 students in the sample said that both hospitals are equally likely to have recorded such days and 21 students each chose the larger and the smaller hospital, respectively. Are the students behaving like the agents in neoclassical economics (sometimes known as *econs*)? If not, what does their behavior reveal?
40. Why do sales at lotto stores that have sold a winning ticket soar in the immediate weeks following the lotto win (this positive effect on sales persists for up to 40 weeks following the lotto win)? How can you test the hypothesis that “the winning store just produced more interest among the local population to buy more lotto tickets, so that this finding is perfectly consistent with neoclassical economics”?
41. Why do so many mergers fail, yet we often observe waves of mergers from time to time?
42. Why do people find it more difficult to make a choice when the set of choices expands (people choose easily among 3 types of jams, but often struggle to choose among 27 types of jams)?
43. There is much cross-country variation in organ donation rates in European countries (98% in Austria, but 12% in Germany; 99.9% in France, but 17.7% in UK; 85.9% in Sweden, but 4.25% in Denmark). It turns out that in countries with high organ donation rates, people are automatically enrolled in the organ donation program, but can opt out if they wish. The situation is exactly the reverse in countries with low organ donation rates, where people can opt in if they wish. Can this empirical fact be explained under neoclassical economics? If you answer yes, then be careful in stating your auxiliary assumptions and think of the evidence for these assumptions.
44. There are only two cab companies in the city, Green and Blue; 85% of the cabs are Green. There was an accident last night. A witness comes forward to testify that the cab involved in the accident was Blue. In similar conditions, the reliability of the witness is 80%, i.e., the probability that he gets it wrong is 20%. What is the probability that the actual cab involved in the accident was Blue? The median and modal response was 80%. Are the students behaving like the textbook economic agents in neoclassical economics? If not, what does their behavior reveal?
45. Why do buyers of a new car often find that the particular model they drive suddenly appears more common on the roads?
46. Why do marketing people play on alternative ways of framing information that has identical information-content? Why for instance, may swimsuit models be placed next to sports cars in advertisements, when the main role of advertisement in the neoclassical framework is to convey information to potential buyers?
47. Why do sales drop if publicly known sales taxes are displayed on price stickers rather than being added at the check-out counter?
48. Why might the financial market price skewness in asset returns?
49. Why are so many financial crises accompanied by no-news (i.e., no information related to fundamental values)?

50. Consider the probability of success that entrepreneurs assign to their startups. In one empirical study, only 5% of startup entrepreneurs believe that their odds are any worse than comparable enterprises and a third believe that their success is assured. Based on French data, 56% expect 'development' and only 6% of startup entrepreneurs expect "difficulty"; three years on, the respective figures are 38% and 17%. Empirically, only half of all startups survive beyond three years and the high failure rate among startups is widely reported in the popular press. How can we square these figures with the supposed rationality of participants in corporate finance? How should we react to this sort of evidence?

PART 1

Behavioral Economics of Risk, Uncertainty, and Ambiguity

INTRODUCTION TO PART 1

In the simplest economic problem, a single decision maker plays a game against nature. Depending on the action chosen by the decision maker, nature induces a probability distribution over a set of possible outcomes. The probability distribution may be *objective* or *subjective*.

If the probability distribution of the relevant outcomes can be estimated objectively, say, from past data or using frequentist methods, then we have a situation of *risk*. For instance, the probability that one obtains a 3 and a 6 in two successive throws of an unbiased dice. However, in some cases, no objective probabilities may be available, e.g., the dice may be known to be biased, but different people may have different views on the degree of the bias. In this case, decision makers may be able to assign a *subjective probability distribution* over outcomes. This is a situation of *uncertainty*.

A third class of events arise when no objective probabilities are available, nor can any *reasonable* subjective probabilities (that are non-negative and sum up to one) be assigned either. In this case, decision makers may be able to assign reasonable subjective probabilities to outcomes arising from each *source* of potential information (readers familiar with the Ellsberg paradox could think of the two urns in the paradox as two sources). However, when the decision maker's subjective probabilities are elicited by mixing up the different sources, then no reasonable subjective probabilities can be assigned. Such a situation of *source-dependent uncertainty* is known as *ambiguity*.

The central question in decision theory, taken up in Part 1, is how does the decision maker choose his optimal action in the presence of risk, uncertainty, or ambiguity?

Chapter 1 considers the elements of neoclassical decision theory. We mainly focus on *expected utility theory* (EU). Our exposition of EU is necessarily brief because most readers will already be familiar with this material. We examine the preference foundations of EU and highlight the critical axioms that have been subject to empirical testing, particularly the *independence axiom*. We also discuss a celebrated result of Leonard J. Savage, that derives a preference foundation for choices under uncertainty. The resulting representation of preference looks similar to EU and is called *subjective expected utility* (SEU). This formulation showed that there is no essential problem in making choices under uncertainty, provided that we can assign reasonable subjective probabilities to the relevant events.

Most lay people would probably believe that probabilities have something to do with risk. However, under EU, risk attitudes are determined entirely by the shape of the utility function. Further, if the decision maker is risk averse over small stakes for all levels of income, then he will be unreasonably risk averse for large stakes. We also discuss various methods of eliciting the utility function under risk and uncertainty. In the rest of Chapter 1, we consider the main refutations of EU. We use the convenient device of a Marshak–Machina probability triangle to illustrate the nature of the refutations. It turns out that most refutations of EU lie along the edges of the probability triangle, but it is precisely along the edges that most important economic situations of interest also occur. Other refutations that we consider include, *preference reversals*, *description invariance*, and *failure of the reduction of compound lotteries axiom*.

EU has two critical features. These are: (i) *linearity in probabilities*, and (ii) *utilities that depend only on final levels of wealth*. In contrast to these features, empirical evidence suggests that

decision makers engage in non-linear probability weighting and their behavior differs fundamentally in the domain of gains and losses. In Chapter 2, we consider a range of behavioral decision theories that relax at least one or both of these features of EU or even introduce new features; these theories explain the available evidence much better.

A central feature of most behavioral alternatives to EU is *non-linear probability weighting*. This is incorporated through a *probability weighting function* that captures the way in which individuals mentally code objective or subjective probabilities. For aggregate data, one typically finds an *inverse S-shaped* probability weighting, i.e., low probabilities are overweighted and high probabilities are underweighted. At the individual level, however, there is a degree of heterogeneity: One observes convex, concave, and inverse S-shaped weighting.

Rank dependent utility (RDU) under risk and under uncertainty is the most satisfactory alternative to EU that incorporates just non-linear probability weighting. RDU replaces the (objective or subjective) probabilities in an EU functional by *decision weights* that are *cumulative transformations of probabilities*. Decision makers who use RDU never choose first order stochastically dominated options.

Original prospect theory (OPT) and *cumulative prospect theory* (PT) incorporate non-linear probability weighting and a utility function that incorporates *reference dependence*. By expressing all outcomes relative to the reference point, decision makers who follow OPT and PT partition the domain of outcomes into a gain and a loss domain. The utility function is concave in gains and convex in losses. Furthermore, losses bite more than equivalent gains, a phenomenon known as *loss aversion*. Human behavior turns out to be fundamentally different in the two domains. PT can be readily extended to the case of uncertainty and ambiguity. Using the essential insight of cumulative transformations of probabilities from RDU, Kahneman and Tversky altered OPT, which was published in 1979, to PT, which was published in 1992. This ensured that decision makers would not choose stochastically dominated options. However, the psychological richness in the editing phase of OPT was also lost in this process.

Under EU, attitudes to risk are determined entirely by the shape of the utility function. However, under RDU, OPT, PT (and other theories that use non-linear weighting), attitudes to risk depend *jointly* on the shapes of the probability weighting function and the utility function. Attitudes to risk are even richer in PT as compared to RDU. One observes a *fourfold classification of risk* that can explain the simultaneous occurrence of insurance and gambling as well as many other phenomena.

In OPT and PT, the reference point is typically specified to be the *status-quo*, or a *fair/just* entitlement, all of which are eminently reasonable in situations where the individual faces no risk. However, under certain circumstances, the endowment of an individual may be stochastic (e.g., owning a stock that can either go up or down in value with some associated probability). In this case, the reference point itself may be stochastic. This has led to the development of *third generation prospect theory* (PT³) that can incorporate stochastic reference points. Another popular approach is the *Kőszegi–Rabin* framework that allows the reference point to be *stochastic and endogenous* in the sense that it requires a rational expectations property.

PT is the main, though not the only, decision theory under consideration in Chapter 2. The evidence suggests that it is the most satisfactory decision theory under risk and uncertainty.¹ We also discuss the elicitation of the various components of PT, give preference foundations for the theory, and note its limitations. We next consider a range of other behavioral decision theories that take account of factors that are not directly present in RDU, OPT, PT. These theories

¹ PT also applies to ambiguity, as we shall see in Chapter 4.

include *regret theory*, the *theory of disappointment aversion*, the role of *salience* and *context* in making choices among risky alternatives, *case-based decision theory*, and *configural weights models*. Existing theories find it difficult to explain human behavior for events of *very low probability*. In many situations of economic interest, one observes that a fraction of decision makers ignore events of very low probability, while others give it more than its objective salience. We consider a modification of PT, *composite prospect theory* (CPT) that can account for such behavior.

The final topic in this chapter considers the interaction between risk and time preferences, which has been a very active area of research in recent times. We shall continue with this topic in Part 3 of the book.

Chapter 3 considers applications of behavioral theories of decision making. An important application is to the disparity between *willingness to accept* (WTA) of sellers who are endowed with an object and *willingness to pay* (WTP) for the same item by buyers. The disparity between WTA and WTP arises because sellers who are endowed with the object experience loss aversion when they part with it. However, loss aversion does not apply to parting with money, giving rise to the disparity. We also consider a range of other possible explanations of exchange disparities and factors that might weaken or enhance it. Loss aversion is a fundamental trait of human nature that we share with close primate relatives such as chimpanzees. This suggests that it precedes the evolutionary separation of humans and chimpanzees and, thus, we may be hardwired to exhibit it. An important implication of these studies is that there might be *no risk aversion beyond loss aversion*. In other words, economists picking out risk aversion, could actually be picking out loss aversion.

Some of the other applications that we consider in Chapter 3 are as follows. In a two-horse race between EU and PT, we show that PT successfully explains the qualitative and quantitative tax evasion puzzles, but EU fails to do so. *Myopic loss aversion*, the empirically supported tendency to use very short horizons in evaluating gains and losses, explains several phenomena, e.g., the *equity premium puzzle* (high returns on equities relative to bonds that cannot be explained by the riskiness of the two assets, or by risk aversion). We show that under PT, *Rabin's puzzle* that arises under EU (risk aversion over small stakes implies implausible risk aversion over larger stakes) can be explained. We show that once *goals* and *targets* are recognized as reference points, PT is able to account for the relevance of goals in influencing human behavior that cannot be explained by EU and RDU. PT can also explain the backward bending labour supply curve of New York taxi drivers. A range of applications of the finding of an inverse S-shaped probability weighting function are also given, although some of these, such as the *psychology of tail events*, are postponed to Part 7. Finally, we apply PT to issues of optimal choice of contracts, the formation of firms, and the renegotiation of long-term contracts. These topics form a part of the exciting new literature on behavioral contract theory. Further developments in this literature based on other-regarding preferences are considered in Part 2 of the book.

Chapter 4, the final chapter in Part 1, considers models of *ambiguity*. The discussion in the chapter is organized around two main sections. Section 4.3 considers *neoclassical models of ambiguity* and Section 4.4 considers *behavioral models of ambiguity*. This is not a watertight separation of the literature into two convenient categories, but it helps in organizing it. The main distinction is that most, but not all, of the neoclassical models of ambiguity reduce to EU under pure risk, while the behavioral models of ambiguity in Section 4.4 do not. The evidence refuting EU under risk should also pose uncomfortable questions for some of the neoclassical models of ambiguity. The empirical evidence for neoclassical models of ambiguity aversion is at best mixed, hence, our discussion of these models is brief. On the other hand, while the behavioral models are extremely promising, these developments are at a relatively early stage. In order to maintain a common

theme across the chapter, we focus on the ability of alternative models to resolve the Ellsberg paradox.

Some of the neoclassical models that we consider are *Choquet expected utility*, *multiple priors models*, *two-stage recursive models* that do not require the reduction of compound lotteries, and models of *second order beliefs* such as the *smooth ambiguity aversion model*. Among the behavioral models, we consider *support theory* and *source-based uncertainty*. Promising new empirical evidence suggests that prospect theory outperforms most of the standard neoclassical models but more empirical testing and replication is required before we could assert this with more confidence. This strengthens the case that prospect theory applies equally well to risk, uncertainty, and ambiguity, a conclusion that is well represented in the title of Peter P. Wakker's book *Prospect Theory: For Risk and Ambiguity*.

CHAPTER 1

The Evidence on Human Choice under Risk and Uncertainty

1.1 Introduction

Suppose that a decision maker takes some action that leads to an *objective probability distribution* over a set of possible outcomes. This is a situation of *risk*. In this chapter, we briefly consider the elements of the neoclassical approach to decision making in such a situation, *expected utility theory* (EU), and the empirical evidence for EU. Most readers of this book would be familiar with EU. For this reason, no more than an outline of the basic elements is provided.¹

Section 1.2 outlines the basic framework of EU, with particular emphasis on its preference foundations (von Neumann and Morgenstern, 1944). We also consider *attitudes to risk* that, for EU, are determined entirely by the shape of the utility function. Although most people may believe that probabilities have something to do with risk, they play no role in EU in determining risk attitudes. We also outline the basic definitions of *stochastic dominance* for later use. The axioms that lead to an EU representation of preferences are also known as the *axioms of rationality*. Ultimately the validity of these axioms is an empirical matter.

In contrast to risk, under *uncertainty* no objective probabilities that are universally agreed upon can be identified. Section 1.3 considers the basic model of uncertainty in economics, *subjective expected utility* or SEU (de Finetti, 1937; Savage, 1954). These results form the basis of the *Bayesian approach to uncertainty*.

Section 1.4 considers a topic of considerable applied interest. Namely, the problem of eliciting the utility function of an EU decision maker under risk (McCord and de Neufville, 1986), and uncertainty (Wakker and Deneffe, 1996).

Section 1.5, the heart of the chapter, describes the violations of EU. Section 1.5.1 focuses on the evidence arising from the violation of the *independence axiom*, one of the main axioms of rationality. These violations take two forms, the *common ratio effect*, and the *common consequence effect* (Allais, 1953). The common ratio violation takes place when scaling down the probabilities in two-outcome lotteries by a common factor that leads to a reversal in preferences. The common

¹ The interested reader may wish to consult any advanced undergraduate or graduate text in economics; see, for instance, Varian (1992) and Mas-Collel et al. (1995). A more formal treatment can be found in Fishburn (1982b).

consequence violation takes place when two pairs of lotteries each have a common consequence, yet the decision maker chooses a different lottery in each pair.

Section 1.5.2 explains a particularly useful device to study the implications of violations of the axioms of rationality: the *Marshall–Machina probability triangle*. The independence axiom that lies at the heart of EU implies that the indifference curves in the probability triangle are parallel straight lines. However, one observes both *fanning-in* and *fanning-out* of indifference curves, which violates the independence axiom. Furthermore, empirical evidence suggests that the violations of EU are more pronounced along the edges of the probability triangle as compared to the interior of the triangle. The violations in many cases arise from non-linear weighting of probabilities that is particularly pronounced close to the edges of the probability triangle.

Section 1.5.3 briefly considers alternative theories that explain the evidence in the probability triangle by relaxing the independence axiom; for instance *weighted utility theory* (Chew and MacCrimmon, 1979). Theories that have the best chance of explaining the evidence incorporate both *fanning-in* and *fanning-out* of indifference curves in the probability triangle. An example is the theory of *disappointment aversion* (Gul, 1991) that we consider in more detail in the next chapter.

Section 1.5.4 considers Rabin's (2000a) *calibration theorem*. Consider an EU decision maker who has an increasing and concave utility function. Rabin showed that if this decision maker turns down a moderate stake gamble (say, 50–50 chance of losing 10 and gaining 11), then the decision maker will turn down the following equiprobable gamble: lose 100 and win an infinite amount. Clearly this is absurd, but it is a logical outcome under EU. We shall see in Chapter 3 that this paradox does not arise under prospect theory.

EU assumes that the choice among pairs of mathematically equivalent lotteries does not depend on how the information in the lotteries is framed, also known as the assumption of *description invariance*. Section 1.5.5 considers a classic problem from Tversky and Kahneman (1981) that powerfully illustrates a violation of description invariance. This problem also illustrates that decision makers are risk loving (respectively, risk averse) when they perceive themselves to be in losses (respectively, gains), a finding of considerable importance that we study more closely in the subsequent chapters.

Section 1.5.6 considers the widely documented phenomenon of *preference reversal* (Lichtenstein and Slovic, 1971). Suppose that we have two lotteries: A *P*-bet has a high probability of winning a low prize and a *\$*-bet has a low probability of winning a high prize. When decision makers have to directly choose between the two bets, they prefer the *P*-bet. However, at the same time they exhibit a higher certainty equivalent for the *\$*-bet. We also consider attempts to explain preference reversals.

Section 1.5.7 closes the chapter by demonstrating that the reduction of compound lotteries axiom typically does not hold. This has far reaching implications for the validity of EU and will play an important role in providing one potential explanation of the Ellsberg paradox in Chapter 4.

1.2 The elements of classical decision theory

Let $X = \{x_1, x_2, \dots, x_n\}$ be a fixed, finite, set of real numbers such that $x_1 \leq x_2 \leq \dots \leq x_n$. One may interpret X as the set of all possible levels of wealth of the decision maker. We define a *lottery*, or *gamble*, as

$$L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n), \quad (1.1)$$

where $p_1, p_2, \dots, p_n$, are the respective probabilities corresponding to the outcomes $x_1, x_2, \dots, x_n$, such that $p_i \in [0, 1]$ and $\sum_{i=1}^n p_i = 1$. The lottery $(x_i, 1)$ denotes an outcome x_i received with certainty, so we sometimes simply denote it as x_i . The lottery in (1.1) is sometimes also known as a *simple lottery*. Given two simple lotteries, L_1 and L_2 , a lottery of lotteries, say, $(L_1, p; L_2, 1 - p)$, where $p \in (0, 1)$, is known as a compound lottery; the special case, $(L, p; 0, 1 - p)$ is sometimes denoted by (L, p) .

A situation of *risk* arises when the probabilities are objectively known. In contrast, when probabilities are not objectively known, then we have a situation of *uncertainty*. We focus on risk first.

Let the set of all lotteries of the form (1.1) be denoted by $\mathcal{L}$. Suppose that the decision maker must choose a lottery from some set $\mathcal{L}' \subset \mathcal{L}$. The fundamental question in decision theory is: Which lottery will the decision maker choose? This is also the simplest possible setting. It is “as if” the decision maker is simply playing a game against nature. Nature chooses the set of lotteries and the decision maker simply picks one or more elements from the set. In game theory, by contrast, the decision maker, in addition, has to take account of the behavior of others.

1.2.1 Preference foundations of expected utility theory (EU)

The most widely used theory under risk in economics is *expected utility theory* (EU).² Many behavioral models in decision theory build on the EU model and the lessons learnt from the empirical anomalies, relative to the EU predictions. We first briefly review the foundations of EU.

The decision maker is endowed with a binary preference relation over $\mathcal{L}$, denoted by $\succeq$; it is interpreted as “at least as good as.” So, for $L_1, L_2 \in \mathcal{L}$, $L_2 \succeq L_1$ means that the lottery L_2 is “at least as good as” the lottery L_1 , or L_2 is “weakly preferred” to L_1 . The notations $L_2 \succeq L_1$ and $L_1 \preceq L_2$ are equivalent, just as $5 < 7$ or $7 > 5$, and one may use either of the two; similar comments apply to strict preference, e.g., $L_2 \succ L_1$ and $L_1 \prec L_2$ are equivalent.

We now strive to represent preferences in a more convenient form. Consider the following conditions, or axioms, on preferences. We assume that all lotteries below belong to the set $\mathcal{L}$, and a typical member of this set is given in (1.1).

Axiom 1.1 (Order) *Order requires the following two conditions.*

- a. *Completeness: For all lotteries L_1, L_2 , either $L_2 \succeq L_1$ or $L_2 \preceq L_1$.*
- b. *Transitivity: For all lotteries L_1, L_2, L_3 , $L_3 \succeq L_2$ and $L_2 \succeq L_1 \Rightarrow L_3 \succeq L_1$.*

Two further binary relations between lotteries can be defined in terms of $\preceq$:

$$\left\{ \begin{array}{ll} \text{Indifference:} & L_1 \sim L_2 \Leftrightarrow L_2 \succeq L_1 \text{ and } L_1 \succeq L_2. \\ \text{Strict preference:} & L_2 \succ L_1 \Leftrightarrow \text{it is not the case that } L_1 \succeq L_2. \end{array} \right.$$

Axiom 1.2 (Best and worst): $x_n \succ x_1$ (i.e., $(x_n, 1) \succ (x_1, 1)$).

Axiom 1.3 (Continuity): *For each lottery, L , there is a $p \in [0, 1]$ such that $L \sim (x_1, 1 - p; x_n, p)$.*

Axiom 1.4 (Independence): *For all lotteries L_1, L_2, L , and all $p \in [0, 1]$, $L_2 \succeq L_1 \Leftrightarrow (L_2, p; L, 1 - p) \succeq (L_1, p; L, 1 - p)$.*

² For the preference foundations of EU, the interested reader can consult Kreps (1990), Varian (1992), and Mas-Colell et al. (1995). Kreps (1990) already makes a strong case for exploring alternatives to EU. For a more advanced and definitive treatment of EU, see Fishburn (1982b).

Axiom 1.5 (*Reduction, or law of compounding lotteries*): Let $p_1, p_2, p \in [0, 1]$. Let $L_1 \sim (x_i, 1 - p_1; x_j, p_1)$ and $L_2 \sim (x_i, 1 - p_2; x_j, p_2)$. Then

$$\begin{aligned} (L_1, p; L_2, 1 - p) &\sim ((x_i, 1 - p_1; x_j, p_1), p; (x_i, 1 - p_2; x_j, p_2), 1 - p) \\ &\sim (x_i, (1 - p_1)p + (1 - p_2)(1 - p); x_j, pp_1 + (1 - p)p_2). \end{aligned}$$

From Axiom 1.2, a decision maker strictly prefers receiving the highest outcome with certainty to receiving the lowest outcome with certainty. The continuity property in Axiom 1.3 asserts that every lottery is equivalent to a simple lottery obtained by probabilistically mixing the highest outcome, x_n , and the lowest outcome, x_1 . The independence axiom, Axiom 1.4, is the most crucial. It requires that if a lottery, L_2 , is preferred to a lottery, L_1 , then mixing each with a third lottery, L , (with the same positive mixing probability, p) does not alter the preference.

“Rationality” has a precise meaning in decision theory that is given in the next definition.³

Definition 1.1 (*Axioms of rationality*): The following axioms: Order, best and worst, continuity, independence, and reduction, collectively, are termed as the axioms of rationality. If a binary relation $\succeq$ on $\mathcal{L}$ satisfies the axioms of rationality, then it is called a rational ordering of $\mathcal{L}$.

Definition 1.2 (*Representation*): Let $\succeq$ be a binary relation on $\mathcal{L}$ and let $U : \mathcal{L} \rightarrow \mathbb{R}$ such that for all $L_1, L_2 \in \mathcal{L}$, $L_2 \succeq L_1$ if, and only if, $U(L_2) \geq U(L_1)$. Then U is said to represent $\succeq$ and we say that $\succeq$ is induced by U .

Definition 1.3 (*von Neumann–Morgenstern expected utility function*): A utility function $U : \mathcal{L} \rightarrow \mathbb{R}$ has the “expected utility form” (or the von Neumann–Morgenstern form) if we can assign a real number, $u(x_i)$, to each possible outcome, x_i , such that for the lottery L in (1.1), we can write

$$U(L) = \sum_{i=1}^n p_i u(x_i). \quad (1.2)$$

We now state the main result, the existence of a von Neumann–Morgenstern expected utility representation.

Proposition 1.1 (*von Neumann and Morgenstern, 1944*): Suppose that the binary relation, $\succeq$, on the set of lotteries $\mathcal{L}$, satisfies the axioms of rationality. Then there is a function, $U : \mathcal{L} \rightarrow \mathbb{R}$, such that, for all $L_1, L_2, L \in \mathcal{L}$,

- (a) $U(x_1) \leq U(L) \leq U(x_n)$ and $U(x_1) < U(x_n)$,
- (b) $L_2 \succeq L_1$ if, and only if, $U(L_2) \geq U(L_1)$,
- (c) for all $p \in [0, 1]$, the utility function is of the von Neumann–Morgenstern form

Proposition 1.1(a) shows that a constant utility function will not suffice. Proposition 1.1(b) shows that a utility function exists that represents the underlying preferences and Proposition 1.1(c) shows that it takes the familiar form under EU that is linear in probabilities.

Among the set of available lotteries, $\mathcal{L}$, the *EU criterion* requires that the decision maker chooses the one that gives the highest expected utility. The converse of Proposition 1.1 also holds. Namely that if a function U with the properties listed in Proposition 1.1 exists, then $\preceq$ satisfies the axioms of rationality. An important property of the EU functional is that it is

³ Notice that rationality does not imply other literal meanings of the word such as welfare or efficiency maximizing choices or preferences that are self regarding or other regarding, etc.

invariant with respect to positive affine transformations. Thus, the utility function $\widehat{U}(L) = \sum_{i=1}^n p_i [a + bu(x_i)]$, where $a \in \mathbb{R}$ and $b > 0$, represents the same preferences as does U in (1.2).

The axioms of rationality appear intuitive and plausible. A violation of the axioms of rationality is not a form of irrationality or madness. The axioms are no more than assumptions about human behavior, and their reasonableness must be tested by empirical evidence. A large number of rigorous tests have rejected the axioms of rationality. The challenge for behavioral economics is to produce a behavioral decision theory that is, on the one hand, in conformity with the evidence and, on the other hand, sufficiently tractable.

Remark 1.1 *EU has two main features:*

- (i) *Linearity in probabilities. Formally, this means that $EU(L_1, p; L_2, 1 - p) = pEU(L_1) + (1 - p)EU(L_2)$. This assumption is fundamental to many areas in economics. For instance, it is required in the proof of the existence of a mixed strategy Nash equilibrium. However, extensive empirical evidence shows that it is violated. Most non-EU decision theories relax the linearity assumption in some manner.*
- (ii) *In most applications of EU, utility typically depends on the final wealth level in each state of the world. Redefining outcomes under EU relative to a reference outcome (or any outcome) is not inconsistent with the axioms of EU. Doing so would partition the domain of outcomes into gains (outcomes greater than the reference point) and losses (outcomes lower than the reference point). However, EU offers no insights about human behavior in the domain of gains and losses. By contrast, empirically observed behavior of decision makers is fundamentally different in the domain of gains and losses. Indeed, differences in behavior in gains and losses are not only an essential driver of many important results in other decision theories such as prospect theory, but there is empirical confirmation of these predictions.*

1.2.2 Attitudes to risk under EU

The EU criterion contrasts with the earlier *expected value maximization criterion* (EV), which evaluates the lottery $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$ as $EV(L) = \sum_{i=1}^n p_i x_i$.

Consider a decision theory in which the utility function $\overline{U}$ is able to represent preferences over lotteries, e.g., under EU, $\overline{U} = U$. In other cases, $\overline{U}$ could be the utility representation under rank dependent utility or under prospect theory.

Definition 1.4 (*Certainty equivalent*): Consider the lottery $(C_L, 1)$, where $C_L \in X \subset \mathbb{R}$. If a solution exists to the equation $\overline{U}(C_L) = \overline{U}(L)$, then C_L is known as the *certainty equivalent* of the lottery L .

Notice that the definition of a certainty equivalent holds for any decision theory that admits a utility representation of preferences over lotteries, although the value of certainty equivalent under alternative decision theories is likely to differ. We now state the meaning of risk aversion; an individual who would rather accept a sure amount that is lower than the expected value of the lottery, in order to avoid playing the lottery, is said to be risk averse.

Definition 1.5 (*Risk aversion*): A decision maker is “risk neutral” if $C_L = EV(L)$, “risk averse” if $C_L < EV(L)$ and “risk loving” if $C_L > EV(L)$.

In this section, we only consider an expected utility representation of preferences ($\overline{U} = U$). The next proposition states a well-known result that you are asked to prove in one of the exercises.

Proposition 1.2 *Under expected utility theory, the properties of risk neutrality, risk aversion, and risk seeking are equivalent, respectively, to a linear, concave, and convex utility function.*

Risk aversion arising from a concave utility function underpins many important economic phenomena. For instance, the study of insurance, the design of contract schemes in principal-agent problems, the optimal rates of taxes, and determination of wage rates.

The EV criterion restricts decision makers to be risk neutral, hence, lotteries that have the same EV but appear different in their risk characteristics are equally preferred by the EV criterion. Daniel Bernoulli showed in 1738 that a famous paradox, the *St. Petersburg paradox*, cannot be resolved by the EV criterion but can be resolved by the EU criterion (you are asked to prove this in one of the exercises). The EU criterion can solve the St. Petersburg paradox because it allows for risk aversion. However, risk preferences are incorporated in EU through the shape of the utility function alone, rather than through probabilities. By contrast, many psychologists would typically argue that risk should be incorporated through probabilities rather than the shape of the utility function.

We can also compare the desirability of two lotteries that have the same outcomes but different probability distributions over them. Consider lotteries of the form $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$, where the outcomes $x_1 < x_2 < \dots < x_n$ belong to the set of real numbers. Under any distribution function P over this set of incomes, the probability of outcome x_i is denoted by $p_i \geq 0$, $\sum_{i=1}^n p_i = 1$. The *cumulative probability distribution* is given by $P_0 = 0$, $P_j = \sum_{i=1}^j p_i$. Denote by Π , the set of all such distributions over X . The *cumulative of the cumulative distribution* is given by $\tilde{P}_0 = 0$, $\tilde{P}_j = \sum_{i=1}^j P_i$, $j = 1, 2, \dots, n$. Let $\tilde{\Pi}$ be the set of all such distributions. The average, or mean, of $x_1, x_2, \dots, x_n$, under the distribution $P \in \Pi$ is $\mu_P = \sum_{i=1}^n p_i x_i$. Let u be the utility function for sure outcomes $(x_i, 1)$.

Notation 1.1 *Denote by $\mathbf{u}$, the class of all non-decreasing utility functions.*

We state here the basic results on *first order stochastic dominance* and *second order stochastic dominance* in the case of discrete outcomes; the continuous analogues can be picked up from any advanced microeconomics book. We shall need the results for the discrete case to prove several Propositions in the book.

Definition 1.6 (*First order stochastic dominance*): Let $P, Q \in \Pi$. Then P first order stochastically dominates Q ($P \succeq_1 Q$) if $P_j \leq Q_j$ for $j = 1, 2, \dots, n$. If, in addition, the inequality is strict for some j , then P strictly first order stochastically dominates Q ($P \succ_1 Q$).

Definition 1.7 We say that the outcome levels are equally spaced if for some positive real number, δ , $x_{i+1} - x_i = \delta$ for $i = 1, 2, \dots, n - 1$.⁴

Definition 1.8 (*Second order stochastic dominance*): Suppose that incomes are equally spaced (Definition 1.12).⁵ Let $P, Q \in \Pi$. Then P second order stochastically dominates Q

⁴ This is not restrictive because we can always introduce extra income levels, each with probability zero, to achieve equal spacing. For example, the incomes $y_1 = 5, y_2 = 7, y_3 = 11$, are not equally spaced. Let $P_1 = \frac{1}{3}$, $P_2 = \frac{2}{3}$, and $P_3 = 1$. Consider $y_1 = 5, y_2 = 7, y_3 = 9, y_4 = 11$, which are equally spaced, and $Q_1 = \frac{1}{3}$, $Q_2 = \frac{2}{3}$, $Q_3 = \frac{2}{3}$, and $Q_4 = 1$. Both P and Q describe the same reality.

⁵ Often "equal spacing" is not stated as part of the definition of second order stochastic dominance. But then it has to be stated in the Propositions. We find it more convenient to state it in the definition. The equal spacing assumption is not needed in the continuous case.

$(P \succeq_2 Q)$ if $\tilde{P}_j \leq \tilde{Q}_j$ for $j = 1, 2, \dots, n$ and if $\mu_P \geq \mu_Q$.⁶ If, in addition, one of these inequalities is strict, then P strictly second order stochastically dominates Q ($P \succ_2 Q$).

So far, the definitions of first order and second order dominance are purely statistical. We now explore their economic content. The results should be familiar to most advanced undergraduates in economics, so the proofs are omitted; readers interested in the continuous case can consult Mas-Collel et al. (1995).

Proposition 1.3 *Let $P, Q \in \Pi$. Then $P \succeq_1 Q$ if, and only if, for any $u \in \mathbf{u}$,*

$$\sum_{i=1}^{i=n} p_i u(x_i) \geq \sum_{i=1}^{i=n} q_i u(x_i), \quad (1.3)$$

and $P \succ_1 Q$ if, and only if, the inequality (1.3) is strict for all strictly increasing $u \in \mathbf{u}$.

Note that Proposition 1.18 holds for all $u \in \mathbf{u}$. Choosing the non-decreasing function $u(x) = x$ as a candidate function in Proposition 1.18, we get that if $P \succeq_1 Q$ ($P \succ_1 Q$), then $\mu_P \geq \mu_Q$ ($\mu_P > \mu_Q$).

Proposition 1.4 *Let $P, Q \in \Pi$. Then $P \succeq_2 Q$ if, and only if, for any concave $u \in \mathbf{u}$,*

$$\sum_{i=1}^{i=n} p_i u(x_i) \geq \sum_{i=1}^{i=n} q_i u(x_i), \quad (1.4)$$

and $P \succ_2 Q$ if, and only if, the inequality (1.4) is strict for all strictly increasing strictly concave $u \in \mathbf{u}$.

It is also possible to give an alternative definition of first order stochastic dominance with a discrete set of outcomes that holds fixed the probability distribution but alters the spread of the outcomes in X . Let $L_2 \succeq_1 L_1$ and $L_2 \succ_1 L_1$ denote that the lottery L_2 first order stochastically dominates L_1 , respectively, in a weak and strict sense.

Definition 1.9 *Let $L_1 = (x_1, p_1; \dots; x_n, p_n)$ and $L_2 = (y_1, p_1; \dots; y_n, p_n)$, then*

$$\begin{aligned} (a) \quad & x_i \leq y_i, i = 1, 2, \dots, n \Rightarrow L_2 \succeq_1 L_1, \\ (b) \quad & x_i \leq y_i, i = 1, 2, \dots, n \text{ and } x_i < y_i \text{ for some } i \Rightarrow L_2 \succ_1 L_1. \end{aligned} \quad (1.5)$$

Some additional properties of EU are taken up in the exercises at the end of Part 1.

1.3 Subjective expected utility theory (SEU)

Let there be n mutually exclusive events $E_1, E_2, \dots, E_n$ that form a partition of some relevant sample space, S . The objective probabilities of these events are not known. The decision maker assigns *subjective probabilities* $\mu(E_1), \mu(E_2), \dots, \mu(E_n)$ to these events such that $\mu(E_i) \geq 0$ for all i and $\sum_{i=1}^n \mu(E_i) = 1$. This is a situation of *uncertainty* because, although objective probabilities are not known, well-defined and consistent subjective probabilities exist. Now suppose that the individual needs to evaluate a special kind of lottery of the form

⁶ Often the condition $\mu_P \geq \mu_Q$ is not included as part of the definition of second order stochastic dominance. But then it needs to be included in the statement of the relevant Propositions. It is slightly simpler to include $\mu_P \geq \mu_Q$ as part of the definition of second order stochastic dominance.

$$f = (E_1, x_1; E_2, x_2; \dots; E_n, x_n), \quad (1.6)$$

where the decision maker receives the outcome x_i if the event E_i occurs, $i = 1, 2, \dots, n$. For pedagogical simplicity, let the outcomes be monetary, such as income or wealth. The object in (1.6) is also known as a *Savage act*. For any partition of a sample space, S , into a set of *mutually exclusive* events $\{E_1, E_2, \dots, E_n\}$, a Savage act, f , maps states of the world to outcomes, i.e., $f : S \rightarrow X$; we use the notation $f(E_i) = x_i$, $i = 1, \dots, n$.

One of the earliest justifications for the use of subjective utility was given in the work of de Finetti (1937). Denote the set of all Savage acts of the form in (1.6) by F , and define a binary relation over F by $\succeq$ which denotes “at least as good as.” The addition operator, $+$, applied to elements of the set F implies state by state addition of outcomes. For instance, let $f_1, f_2, f_3 \in F$:

$$f_1 = (E_1, x_1; E_2, x_2), f_2 = (E_1, y_1; E_2, y_2), f_3 = (E_1, z_1; E_2, z_2) \quad (1.7)$$

then,

$$f_1 + f_3 = (E_1, x_1 + z_1; E_2, x_2 + z_2), f_2 + f_3 = (E_1, y_1 + z_1; E_2, y_2 + z_2). \quad (1.8)$$

We now define the analogue of the independence axiom of EU under uncertainty, which is termed as *additivity*.

Definition 1.10

- (i) (*Additivity*): Suppose that we have Savage acts $f_1, f_2, f_3 \in F$ such that $f_1 \succeq f_2$. Then additivity implies that $f_1 + f_3 \succeq f_2 + f_3$.
- (ii) (*Monotonicity*): Let $f_1 = (E_1, x_1; E_2, x_2; \dots; E_n, x_n)$, $f_2 = (E_1, y_1; E_2, y_2; \dots; E_n, y_n)$. Suppose that $x_i \geq y_i$ for $i = 1, 2, \dots, n$. Then monotonicity implies that $f_1 \succeq f_2$.

Suppose that in addition to additivity, $\succeq$ is a weak order (transitive and complete), and *monotonicity* holds. Let f be as defined in (1.6) and $g = (E_1, y_1; E_2, y_2; \dots; E_n, y_n)$, where $f, g \in F$. Then (under a further continuity assumption) de Finetti (1937) obtained the following remarkable result (for details, see Wakker (2010) and Gilboa (2009)).

$$f \succeq g \Leftrightarrow \sum_{i=1}^n \mu(E_i) x_i \geq \sum_{i=1}^n \mu(E_i) y_i.$$

Thus, the individual acts so as to maximize the *expected value of a lottery*. Furthermore, the numbers $\mu(E_1), \mu(E_2), \dots, \mu(E_n)$, which may be interpreted as *subjective probabilities*, are *unique*.

In many contexts, expected value maximization might not be very attractive.⁷ Despite the drawbacks of the expected value criterion, de Finetti’s (1937) result provided the basis and initial impetus for using subjective probabilities in a formal manner. For small stake experiments, expected value might not necessarily be a bad approximation.

Let $f(E_i), g(E_i)$ denote the respective outcomes under the Savage acts f, g , when the event E_i occurs. Define a function $u : S \rightarrow R$ that it is unique up to a positive affine transformation;

⁷ Consider the binary Savage acts, f_1, f_2, f_3 in (1.7) and their addition, defined in (1.8). Let the individual be declared bankrupt if his income in any state falls below some monetary level b . Suppose that all monetary outcomes in (1.7), (1.8) are greater than b except for $x_1 + z_1$, which is below b . Then the individual might express the preference $f_2 + f_3 \succsim f_1 + f_3$ which violates additivity.

$u(f(E_i))$ has the interpretation of the utility of the outcome $f(E_i)$. The following functional has the interpretation of *subjective expected utility* from the Savage act f .

$$V(f) = \sum_{i=1}^n \mu(E_i)u(f(E_i)), \quad (1.9)$$

where $\mu(E_i) \geq 0 \forall i$ and $\sum_{i=1}^n \mu(E_i) = 1$. This is the sense in which EU can be plausibly extended to subjective beliefs. Risk can now be seen as a special case of uncertainty when there exists an objective probability p_i such that $p_i = \mu(E_i)$ for $i = 1, \dots, n$. When new information arrives, the decision maker engages in Bayesian updating to update his prior beliefs into a set of posterior beliefs that comprise the new, unique, additive probability measure.

In one of the most brilliant results in all of social science, Savage (1954) derived the following representation of preferences of the individual. For any two lotteries, f, g :

$$f \succeq g \Leftrightarrow \sum_{i=1}^n \mu(E_i)u(f(E_i)) \geq \sum_{i=1}^n \mu(E_i)u(g(E_i)), \quad (1.10)$$

where μ is a unique additive probability measure such that $\mu(E_i) \geq 0$ for all i and $\sum_{i=1}^n \mu(E_i) = 1$.⁸ Savage (1954) provides an axiomatic foundation of *subjective expected utility* (SEU), also sometimes known as the *Bayesian approach to uncertainty* because beliefs are updated in a Bayesian manner.⁹ In addition to the standard axioms of completeness and transitivity, the substantive new axiom in the Savage framework is the *sure thing principle* that is the analogue of the independence axiom under EU.¹⁰

Definition 1.11 (*Sure thing principle*): Consider the following pairwise choices between four Savage acts, $f_1, f_2, f_3, f_4 \in F$ that are defined over the events E_1, E_2, E_3 ; let y, x_1, x_2, x_3, x_4 be the possible outcomes.

$$\begin{aligned} f_1 &= (E_1, y; E_2, x_2; E_3, x_3), f_2 = (E_1, x_1; E_2, x_2; E_3, x_3), \\ f_3 &= (E_1, y; E_2, x_2; E_3, x_4), f_4 = (E_1, x_1; E_2, x_2; E_3, x_4). \end{aligned}$$

The sure thing principle holds if $f_1 \succ f_2 \Leftrightarrow f_3 \succ f_4$.

The remarkable thing about Savage's axiomatic framework is that the axioms make no assumptions about objects such as probabilities. However, the actual representation of preferences in (1.10) is similar to that under EU except that the (unique) objects $\mu(E_i)$ have the interpretation of subjective probabilities.

We now define *probabilistic sophistication*, a term that we require in Chapter 4.

Definition 1.12 Lotteries or Savage acts, as defined in (1.6), are known as *event contingent lotteries*.¹¹ By contrast, lotteries written in the standard form, $L = (x_1, p_1; \dots; x_n, p_n)$, such that $p_i \geq 0$ and $\sum_{i=1}^n p_i = 1$, are known as *probability contingent lotteries*.

Suppose that the decision maker assigns the probability p_i to the event E_i . $i = 1, \dots, n$. Then the decision maker may consider the lotteries $(x_1, p_1; \dots; x_n, p_n)$ and $(E_1, x_1; E_2, x_2; \dots; E_n, x_n)$

⁸ μ is an additive probability measure if $\mu(\cup_{i=1}^n E_i) = \sum_{i=1}^n \mu(E_i)$.

⁹ While Savage's preference foundations have received the most attention, there are others, such as Ramsey (1931), de Finetti (1937), and Anscombe and Aumann (1963).

¹⁰ There are two further axioms that allow one to make a distinction between beliefs of the individual and the individual's tastes. For a discussion of these axioms, see Karni (2003) and Gintis (2009, Section 1.5).

¹¹ One could give a more formal measure theoretic construction if required, but our discussion here is at a heuristic level only.

to be identical and treat them interchangeably; this is known as probabilistic sophistication and summarized in the next definition.

Definition 1.13 (*Probabilistic sophistication*): Consider Definition 1.12. The decision maker is said to be probabilistically sophisticated when event contingent lotteries can be replaced by probability contingent lotteries. The subjective probabilities in probability contingent lotteries constitute a probability measure. However, there is no presumption, under probabilistic sophistication, that in comparing two lotteries, the decision maker uses SEU. The decision maker is allowed to follow any of the non-expected utility theories. Furthermore, the decision maker is indifferent between two event contingent lotteries that lead to the same probability contingent prospect.¹²

In Chapter 4 we will show an example in which the *Ellsberg paradox* implies a violation of probabilistic sophistication.

1.4 Eliciting the utility function under EU

In this section, we consider the elicitation of the underlying utility function when the decision maker follows EU. We consider the two cases of known and unknown probabilities.

1.4.1 The case of known probabilities

Suppose that probabilities and outcomes are known. Consider any two outcomes such that $x_l < x_h$. Then, without loss of generality, we can choose the following convenient normalization.

$$u(x_l) = 0, u(x_h) = 1. \quad (1.11)$$

Example 1.1 Suppose that x_l, x_h are, respectively, the lowest and highest monetary outcomes. Suppose that there is a utility function v such that $v(x_l)$ and $v(x_h)$ are known real numbers. We wish to renormalize the utility function such that the utility from the lowest outcome is 0 and the utility from the highest outcome is 1. Recall that if v represents the decision maker's preferences under EU, then so does $u = a + bv$, $a \in \mathbb{R}$ and $b > 0$ (invariance to positive affine transformations). Solving the two simultaneous equations $u(x_l) = 0 = a + bv(x_l)$ and $u(x_h) = 1 = a + bv(x_h)$ gives the required values of $a = -bv(x_l)$ and $b = \frac{1}{v(x_h) - v(x_l)}$.

We now offer the decision maker, lotteries of the form

$$L = (x_l, 1 - p; x_h, p), \quad (1.12)$$

and compute the certainty equivalent, x , of the lottery. Under EU, and using (1.11), this is given by the solution to

$$u(x) = (1 - p)u(x_l) + pu(x_h) = p. \quad (1.13)$$

¹² The axiomatic justification of probabilistic sophistication can be found in Grant et al. (2008), Chew and Sagi (2006), Abdellaoui and Wakker (2005), Sarin and Wakker (2000), Epstein and LeBreton (1993), and Machina and Schmeidler (1992).

From (1.13) we can find the utility of the decision maker at the certainty equivalent as simply the known probability of the best outcome. The requirement that a solution exists to (1.13) is called *standard gamble solvability*. This procedure for eliciting the utility function is also known as the problem of eliciting standard gamble probability (SG) with respect to the outcomes x_l, x_h . Suppose that the decision maker's preferences are a *weak order* (complete and transitive) and the following condition, known as *standard gamble dominance*, holds:¹³

$$(x_l, 1 - p; x_h, p) \succ (x_l, 1 - q; x_h, q) \text{ for } p > q.$$

Then it can be shown that p in (1.13) is unique.¹⁴ When p is unique, then keeping fixed x_l and x_h , we can vary x , generating a corresponding series of values of p that reveal the decision maker's utility function.

Under SG, as shown in (1.13), the decision maker compares a risky choice (the RHS of the first equality) with a riskless choice (LHS of the first equality). McCord and de Neufville (1986) have criticized this approach and argued for eliciting the utility function from more general risky choices. In the SG method, for instance, if individuals are not really EU maximizers and evaluate probabilities non-linearly, then because high probabilities are underweighted, forcing probabilities to be linear will overestimate the concavity of the utility function.¹⁵ Furthermore, a strong *certainty effect* could magnify the problems created on account of the riskless choice in the SG method.¹⁶ In order to control for the certainty effect, McCord and de Neufville (1986) propose an improvement in the SG method by calculating the value of x such that

$$(x, \lambda; a, 1 - \lambda) \sim ((x_l, 1 - p; x_h, p), \lambda; a, 1 - \lambda), \quad (1.14)$$

where $a \in \mathbb{R}$ and $\lambda \in (0, 1)$. The indifference in (1.14) is arrived at by asking a series of questions from subjects in experiments that pit the two lotteries against each other and using the tipping point where the preferences flip from one direction to the other, as the point of indifference. This remark applies to all the indifference elicitation here and in Section 2.5.

For an EU maximizer, the indifference in (1.14) implies that

$$\lambda u(x) + (1 - \lambda) u(a) = \lambda [(1 - p)u(x_l) + pu(x_h)] + (1 - \lambda) u(a). \quad (1.15)$$

Using (1.11), we get from (1.15) that $u(x) = p$, which is identical to (1.13). When one applies EU, one expects the SG method and the method of McCord and de Neufville (1986) to give identical results. This is called *standard gamble equivalence*. In practice, however, the results differ, possibly because individuals in fact use non-linear weighting of probabilities.¹⁷

¹³ For $x_l = x_1$ and $x_h = x_n$ standard gamble dominance is equivalent to monotonicity.

¹⁴ See exercise 2.6.3 in Wakker (2010).

¹⁵ For instance, it has been shown that EU is violated for health outcomes (Rutten-van Mölken et al., 1995; Stalmeier and Bezembinder, 1999). One would then expect that measurements of utility of health outcomes based on the SG method would lead to biased estimates of utility. This was shown by Bleichrodt et al. (2007).

¹⁶ The certainty effect refers to relatively greater sensitivity to changes in probability around zero as one approaches the certainty of an outcome.

¹⁷ It can be shown (See Theorem 2.6.3 in Wakker, 2010, p. 62) that EU is equivalent to $\succeq$ being a weak order in the presence of the following conditions (defined above in this subsection). (1) Standard gamble solvability. (2) Standard gamble dominance. (3) Standard gamble equivalence.

1.4.2 The case of unknown probabilities

Now suppose that probabilities are unknown, i.e., they are not objectively given. This is a more difficult problem because both probabilities and the utility function are unknown. We now give a simple method of eliciting utilities and probabilities in this case.¹⁸ The basis of this elicitation is the *trade-off method* that is given in Wakker and Deneffe (1996); for the relevant preference foundation, see Section 2.6.1. This section will also help us to address the problem of eliciting probability weights and utilities under rank dependent utility and under cumulative prospect theory.

Suppose that there are two possible events E_1 and E_2 with unknown objective probabilities. The decision maker, however, forms subjective beliefs $\mu(E_1) \geq 0$ and $\mu(E_2) \geq 0$ such that $\mu(E_1) + \mu(E_2) = 1$, and evaluates the lottery $(E_1, x_1; E_2, x_2)$ as in *subjective expected utility* (SEU) (see Section 1.3), i.e.,

$$\mu(E_1)u(x_1) + \mu(E_2)u(x_2). \quad (1.16)$$

This form of evaluation can be extended to finitely many outcomes.

Suppose that an initial monetary reward y_0 is given. Consider the following sequence of lotteries that elicit a value $y_j, j = 1, 2, 3, 4$, in order to ensure the indifference relation

$$(E_1, y_j; E_2, a) \sim (E_1, y_{j-1}; E_2, b), \quad (1.17)$$

where $a, b \in$ and E_1, E_2 are given. Thus, y_1, y_2, y_3, y_4 are to be elicited using (1.17), over four iterations.

Using (1.16), (1.17) we get equalities of the form:

$$\mu(E_1)u(y_j) + \mu(E_2)u(a) = \mu(E_1)u(y_{j-1}) + \mu(E_2)u(b); j = 1, 2, 3, 4. \quad (1.18)$$

On rearranging, we get

$$\mu(E_1) [u(y_j) - u(y_{j-1})] = \mu(E_2) [u(b) - u(a)]; j = 1, 2, 3, 4. \quad (1.19)$$

Using the fact that the RHS in (1.19) is identical for all four iterations, we get the following system of equations.

$$u(y_4) - u(y_3) = u(y_3) - u(y_2) = u(y_2) - u(y_1) = u(y_1) - u(y_0). \quad (1.20)$$

In (1.20), we have eliminated the unknown probabilities. As in Example 1.1, normalize so that $u(y_0) = 0$ and $u(y_4) = 1$. This gives rise to the following system of three equations in three unknowns.

$$\begin{aligned} 1 - u(y_3) &= u(y_3) - u(y_2) \\ u(y_3) - u(y_2) &= u(y_2) - u(y_1) \\ u(y_2) - u(y_1) &= u(y_1) \end{aligned}$$

¹⁸ The interested reader can consult Wakker (2010, Ch.4) for a more detailed discussion.

Solving these equations simultaneously we get,

$$u(y_0) = 0; u(y_1) = \frac{1}{4}; u(y_2) = \frac{1}{2}; u(y_3) = \frac{3}{4}; u(y_4) = 1.$$

Recall that only y_0 is given, while y_1, y_2, y_3, y_4 are elicited from the choices made by the decision maker. By generating sufficiently many points such as these, one can recover the underlying utility function. By extending the number of iterations, and adjusting the value of y_0 , one can extend the domain over which the utility function is elicited.

Once the utility function is elicited, then the subjective probabilities of an event E in the sample space can be found. Suppose that the decision maker is asked for a value of x such that the following indifference relation holds.

$$x \sim (E, y; E^c, 0); i = 1, 2, \quad (1.21)$$

where E^c is the complement of E . Under SEU, the indifference relation in (1.21) implies that $u(x) = \mu(E)u(y)$ (because $u(0) = 0$). Since the utility function has already been elicited, $\mu(E) = u(x)/u(y)$ is the required answer. In actual practice, there are problems, however. Consistency might be violated (i.e., subjective probabilities might not add up to 1) and the utility function might not have been fitted (in the first stage) corresponding to the outcome x .

Another method for finding the relevant subjective probabilities is the *method of matching probabilities*. Here, the decision maker is asked to state the probability such that

$$(E, 1; E^c, 0) \sim (1, p; 0, 1 - p). \quad (1.22)$$

Notice the difference in the representation of the two lotteries under uncertainty (LHS) and certainty (RHS). In (1.22), p is said to be the matching probability. If EU holds for the lottery on the RHS, then $\mu(E) = p$.

1.5 Violations of expected utility theory

In this section we show that a great deal of evidence is inconsistent with the predictions of EU; indeed, it would not be unfair to say that EU is rejected by the evidence.¹⁹

1.5.1 Violations of the independence axiom

We first show a violation of the independence axiom, originally due to Allais (1953). Example 1.2, below, draws on Kahneman and Tversky (1979) who showed that the Allais paradox can be explained by assuming that decision makers overweight low probabilities and underweight high probabilities. In contrast, EU is linear in probabilities (Remark 1.1).

¹⁹ Strictly speaking, a *refutation* is an empirical finding that rejects any of the axioms of EU. A *violation* of EU occurs when the empirical evidence rejects an auxiliary assumption of EU. We use these terms interchangeably in this section. Readers can consult the excellent discussions in Kahneman and Tversky (1979), Kahneman and Tversky (2000), Starmer (2000), and Wakker (2010).

Example 1.2 (Allais paradox as a “common ratio violation.” Problems 3 and 4 in Kahneman and Tversky, 1979) Consider a decision maker with initial wealth, x_0 , and utility function u . Outcomes are in units of Israeli pounds.

Problem 3: (95 subjects) Choose between the two lotteries

$$b_1 = (x_0, 0; x_0 + 3000, 1) \text{ and } b_2 = (x_0, 0.2; x_0 + 4000, 0.8),$$

80% chose b_1 , while 20% chose b_2 .

Problem 4: (95 subjects) Choose between the two lotteries

$$b_3 = (x_0, 0.75; x_0 + 3000, 0.25) \text{ and } b_4 = (x_0, 0.8; x_0 + 4000, 0.2),$$

35% chose b_3 , while 65% chose b_4 .

Denoting by $\prec_{EU}$ the binary EU preference relation, the prediction of EU is,

$$b_1 \prec_{EU} b_2 \Leftrightarrow b_3 \prec_{EU} b_4. \quad (1.23)$$

The proof of (1.23) runs as follows. Since EU preferences are invariant to a positive affine transformation, we can assume $u(x_0) = 0$. Hence, the expected utility of the 2 pairs of lotteries in each problem is:

$$EU(b_1) = u(x_0 + 3000), EU(b_2) = 0.8u(x_0 + 4000). \quad (1.24)$$

$$EU(b_3) = 0.25u(x_0 + 3000), EU(b_4) = 0.2u(x_0 + 4000). \quad (1.25)$$

From (1.24) we get that

$$b_1 \prec_{EU} b_2 \Leftrightarrow u(x_0 + 3000) < 0.8u(x_0 + 4000).$$

Dividing both sides by 4, we get

$$0.25U(x_0 + 3000) < 0.2U(x_0 + 4000) \Leftrightarrow b_3 \prec_{EU} b_4.$$

Hence, $b_1 \prec_{EU} b_2 \Rightarrow b_3 \prec_{EU} b_4$. A similar argument shows that $b_3 \prec_{EU} b_4 \Rightarrow b_1 \prec_{EU} b_2$. Hence, (1.23) holds. However, since a majority of subjects chose b_1 over b_2 and b_4 over b_3 , at least some decision makers must have violated (1.23) and, hence, EU.

In Allais's original presentation to Leonard Savage, Paul Samuelson, and others in Paris in 1952 (in units of millions of 1952 Francs), $b_1 = (100, 1)$, $b_2 = (500, 0.98)$, $b_3 = (100; 0.01)$ and $b_4 = (4000; 0.0098)$. To quote from Allais: “The author of this memoir, who is perfectly familiar with Samuelson's arguments, unhesitatingly prefers lottery $[b_1]$ to lottery $[b_2]$ and lottery $[b_4]$ to lottery $[b_3]$ and he thinks that most of his readers will share his preference; yet to the best of his knowledge, he believes that he is not irrational. He is perfectly aware that 2 chances in 100,000 is a non-negligible quantity, but his view is that this quantity does not offset for him the reduction in the possible gain from 500 to 100 million, whereas for him by contrast, the achievement of certainty by raising the chance of winning from 98% to 100% is well worth this reduction” (Allais and Hagen 1979, p. 102).

Savage (like Allais) initially chose b_1 over b_2 and b_4 over b_3 . However, after an EU calculation, Savage concluded that he had made a mistake. Savage's response was that EU is needed to guide us to correct decision making. Of course, both positions may be correct. Savage may be right to conclude that decision makers should be trained in EU. Allais may be right to conclude that, in fact, most decision makers do not follow EU.

The Allais paradox can be explained as follows. In problem 4, the decision maker codes the probability 0.2 as close to 0.25 (and 0.75 as close to 0.80). Hence, he prefers b_4 to b_3 because it

gives him a higher outcome (4000 instead of 3000). By contrast, in problem 3, the decision maker does not code the probability 0.8 as close to 1; the certain outcome is particularly salient (this is an example of the *certainty effect*). In other words, he *underweights* the probability 0.8. Hence, *non-linear weighting of probabilities* is a potential explanation of the Allais paradox but EU does not allow it. However, it is not simply a matter of arbitrarily using non-linear transformations of probabilities. We show below that unless carefully applied, non-linear weighting can also allow stochastically dominated options to be chosen.

When the Allais paradox first appeared, it was thought to be an isolated example for a long time. However, it was realized later that the Allais paradox was part of a family of paradoxes that took two forms, the *common ratio violation* form, and the *common consequence violation* form. Both forms violate the independence axiom of EU (Axiom 1.4) and have been widely replicated. There is some evidence that professional traders also exhibit Allais-type violations but to a lesser extent than students, who are the main subject pool of these experiments; see List and Haigh (2005).

Definition 1.14 (*Common ratio violation*) Consider two probabilities $p, P \in (0, 1]$ and two prizes z, Z ; typically, $p < P$ and $z < Z$. Let $\mu \in [0, 1]$. Recall our convention that (x, p) denotes the lottery $(x, p; 0, 1 - p)$. Consider a choice between the following pairs of lotteries.

$$b_1 = (z, P) \text{ and } b_2 = (Z, p), \quad (1.26)$$

$$b_3 = (z, \mu P) \text{ and } b_4 = (Z, \mu p). \quad (1.27)$$

The “common ratio violation” occurs if for $\mu > 0$ a decision maker prefers b_1 over b_2 and b_4 over b_3 (or b_2 over b_1 and b_3 over b_4). The name “common ratio” derives from the fact that the ratio of probabilities for the outcomes in each of the two choices is the same, i.e., P/p .

Example 1.2, above, is a special case of this violation if we assume that the returns on the asset are not integrated with existing wealth level x_0 . Empirical evidence is consistent with non-integration of assets or, at best, partial integration (Andersen et al., 2012). Fafchamps et al. (2014) find no evidence that subjects in experiments integrate asset returns in the lab with their real-life income/wealth, although winnings in one round may influence subsequent risk attitudes. One explanation is that subjects create different *mental accounts* for the lab and non-lab earnings; see Chapter 20 for mental accounting.

Assuming non-integration and using the notation of Definition 1.14, in Example 1.2 $p = 0.8$, $P = 1$, $z = 3000$, $Z = 4000$, and $\mu = 1/4$. For other experimental tests of the common ratio violation, see, for instance, Chew and Waller (1986) and MacCrimmon and Larsson (1979). Blavatskyy (2010) reports a reverse common ratio violation effect that takes place when the probability p in Definition 1.14 drops below 0.5. The pattern of violation of EU that is observed is then the reverse of the normal one that we observe with the Allais paradox.²⁰

We already know, from Example 1.2, that an observation of a common ratio violation is a refutation of EU. We now consider the question of which axiom (or axioms) might be responsible for the refutation.

Proposition 1.5 *The common ratio violation is a violation of the independence axiom, or the reduction axiom, or of both axioms.*

²⁰ Blavatskyy (2011) suggests an explanation based on the *stochastic expected utility theory* of Blavatskyy (2007) and the *perceived relative argument model* of Loomes (2008).

Proof: Assume that $b_1 \succ b_2$, so $(z, P) \succ (Z, p)$. Hence, $(z, P) \succeq (Z, p)$. From the independence axiom (Axiom 1.4) we get that $((z, P), \mu; 0, 1 - \mu) \succeq ((Z, p), \mu; 0, 1 - \mu)$, which, given our notation, can be denoted as $((z, P), \mu) \succeq ((Z, p), \mu)$. From the reduction axiom (Axiom 1.5) it follows that $((z, P), \mu)$ and $((Z, p), \mu)$ are equivalent to $(z, \mu P)$ and $(Z, \mu p)$, respectively. Hence, $(z, \mu P) \succeq (Z, \mu p)$, i.e., $b_3 \succeq b_4$. Thus, the observation of a common ratio violation, namely, $b_1 \succ b_2$ and $b_4 \succ b_3$ is a rejection of the independence axiom, given the other axioms of EU. Alternatively, we may view the observation of a common ratio violation as a rejection of the reduction axiom, given the other axioms of EU, an observation that is missed by many texts in microeconomics. ■

We now move on to another generic class of paradoxes, associated with the *common consequence violation*, which was also given by Allais (1953).

Definition 1.15 (*Common consequence violation*) Let A, B, C, D be lotteries and $\mu \in [0, 1]$. Suppose that we have the following four compound lotteries, a_1, a_2 and a_3, a_4 , that are compared in a pairwise manner, namely, a_1 with a_2 and a_3 with a_4 .

$$a_1 = (A, \mu; D, 1 - \mu); a_2 = (B, \mu; D, 1 - \mu), \quad (1.28)$$

$$a_3 = (A, \mu; C, 1 - \mu); a_4 = (B, \mu; C, 1 - \mu). \quad (1.29)$$

The “common consequence violation” occurs if a decision maker prefers a_1 over a_2 and a_4 over a_3 (or a_2 over a_1 and a_3 over a_4). The following restrictions are typically imposed on the lotteries A, B, C, D : (1) The lottery A gives a sure prize of x , i.e., $A = (x, 1)$. (2) The lottery B has some outcomes that are greater than x and others that are less than x . (3) Lottery D first order stochastically dominates lottery C .

The independence axiom implies either of the following two scenarios. Since D is common in the first pair in (1.28) and C is common in the second pair in (1.29), it follows that: (1) If A is preferred to B , then subjects must choose a_1 over a_2 and a_3 over a_4 . If, on the other hand, B is preferred to A , then subjects must prefer a_2 over a_1 and a_4 over a_3 . Thus, the observation of a “common consequence violation,” namely, the empirically observed preference of a_1 over a_2 and a_4 over a_3 , is a refutation of EU, and, in particular, of the independence axiom.

Example 1.3 (*Allais paradox as a common consequence violation. Problems 1 and 2 from Kahneman and Tversky, 1979*) Let a decision maker have initial wealth, x_0 , and utility function, u . All lotteries are in units of Israeli pounds.

Problem 1: (72 subjects) Choose between

$$a_1 = (x_0, 0; x_0 + 2400, 1) \text{ and } a_2 = (x_0, 0.01; x_0 + 2400, 0.66; x_0 + 2500, 0.33).$$

Problem 2: (72 subjects) Choose between

$$a_3 = (x_0, 0.66; x_0 + 2400, 0.34) \text{ and } a_4 = (x_0, 0.67; x_0 + 2500, 0.33).$$

82% of the subjects chose a_1 in problem 1 and 83% of the subjects chose a_4 in problem 2. Each of these preferences was significant at the 1% level.

Example 1.3 can be recast as a common consequence violation as defined in Definition 1.15. To see this, let $\mu = 0.34$ and define the following lotteries.

$$A = (x_0 + 2400, 1); B = \left(x_0 + 2500, \frac{33}{34}; x_0; \frac{1}{34}\right);$$

$$C = (x_0, 1); D = (x_0 + 2400, 1).$$

Then the pairwise comparison lotteries (1.28), (1.29) can be written, in full standard form, as follows.

$$a_1 = (A, 0.34; D, 0.66) = (x_0, 0; x_0 + 2400, 1; x_0 + 2500, 0), \quad (1.30)$$

$$a_2 = (B, 0.34; D, 0.66) = (x_0, 0.01; x_0 + 2400, 0.66; x_0 + 2500, 0.33), \quad (1.31)$$

$$a_3 = (A, 0.34; C, 0.66) = (x_0, 0.66; x_0 + 2400, 0.34; x_0 + 2500, 0), \quad (1.32)$$

$$a_4 = (B, 0.34; C, 0.66) = (x_0, 0.67; x_0 + 2400, 0; x_0 + 2500, 0.33). \quad (1.33)$$

1.5.2 *The probability triangle and violations of the axioms of rationality*

The lotteries, b_1, b_2, b_3, b_4 in (1.26), (1.27) can be written in the following alternative but equivalent notation.

$$b_1 = (0, 1 - P; z, P; Z, 0) \text{ and } b_2 = (0, 1 - p; z, 0; Z, p),$$

$$b_3 = (0, 1 - \mu P; z, \mu P; Z, 0) \text{ and } b_4 = (0, 1 - \mu p; z, 0; Z, \mu p).$$

Using Definition 1.14, we can illustrate the common ratio violation through a useful device, *the probability triangle* (also known as the *Marshak–Machina probability triangle*). Order the three outcomes in Definition 1.14 as $0 < z < Z$ and suppose that we denote their respective probabilities by p_1, p_2 and p_3 . Since p_1, p_3 are the probabilities of outcomes 0 and Z respectively, the probability of the outcome z is simply calculated as a residual, $p_2 = 1 - p_1 - p_3$. Hence, we need only two independent probabilities, p_1, p_3 . Expressing the lotteries, b_1, b_2, b_3, b_4 , in terms of the ordered pair (p_1, p_3) , corresponding to the outcomes 0, Z (probability of z being calculated as a residual) we get:

$$(p_1, p_3): b_1 = (1 - P, 0); b_2 = (1 - p, p); b_3 = (1 - \mu P, 0); b_4 = (1 - \mu p, \mu p) \quad (1.34)$$

The probability triangle corresponding to this case is shown in Figure 1.1. We measure p_1 along the horizontal axis and p_3 along the vertical, such that $p_1, p_3 \in [0, 1]$ (by definition, $p_2 = 1 - p_1 - p_3$). Along the *left edge* of the diagram, $p_1 = 0$, so we get combinations of p_2, p_3 such that $p_2 + p_3 = 1$. Along the *hypotenuse* of the triangle, $p_2 = 0$, so we get combinations of p_1, p_3 such that $p_1 + p_3 = 1$. Along the *lower edge* of the diagram $p_3 = 0$, so we get combinations of p_1, p_2 such that $p_1 + p_2 = 1$.

The lotteries in (1.26), (1.27), expressed in terms of the ordered pair (p_1, p_3) in (1.34), can be represented in the probability triangle. We now draw the indifference curves corresponding to these lottery within the probability triangle. Consider the generic lottery $(0, p_1; z, 1 - p_1 - p_3; Z, p_3)$; we would like to find all combinations of (p_1, p_3) that (for fixed outcomes) generate identical levels of utility, $\bar{u}$, i.e.,

$$p_1 u(0) + (1 - p_1 - p_3) u(z) + p_3 u(Z) = \bar{u}. \quad (1.35)$$

From (1.35), the equation of the indifference curves in the probability triangle is,

$$p_3 = \frac{\bar{u} - u(z)}{u(Z) - u(z)} + \frac{u(z) - u(0)}{u(Z) - u(z)} p_1. \quad (1.36)$$

The outcomes 0, z , Z and $\bar{u}$ are held fixed, hence, (1.36) is the equation of a straight line. Since $0 < z < Z$, and u is a non-decreasing function, it follows that the slope, $[u(z) - u(0)] / [u(Z) - u(z)]$ is constant and positive. Hence, under EU, the indifference curves are all parallel, positively sloping, straight lines. Furthermore, for a fixed p_1 , higher points in the probability triangle (corresponding to higher values of p_3) represent higher values of $\bar{u}$, and lie on a higher indifference curve. The reader can now prove the following two propositions to gain useful practice with the probability triangle (part of the second proposition summarizes some results that we have already proved above).

Proposition 1.6 *The axioms of rationality (see Definition 1.1) translate into various features of the probability triangle. Completeness (see Axiom 1.1a) implies that any two points in the probability triangle lie either on the same indifference curve or different indifference curves. Transitivity (Axiom 1.1b) ensures that no two indifference curves intersect. Continuity (Axiom 1.3) ensures that indifference curves are not thick lines. Independence (Axiom 1.4) implies that indifference curves are parallel straight lines.*

Proposition 1.7 *In the probability triangle, the following properties hold:*

- (i) *The indifference curves under EU are parallel, positively sloping, straight lines.*
- (ii) *Upward shifts (in the north-west direction) of the indifference curves increase utility.*
- (iii) *Steeper indifference curves are associated with greater risk aversion.*

Using the fact that $P > p$, $\mu \in [0, 1]$, and the machinery developed above, the lotteries in (1.34) can now be expressed in the probability triangle in Figure 1.1. Two sets of indifference curves are shown, bold and dotted. The bold indifference curves correspond to EU; these are parallel, straight lines. From Figure 1.1, it is immediate that under EU, decision makers should

Figure 1.1 Illustration of the common ratio effect in a probability triangle.

either choose (1) b_1 over b_2 and b_3 over b_4 (this is the case shown in Figure 1.1), or (2) b_2 over b_1 and b_4 over b_3 (this would be obtained by making the indifference curves in Figure 1.1, flatter). A similar illustration can be given for the common consequence violation.

The actual evidence in the case of the common ratio violation is that the majority of decision makers choose b_1 over b_2 and b_4 over b_3 . These choices provide a clue to the behavior of decision makers relative to the predictions of EU. In order to explain the evidence, as one moves towards the south east corner of the probability triangle, the indifference curves must flatten out, i.e., the decision maker becomes less risk averse (see Proposition 1.7(iii)). This is called the *fanning-out hypothesis* and it is able to explain the common consequence violation and the common ratio violation. By contrast, the independence axiom in EU forces the indifference curves to be parallel, hence, they cannot fan out. Figure 1.1 shows two dotted indifference curves that demonstrate fanning-out.

1.5.3 Some attempts to relax the independence axiom

A number of theoretical models, underpinned by preference foundations, are able to incorporate fanning-out. These models relax the independence axiom, which leads to Allais type violations. We briefly mention some of these models here to give a flavor of the arguments.²¹ One model that generates fanning-out but retains the linearity of indifference curves is the *weighted utility theory* of Chew and MacCrimmon (1979).²² In this case, the utility arising from the lottery $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$ is given by²³

$$U(L) = \frac{\sum_{i=1}^n p_i \phi(x_i) u(x_i)}{\sum_{i=1}^n p_i \phi(x_i)},$$

where $\phi : \mathbb{R} \rightarrow \mathbb{R}_+$. Weighted utility theory uses a weak form of the independence axiom, called *weak independence*; Starmer (2000) raises concerns about the intuitive appeal of this axiom.

Definition 1.16 (*Weak Independence*) Suppose that for lotteries $L_1, L_2 \in \mathcal{L}$, $L_1 \prec L_2$. Then, for each $p \in (0, 1)$, there is a unique $q \in (0, 1)$ such that for all $L_3 \in \mathcal{L}$,

$$qL_1 + (1 - q)L_3 \prec pL_2 + (1 - p)L_3.$$

Another theory that allows for fanning-out is the theory of *disappointment aversion*; see for instance, Bell (1985) and Loomes and Sugden (1986).²⁴ In this formulation, for a lottery $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$ such that $x_1 < x_2 < \dots < x_n$, the decision maker derives the utility

$$D(L) = \sum_{i=1}^n p_i [u(x_i) + D(u(x_i) - \bar{U})]. \quad (1.37)$$

In (1.37), $\bar{U}$ is the utility that the decision maker expects from the lottery, say, the certainty equivalent of the lottery. $u(x_i)$ is the utility that actually arises when the outcome is x_i . If $u(x_i) - \bar{U} > 0$,

²¹ The interested reader can consult Wakker (2010), Sugden (2004), and Starmer (2000) for more details.

²² For various axiomatic foundations of weighted utility theory, see Chew and MacCrimmon (1979), Chew (1983), and Fishburn (1983).

²³ Two other models that retain linearity of the indifference curves but also permit fanning-out are the *implicit expected utility model* of Dekel (1986) and the *implicit weighted utility model* of Chew (1989).

²⁴ See Section 2.10.2 for a more detailed exposition of disappointment aversion.

the decision maker experiences *elation*. *Disappointment* is experienced if $u(x_i) - \bar{U} < 0$. *Disappointment aversion* is built into the model by assuming that $D(x)$ is concave for $x < 0$ and convex for $x > 0$.

It turns out that linearity of indifference curves in the probability triangle is equivalent to the *betweenness axiom*, which weakens the independence axiom by requiring the indifference curves to be straight lines, not necessarily parallel.

Definition 1.17 (*Betweenness*): Given two lotteries a_1, a_2 , if $a_2 \prec a_1$, then *betweenness* implies that for all $p \in (0, 1)$, $a_2 \prec (a_1, p; a_2, 1 - p) \prec a_1$.

To visualize betweenness, think of straight line indifference curves in a probability triangle. Suppose that a_1 lies on a higher indifference curve than a_2 . Then all linear combinations of a_1, a_2 lie on an indifference curve no higher than the indifference curve on which a_1 lies and no lower than the indifference curve on which a_2 lies. If the binary relation is one of indifference, betweenness implies that if $a_1 \sim a_2$, then for all $p < 1$, $a_1 \sim (a_1, p; a_2, 1 - p) \sim a_2$. This is also immediately seen by looking at one of the straight line indifference curves in the probability triangle. If the lotteries a_1, a_2 lie on the same indifference curve, then the decision maker is also indifferent between all linear combinations of a_1, a_2 because they too lie on the same indifference curve. However, while betweenness implies (and is implied by) linear indifference curves, it does not impose the restriction that the indifference curves be parallel in the probability triangle.

Now suppose that we relax betweenness and consider the two cases: concave indifference curves (i.e., quasi-convex preferences), and convex indifference curves (i.e., quasi-concave preferences). These cases are shown in Figures 1.2 and 1.3, respectively. In each diagram, the dotted line connecting the two lotteries, a_1, a_2 , among which the decision maker is indifferent, represents all possible linear combinations of a_1, a_2 , i.e., lotteries of the form $(a_1, p; a_2, 1 - p)$. When the indifference curves are concave, then any lottery of the form $(a_1, p; a_2, 1 - p)$ lies on a lower indifference curve. Hence, the decision maker is averse to randomizing among a_1, a_2 . The converse applies in Figure 1.3 where the indifference curves are convex, and the decision maker prefers to randomize.

Figure 1.2 Concave indifference curves.

Figure 1.3 Convex indifference curves.

The possibilities shown in Figures 1.2 and 1.3 are not the only ones. For instance, Chew et al. (1991) propose a model that is quadratic in probabilities. In this model, the utility from a lottery $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$ is written as follows.

$$Q(L) = \sum_{i=1}^n \sum_{j=1}^n p_i p_j v(x_i, x_j). \quad (1.38)$$

The utility function in (1.38) is generated by a weakened form of the independence axiom called *mixture symmetry*, which we define next.

Definition 1.18 (*Mixture asymmetry*) *Mixture symmetry requires that for all lotteries, a_1, a_2 , if $a_1 \sim a_2$, then for all $p < 1$, $(a_1, p; a_2, 1-p) \sim (a_2, p; a_1, 1-p)$.*

In the probability triangle, the indifference curves generated by (1.38) can exhibit both concavity and convexity over different domains. In other words, these indifference curves exhibit both fanning-in and fanning-out. The *theory of disappointment* in Gul (1991) incorporates both these features.

We now turn briefly to the empirical evidence.²⁵ Empirical evidence for fanning-out is, at best, mixed. The results do not change if we use real or hypothetical gambles (Camerer, 1995, p. 634). In a careful empirical study, Chew and Waller (1986) reported violations of the independence axiom in the common consequence and the common ratio forms. They also found that betweenness is not consistent with their data. Other studies have also subsequently cast doubt on the betweenness axiom. It is not easy, however, to discern a pattern to these violations; for a review of nine studies see Camerer and Ho (1994). Fanning-out is found when the gambles are unattractive but not when they are attractive; in the probability triangle, these are respectively the southeast and northwest corners (Camerer, 1989).

Fanning-in has been found in several parts of the probability triangle. For instance, along the *lower edge* (Starmer and Sugden, 1989a; Battalio et al., 1990), northwest corner (Conlisk, 1989), lower edge and southeast corner (Prelec, 1990), and moving up along the left edge (Starmer, 1992).

²⁵ For more detailed surveys, see Camerer (1995), Starmer (2000), Sugden (2004), and Wakker (2010).

While it is difficult to establish a pattern, it would seem that there is sufficient evidence of fanning-in. This, however, casts doubt on fanning-out as an explanation of the common consequence and the common ratio violations.

In the light of this evidence, theories which incorporate both fanning-in and fanning-out appear to have a better chance of explaining the data. This includes theories such as those proposed by Gul (1991) and Neilson (1992); however, the lack of evidence supporting the betweenness axiom, which both these papers assume, is a cause for concern.

Violations of EU are less pronounced, but still significant, in the interior of the probability triangle as compared to the edges (Conlisk, 1989; Camerer, 1992; Harless, 1992). This is most likely caused by non-linear weighting of probabilities and the certainty effect. However, a reduction in violations towards the interior of the probability triangle does not rescue EU. We shall see below that many economically important events involve events that occur towards the boundary of the probability triangle.

There is also evidence that some salient aspects of the behavior of human decision makers under risk might be shared with that of other animals. For instance, it has been found that rats also violate betweenness. They have indifference curves that fan-in and fan-out and that exhibit the common ratio violation.²⁶ There are also evolutionary reasons why animals may neglect events of very low probability.²⁷ Hence, many violations of EU arise from a shared evolutionary history of mammals.

1.5.4 *Attitudes to risk for small and large stakes: Rabin's paradox*

In a fundamental result, Rabin (2000a) showed that under EU risk aversion over small stakes implies implausibly high risk aversion over large stakes. A more accessible treatment of the issues can be found in Rabin (2000b).²⁸ We first state the result informally. Suppose that the utility function of a decision maker who follows EU is increasing and concave. Then if the decision maker turns down a moderate stakes gamble, then he/she will always turn down a large stakes gamble.

Let a decision maker have initial wealth, w . Define three lotteries, L_0, L_1, L_2 as follows. $L_0 = (w, 1)$, $L_1 = (w - 10, 0.5; w + 11, 0.5)$, and $L_2 = (w - 100, 0.5; w + m, 0.5)$, where m is any positive level of wealth. Consider assumption A1.

A1. Suppose that for all levels of w the decision maker expresses the preference

$$L_1 \prec L_0. \quad (1.39)$$

Under EU, (1.39) implies that

$$u(w) > 0.5u(w - 10) + 0.5u(w + 11), \quad (1.40)$$

²⁶ See Battalio et al. (1985), Kagel et al. (1990), and MacDonald et al. (1991).

²⁷ I am grateful to Herbert Gintis for bringing this to my attention. Evolutionary dynamics show that very small probabilities will be ignored because (a) the rate of false positives will be high and (b) the cost of maintaining the neural machinery to detect and react to low probability events is too high; see Heiner (1983).

²⁸ Wakker (2005) not only gives a particularly lucid account of these results but also discusses the context of subsequent remarks and some confusions in the literature.

where $u(w)$ is the utility from outcome w . Since the expected value of lottery L_1 is higher, yet $L_1 \prec L_0$, thus, the decision maker is risk averse over small stakes.²⁹ Under EU this implies that the utility function u must be concave. Rabin's (2000a) central insight is to show that for arbitrarily large values of m , the decision maker must then have the preferences

$$L_2 \prec L_1, \quad (1.41)$$

i.e., by turning down a lottery that offers infinite wealth with probability 0.5, the decision maker expresses an unreasonable amount of risk aversion. We now give a heuristic proof of Rabin's result.

Rewriting (1.40) we get

$$u(w + 11) - u(w) < u(w) - u(w - 10). \quad (1.42)$$

At this stage, the reader may find it useful to visualize an increasing, concave, utility function u at three values: $w - 10$, w , $w + 11$. The following sequence of steps can then be constructed:

$$\begin{aligned} u'(w + 11) &< \frac{u(w + 11) - u(w)}{11} \quad (\text{from concavity of } u), \\ \frac{u(w + 11) - u(w)}{11} &< \frac{u(w) - u(w - 10)}{11} \quad (\text{since (1.42) holds}), \\ &= \frac{10}{11} \frac{[u(w) - u(w - 10)]}{10}, \\ &\leq \frac{10}{11} u'(w - 10) \quad (\text{from concavity of } u). \\ \Rightarrow u'(w + 11) &< \frac{10}{11} u'(w - 10). \end{aligned} \quad (1.43)$$

In other words, over an interval of length 21, marginal utility drops by $\frac{10}{11}$ of the original value. Thus, each unit of money between w and $w + 11$ is valued, on average, at most $\frac{10}{11}$ of each unit of money, on average, between $w - 10$ and w .

Table 1.1 Drop in marginal utility for successive intervals in Rabin's calibration theorem.

Interval size	21	210	2100	21000	210000
Final to initial marginal utility	0.90909	0.38554	73×10^{-6}	4.0487×10^{-42}	1.1834×10^{-414}

Table 1.1 shows this drop as the interval size increases successively (recall that m can be as large as we want it to be). Successive numbers in the second row of table 1.1 are derived from the sequence $(\frac{10}{11})^1, (\frac{10}{11})^{10}, (\frac{10}{11})^{100}, \dots$

The problem is that under EU, the marginal utility drops off too rapidly. Consequently, and this is crucial to Rabin's results, for extremely large rewards, the marginal utility of the large reward

²⁹ The expected value of the lottery L_1 is $w + 0.5$ but the certainty equivalent is less than w , hence, the decision maker is risk averse.

relative to a relatively small loss becomes so miniscule that the lottery has little attraction for the decision maker, hence, accounting for the preferences shown in (1.41). Thus, if an EU decision maker is risk averse for small stake gambles (which is reasonable), then the same decision maker is absurdly risk averse for large stake gambles (which is unreasonable). By contrast, there is no puzzle under prospect theory (see Section 3.6).

Example 1.4 Let us now consider a concrete example to illustrate Rabin's paradox under EU.³⁰ If the utility function, u , is not bounded above, then, clearly, $u(\infty) = \infty$, hence, $\frac{1}{2}u(w + \infty) = \infty$. It follows that for any real numbers, w and x , i.e., for any finite level of wealth, w , and any finite loss, x ,

$$EU(L_2) = \frac{1}{2}u(w - x) + \frac{1}{2}u(w + \infty) = \infty > u(w).$$

Thus, any decision maker who follows EU will accept the gamble L_2 . Hence, the utility function must be bounded above. Consider the utility function

$$u(w) = 1 - e^{-w}, \quad (1.44)$$

Thus, $u'(w) > 0$ and $u''(w) < 0$. Under the utility function in (1.44), the preference $L_1 \prec L_0$ for any level of initial wealth, w , implies that

$$\frac{1}{2}(1 - e^{-(w-10)}) + \frac{1}{2}(1 - e^{-(w+11)}) < 1 - e^{-w} \Leftrightarrow 22026 > 1$$

Hence, assumption A1 holds for the utility function in (1.44). We now wish to show that for this utility function, it is also the case that $L_2 \prec L_1$, i.e., the decision maker turns down a lottery that offers infinite wealth with a probability of 0.5. The preference $L_2 \prec L_1$ for any level of initial wealth, w , implies that

$$\frac{1}{2}u(w - 100) + \frac{1}{2}u(w + \infty) < \frac{1}{2}u(w - 10) + \frac{1}{2}u(w + 11).$$

For the utility function in (1.44) we have

$$u(w + \infty) = 1 - e^{-(w+\infty)} = 1 \text{ and } u(w - 100) = 1 - e^{-(w-100)},$$

It follows that the preference $L_2 \prec L_1$ implies

$$\frac{1}{2}(1 - e^{-(w-100)}) + \frac{1}{2}(1 - e^{-(w+\infty)}) < \frac{1}{2}(1 - e^{-(w-10)}) + \frac{1}{2}(1 - e^{-(w+11)})$$

or $e^{100} > e^{10} + e^{-11}$, which is true. Hence, under Assumption A1, an EU decision maker exhibits the absurd preference $L_2 \prec L_1$ (Rabin's paradox).

1.5.5 Violations of description invariance

In the typical applications of EU, alternative methods of describing lotteries are assumed not to have any effect on choices. This is known as *description invariance* or the absence of *framing effects*. Description invariance is not required by the axioms of EU. Human behavior is state, time, and context dependent, irrespective of the decision theory that is used. However, as we shall see below, in Example 1.5, a particular violation of description invariance served as a building

³⁰ I am grateful to Ali al-Nowaihi for suggesting this example.

block of a non-EU theory, prospect theory, that we study in more detail below. This example also illustrates the relative risk attitudes of subjects when they perceive that they are in a gain situation as compared to a loss situation.

Example 1.5 (Tversky and Kahneman, 1981): *Imagine that the US is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows:*

Positive Framing: If program A is adopted, 200 people will be saved. If program B is adopted, there is a one-third probability that 600 people will be saved and a two-thirds probability that no people will be saved. Which of the two programs would you favor?

Negative Framing: If program C is adopted, 400 people will die. If program D is adopted, there is a one-third probability that nobody will die and a two-thirds probability that 600 people will die. Which of the two programs would you favor?

Under positive framing, the solution is framed in terms of lives saved (a gain situation). The result was that 72% of the subjects chose A, the safe program, and 28% chose the risky program B. For the case of negative framing, i.e., lives lost (a loss situation), 22% voted for C and 78% for D, the risky program. The options in each frame are identical. In each frame, two hundred lives are saved for sure in the first option (options A and C) and two hundred lives are expected to be saved in the second option (options B and D). While the aim of Kahneman and Tversky was to show that individuals are risk averse for gains and risk loving for losses, an issue of critical importance in prospect theory (see Chapter 2), the framing of the same question leads to completely different choices.

In this book, we shall review overwhelming evidence of framing effects, which shows that description invariance is not supported.³¹ Among the main decision theories, only prospect theory is able to handle framing effects by altering the *reference point*.

1.5.6 Preference reversals

The basic preference reversal problem is that under one elicitation method, lottery A is preferred to lottery B, while under another method, B is preferred to A; this result also holds for experienced players (Lichtenstein and Slovic, 1971).³² Consider two probabilities $p < P$, two outcomes $z < Z$, and the following pair of lotteries.

$$P\text{-bet} = (0, 1 - P; z, P), \quad \$\text{-bet} = (0, 1 - p; Z, p). \quad (1.45)$$

The names *P*-bet and *\$*-bet come from the fact that the first lottery has a higher probability of winning, while the second has a higher prize. The decision maker must make a choice between the two bets in two different tasks.

1. In the first task, decision makers directly choose between the *P*-bet and the *\$*-bet.
2. In the second task, decision makers are asked to assign certainty equivalents to the *P*-bet and the *\$*-bet, respectively, C_P and $C_\$$.

³¹ It is likely that future decision theories will take greater account of the choice heuristics used by decision makers. We consider some models of choice heuristics elsewhere in the book. Rubinstein's (1998) similarity relation is one example of a model that takes account of the procedural elements of choice.

³² For the literature circa late 1980s see Tversky and Thaler (1990).

The typical empirical finding in a large number of studies is that the P -bet is chosen over the $\$$ -bet in the first task and $C_P < C_\$$ in the second task (Lichtenstein and Slovic, 2006).³³ These findings of *preference reversals* contradict EU (or equivalently, the axioms of rationality).

The empirical findings from tasks 1 and 2 imply that: $\$ \text{-bet} \sim C_\$ > C_P \sim P \text{-bet} > \$ \text{-bet}$, which is a failure of transitivity. Theories that allow for violation of transitivity such as regret theory (Loomes and Sugden, 1982) can potentially explain these findings. Other attempts to explain preference reversals include abandoning the reduction principle (Segal, 1988), and abandoning the independence axiom (Holt, 1986; Karni and Safra, 1987). Tversky and Thaler (1990) argue that none of these attempts can fully account for preference reversals. Tversky et al. (1990) put the various explanations to the test and find that it is violations of *procedure invariance* that explain the finding of preference reversals. Gintis (2009, p. 238) expresses the view that the expected value of the lotteries used in preference reversal experiments is too close to permit firm conclusions to be drawn. Lichtenstein and Slovic (2006) offer a recent view on the subject.

If transitivity does not hold, then there can be no preference foundations for utility functions. For this reason, most economists may feel uneasy about abandoning transitivity. Insofar as intransitivity arises from changing the frame, context, or reference point, one may consider preferences over objects, conditional on a given frame, context, or reference point. Such conditional preferences would then be transitive. This idea is formally pursued in Sugden (2003). However, the resulting utility representation is linear in probabilities, as in subjective expected utility, hence, it would contradict the burgeoning evidence on non-linear probability weighting (Fehr-Duda and Epper, 2012).

We shall show later in Part 1 that preference reversals can also be explained using the *third generation of prospect theory* due to Schmidt et al. (2008). Preference reversals can also arise under *ambiguity* but they are of a different nature; see Trautmann et al. (2011).

1.5.7 *Is the reduction axiom supported by the evidence?*

Under EU, decision makers are able to reduce a compound lottery (where the outcomes themselves are lotteries) to a simple lottery of the form $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$ (see the *reduction axiom*, Axiom 1.5, above). However, empirical evidence is not supportive of the reduction axiom (Bernasconi and Loomes, 1992; Conlisk, 1989; Miao and Zhong, 2012). Harrison et al. (2012) find mixed support for the hypothesis. In simple one outcome choice problems there is support for the reduction axiom but in multichoice problems, the axiom does not hold.

Abdellaoui et al. (2014) find that the reduction axiom does not hold. They compute the certainty equivalent of compound lotteries, C_c , and the certainty equivalent of their associated reduced form lotteries, C_r . They term the difference between the two certainty equivalents, $C_r - C_c$, as the *compound risk premium*. If the difference is zero, the reduction axiom holds; if the difference is positive, the decision maker is *compound risk averse*; and if the difference is negative, the decision maker is *compound risk seeking*. They find that the difference is non-zero and most individuals are compound risk averse, i.e., they are more unwilling to play the compound lottery relative to the equivalent reduced lottery.

It also turns out that there are important links between the decision maker's attitudes to ambiguity aversion and the compound risk premium. Halevy (2007) found the presence of compound

³³ Also see Hershey and Schoemaker (1985) and Johnson and Schkade (1989).

risk premium as a necessary condition for non-neutral ambiguity attitudes. Indeed, he proposed that the failure of the reduction axiom is an important explanation of the Ellsberg paradox (see Chapter 4). Abdellaoui et al. (2014) find support for this view but their evidence suggests a weaker link between ambiguity aversion and compound risk premium. We postpone a discussion of models of ambiguity to Chapter 4.

CHAPTER 2

Behavioral Models of Decision Making

2.1 Introduction

Under expected utility theory (EU), decision makers weight probabilities linearly, and in each state of the world, they derive utility from the final level of wealth 1. In this chapter, we relax both these features of EU and consider the main behavioral decision theories under risk and uncertainty. Theories of ambiguity are considered in Chapter 4.

The theories considered in this chapter include behavioral decision theories such as *rank dependent utility* (RDU), *original prospect theory* (OPT), *cumulative prospect theory* (PT), and theories of *regret and disappointment aversion*. We also consider the more recent theories such as *third generation prospect theory*, *prospect theory with endogenous reference points*, and *composite prospect theory* (CPT). The behavioral decision theories explain the evidence much better than EU. The continued use of EU in large swathes of contemporary research in economics remains an enduring puzzle for most behavioral economists.

The linear weighting of probabilities under EU leads to many puzzles. For instance, Chapter 1 described the Allais paradox that is highly suggestive of *non-linear probability weighting*; evidence reviewed in this chapter gives further support to non-linear probability weighting. A *probability weighting function* reflects the mental representation of objective or subjective probabilities by a decision maker. It is central to almost all alternatives to EU. Section 2.2 introduces the basics, with particular emphasis on the *Prelec probability weighting function* (Prelec, 1998), although several other weighting functions are also outlined.

Empirical evidence shows heterogeneity in probability weighting functions for individual decision makers. One observes convex weighting, concave weighting, and *inverse S-shaped weighting* (Fehr-Duda and Epper, 2012). However, once we pool this information, at the aggregate level, the typical finding is that of an *inverse S-shaped* probability weighting, i.e., low probabilities are overweighted and high probabilities are underweighted. It turns out that one cannot simply replace probabilities under EU/SEU by probability weighting functions because this may lead to violation of first order stochastic dominance (Fishburn, 1978); we shall show this formally.

Section 2.3 introduces RDU under risk (Quiggin, 1982) and under uncertainty (Schmeidler, 1989). The idea under RDU is to replace the probabilities in an EU functional by *decision weights* that are *cumulative transformations of probabilities*. Decision makers who use RDU do not choose first order stochastically dominated options. RDU can explain several puzzles that EU cannot—the Allais paradox is a prominent example. Not surprisingly, preference foundations of RDU relax

the independence axiom in EU. One implication of inverse S-shaped probability weighting under RDU is that since low probabilities are overweighted, financial markets may price the skewness of asset returns; these issues are considered in more detail in Part 7 (Barberis, 2013).

Under EU, attitudes to risk, for instance, the degree of risk aversion, depend entirely on the shape of the utility function. However, under RDU, attitudes to risk depend *jointly* on the shapes of the probability weighting function and the utility function. This also holds for other behavioral decision theories that use non-linear probability weighting. For instance, under RDU, if the probability weighting function is convex throughout, then the decision maker can be shown to be *pessimistic* in the sense that he assigns relatively higher decision weights to lower outcome. A decision maker with a weighting function that is concave throughout, on the other hand, can be shown to be *optimistic* and places relatively higher decision weights on higher outcomes.

In what follows, we abbreviate the *original prospect theory* of Kahneman and Tversky (1979) by OPT and *cumulative prospect theory* of Tversky and Kahneman (1992) by PT. The main difference between these theories is the way that they account for non-linear probability weighting. Following convention, unless we wish to make a distinction between the two theories, we shall use the abbreviation PT for both theories.¹

Both EU and RDU assume that decision makers derive utility from *final levels* of variables of interest, such as wealth. These theories can account for utility that is derived from changes in outcomes relative to a *reference point*. However, since EU/SEU/RDU do not have insights about how behavior in the domain of gains and losses may differ, incorporating a reference point in these theories is not very illuminating.

In contrast, PT appeals to robust psychological evidence to argue that decision makers derive utility from *changes* in variables of interest relative to some *reference point*. While it is usually argued that the reference point under PT is exogenous, Kahneman and Tversky justified the status quo as a useful reference point. In other cases, a social norm of fairness, or a legal entitlement may serve as reference points. The reference point partitions the domain of outcomes into *gains* and *losses*. Furthermore, there are robust differences in behavior in gains and losses. For example, decision makers exhibit *loss aversion*: losses bite more than equivalent gains. Section 2.4 considers PT under risk when the reference point is a fixed, non-stochastic, entity. Section 2.4.1 shows that the extension of PT to uncertainty is straightforward.

The utility function of the decision maker under PT (unlike EU/SEU/RDU) is *concave in gains* and *convex in losses*. Thus, a central insight of PT, based on robust evidence, is that attitudes to risk are fundamentally different in the two domains. Section 2.4.2 shows that risk attitudes under PT are even richer than RDU, since they are jointly determined by the shapes of the utility function and the probability weighting function, and we distinguish between gains and losses. Under PT, one observes a *four fold pattern of attitudes to risk aversion* (Tversky and Kahneman, 1992). Although decision makers can choose stochastically dominated options under OPT they cannot do so under PT. The reason is that PT borrows its machinery on non-linear probability weighting from RDU in which decision makers never choose dominated options.

While PT is the most satisfactory and influential account of human behavior under risk and uncertainty (Wakker, 2010), it is work in progress. Section 2.4.4 considers some common criticisms of PT that are misplaced. In contrast, Section 2.9 considers more serious criticisms of PT that an even more complete theory of decision making may wish to address in due course.

¹ Daniel Kahneman won the Nobel prize for PT in 2003. Amos Tversky, who would almost surely have shared this prize, had sadly died by that time, and the Nobel prize cannot be conferred posthumously.

Section 2.5 considers the applied problem of eliciting the utility function and the probability weighting function under PT (Wakker and Deneffe, 1996; Bleichrodt and Pinto, 2000; Abdellaoui, 2000; Köbberling and Wakker, 2003; Abdellaoui et al., 2007). In this section, we also consider the various definitions of loss aversion, as well as a brief discussion of some of the parameter estimates under PT.

Section 2.6 considers the preference foundations of PT in three different subsections. Section 2.6.1 considers the preference foundations of PT based on the *trade-off consistency method* (Chateauneuf and Wakker, 1999; Köbberling and Wakker, 2003). The trade-off consistency method is one of the most profound and practical achievements in behavioral decision theory. This method is able to provide a unified account of the preference foundations of PT, RDU, and EU in terms of risk and uncertainty.² Next, we consider the preference foundations of the two most widely used components in applied PT: the *Prelec probability weighting function*, and the *power form of utility* that fits well the experimental data.

Section 2.6.2 considers the preference foundations of the Prelec function (al-Nowaihi and Dhami, 2006). Section 2.6.3 considers the preference foundations of the power form of utility (al-Nowaihi et al., 2008). In particular, we show that under the axiom of *preference homogeneity*, not only does the utility function take the power form, but it also implies loss aversion, identical powers of utility in the domain of gains and losses, and identical probability weighting functions in the domain of gains and losses.

A decision maker's endowment may be stochastic. For instance, houses, consumer durables, financial assets, and other personal belongings may suffer a loss in value with some probability, arising on account of, say, changes in market value, theft, accidents, and other natural hazards. Thus, expectations of the loss may influence one's reference point. We now consider two ways in which stochastic reference points have been incorporated into PT.

The first proposal, in Section 2.7, considers *third generation prospect theory*, PT³ (Schmidt et al., 2008). *Reference dependent expected utility* (Sugden, 2003) is a special case of this model. PT³ proposes a representation of preferences over *Savage acts*.³ The representation is similar to PT, except that the utility function is now defined over outcomes and a *stochastic reference point*. This framework can explain disparities between *willingness to pay* (WTP) and *willingness to accept* (WTA), sometimes also known as the *endowment effect* (see Chapter 3). It can also explain *preference reversals*.

The second proposal, in Section 2.8, considers the Köszegi–Rabin framework for *endogenous stochastic reference points* (Köszegi and Rabin, 2006, 2007, 2009). They distinguish between three equilibrium concepts—the two main concepts differ in the timing of actual decisions, prior to the resolution of uncertainty. Conditional on a stochastic reference point, the decision maker makes ex-ante choices for future states of the world, which, in equilibrium, are confirmed to be optimal, ex-post. The initial choices then become self-fulfilling; this is the sense in which reference points are endogenous.

We consider several illustrative examples of this framework to convey the insights of the two main equilibrium concepts. In particular, in Section 2.8.1 we consider the newsvendor problem (Herweg, 2013) and in Section 2.8.2, the backward bending labour supply curve. In Section 2.8.3, we consider the empirical evidence, which is consistent with the predictions of the Köszegi–Rabin framework (Abeler et al. 2011; Ericson and Fuster, 2011). On the one hand, the Köszegi–Rabin

² Our discussion is necessarily condensed. For a more detailed account, see the masterful treatment by one of the leaders in this area, Wakker (2010).

³ Given a set of uncertain events that form a partition of the sample space, a Savage act specifies the outcome (possibly monetary) for the decision maker, for each uncertain event.

framework appeals to those who were uneasy with the traditional justifications for a reference point in PT (e.g., status quo, social norms, and other legal or social entitlements). However, on the other hand, this framework has extremely high cognitive requirements, which sit uneasily with the main thrust of behavioral models. The authors are fully aware of these difficulties, and are at pains to highlight them, but no practical alternatives to the rational expectations requirement that could be used in applied work have been proposed. Whatever the merits of these arguments, empirical evidence must be the final arbiter. Future research must consider even more stringent tests of the framework; this is likely to be an area of continued importance.

Section 2.9 considers some limitations of PT. In Section 2.9.1, we consider the critique based on several papers by Michael Birnbaum and associates; for a summary, see Birnbaum (2008). These experiments consider the implications of splitting outcomes or probabilities that, under PT, are not predicted to alter the choice between lotteries. Yet, empirically, this is found to be violated. However, this evidence appears to reject most decision theory models. The associated theoretical alternatives suggested by this literature that go under the name of *configural weights models* are considered in a later section, however, these are not without problems either.

Section 2.9.2 considers an implication of PT, *gain-loss separability* (Wu and Markle, 2008). Suppose that we split two mixed lotteries,⁴ A and B , into their respective gain and loss components. If the decision maker prefers each of the components of A over the corresponding components of B , then, under PT, he should also prefer A to B . Yet this is found to be violated. However, these results need to be replicated with a wider range of probabilities and payoffs to judge not just how general they are, but also to discover the mechanisms at work.

Section 2.9.3 considers the *stake size effect*, that cannot be accounted for by any theory that separates utilities from probabilities.⁵ The stake size effect refers to the observed change in relative risk aversion as the stake size in the domain of gains goes up. In an important advance, it has been shown that the stake size effect arises not from the utility function but from the probability weighting function (Fehr-Duda et al., 2010). This suggests that the development of theories that are non-separable in probabilities and outcomes might be a fruitful area of research in the future.

Most non-stochastic decision theories of choice typically predict an unambiguous choice of one lottery over another. However, the typical experimental finding is a dispersion of choices across subjects for pairs of lotteries. One possible resolution is to introduce arbitrary noise or errors into the choices of subjects. Although not uncommon in empirical work, this is neither intellectually satisfying, nor well founded unless one has good reasons for preferring one noise structure to another. A second resolution, is to allow for the possibility that different individuals may follow different decision theories. This has led to the exploration of heterogeneity in preferences using a *mixture model approach* (Bruhin et al., 2010; Fehr-Duda et al., 2010; Conte et al., 2011). The main empirical finding is the presence of *preference heterogeneity*. For instance, in three separate datasets, Bruhin et al. (2010) find the respective shares of EU and RDU/PT preferences to be 20% and 80%. By contrast, the shares of SEU types are much higher in the absence of a mixture model approach that relies instead on noisy choices (Hey, 2014).

Section 2.10 considers a range of other behavioral theories of decision making. These theories offer additional insights into decision making that we have not considered so far. Section 2.10.1 considers *regret theory* (Bell, 1982; Loomes and Sugden, 1982; Fishburn, 1982a). The idea is that in any state of the world, the decision maker derives utility not only from his own choice but also from the forgone outcomes from other choices that were not made. Regret theory allows for the

⁴ Mixed lotteries contain outcomes in the domain of gains and losses.

⁵ These theories include EU, RDU, OPT, PT with fixed and stochastic reference points, PT³, CPT, and disappointment aversion.

violation of transitivity. One can also explain the Allais paradox using regret theory. However, the evidence is not always consistent with the pattern of intransitivity predicted by the theory (Starmer, 2000).

Section 2.10.2 considers the *theory of disappointment aversion* (Gul, 1991). This is a theory of endogenous reference points because the decision maker treats the certainty equivalent of the lottery under consideration as his reference point. All outcomes in the lottery that are less than the certainty equivalent are coded as loss outcomes, and all outcomes that are greater than the certainty equivalent are coded as gain outcomes. Non-linear probability weights are then used to form decision weights. However, the construction of decision weights is different from RDU and PT. The resulting model may, however, be observationally similar to RDU (Fehr-Duda and Epper, 2012).

Section 2.10.3 considers the role of *salience* and *context* in making choices among risky alternatives (Bordalo et al., 2012). In this case, the decision maker compares pairwise outcomes in each choice and assigns salience to the outcomes, using a salience function that depends on the relative and the absolute sizes of the outcomes. The outcomes are then ranked by salience and decision weights assigned to the outcomes. More salient outcomes receive higher decision weights. This theory can explain the Allais paradox, preference reversals and context dependent preferences.

In Section 2.10.4, we consider *case-based decision theory* (Gilboa and Schmeidler, 1995, 1996, 1997, 2001). The model is based on an extremely plausible idea. Namely, that in deciding on our current actions, we first identify the environment, or situation. Next, we look at past actions taken in various environments and compare the current environment–action pairs to all environment–action pairs in the past using a *similarity function*. Such a comparison may suggest the optimal action that we must take today. Under certain conditions, the long–run behavior of this process converges to one that would be chosen by an expected utility maximizer. However, the evidence strongly indicates that expected utility is refuted (see Chapter 1). A drawback of case-based decision theory is that it does not allow one to construct hypothetical cases. Indeed, it would seem that since no environment is likely to be an exact replica of another, one’s ability to construct hypothetical cases (perhaps also based on past environment–action pairs) are critical in constructing an even better theory. However, some emerging evidence is consistent with the theory (Pape and Kurtz, 2013; Bleichrodt et al., 2013).

Section 2.10.5 considers *configural weights models* that can explain the evidence that we outline in Section 2.9.1 (Birnbbaum, 2008). We consider a range of models in this class. These include the *rank affected multiplicative weights model*, the *transfer of attention in exchange model*, and the *gains decomposition utility model*. Unlike most other behavioral models that we consider, there are no preference foundations for these models. Further, the construction of decision weights in these models are likely to appear arbitrary to many economists. Perhaps for this reason, this class of models has not yet gained prominence in economics.

Section 2.11 considers the extremely important, but often neglected issue of the behavior of decision makers towards *events of very low probability*. In a range of situations, one observes that a fraction of decision makers ignore events of very low probability, which can lead to serious consequences for the decision maker.⁶ Examples, with well-documented empirical support include the following (al-Nowaihi and Dhami, 2010a). Reluctance to buy insurance against low probability natural hazards; running red traffic lights; driving and talking on mobile phones; and not wearing non-mandatory seat belts. Existing theories cannot explain human behavior in these cases. EU certainly cannot explain it but the problem is even worse when one uses a typical

⁶ Peter Wakker (personal communication) points out that Buffon (1777, p. 72) argued that all probabilities less than .0001 be treated as “morally” equal to zero.

probability weighting function (such as the Prelec function) in any of the non-EU theories such as RDU and PT. The reason is that the typical probability weighting function is too steep near the origin, so, such probabilities should be tremendously salient, rather than be ignored.

In other words EU and most non-EU theories (except OPT) predict that nobody should run red traffic lights, or refrain from wearing seat belts in vehicles, or drive and talk on mobile phones simultaneously, or refrain from buying insurance against even the most unlikely natural hazard. In Section 2.11.1, we argue that Kahneman and Tversky (1979) were well aware of these issues in OPT. In the *editing phase* in OPT, a fraction of the decision makers simply omit very low probability events from the lotteries that they are presented with. In the next step, the *evaluation phase*, decision makers choose among alternatives that have been edited in the first phase.

Our main explanation of human behavior for low probability events is based on *composite prospect theory* (CPT) (al-Nowaihi and Dhami, 2010a). In CPT, a fraction of the decision makers use a standard, inverse S-shaped, probability weighting function, e.g., the Prelec function. However, the remaining fraction use the *composite Prelec function* (CPF), which is an axiomatically founded modification of the Prelec function. Decision makers who use CPF, significantly underweight very low probability events (unlike the Prelec function). Although CPT can explain human behavior in all the above mentioned puzzles of human behavior for very low probability events, it awaits empirical testing.

The outcomes of most human decisions are *uncertain* and take *time* to materialize. Yet, it is usual practice to treat *risk preferences* and *time preferences* separately. An emerging literature makes a strong case to integrate the two. Section 2.12 considers the relation between risk and time preferences. We also give a complementary discussion of this topic in Part 4 of the book.

The usual method of integrating risk and time preferences is to offer decision makers a sequence of dated payoffs, but future payoffs materialize with a probability less than one. In Section 2.12.1, we use this method, and first consider evidence which suggests that neither EU, nor any of the mainstream behavioral alternatives can explain the experimental choices (Andreoni and Sprenger, 2012b). However, it is crucial to specify how one reduces lotteries that have a time dimension. Using a plausible method of reduction, the portfolio method, one can explain the experimental findings in Andreoni and Sprenger (2012b) if the decision maker follows RDU (Epper and Fehr-Duda, 2014a).

Section 2.12.2 introduces the concept of *intertemporal risk aversion*. Section 2.12.3 lays out the agenda for future research for the study of the interaction between risk and time preferences (Epper and Fehr-Duda, 2014b). Some features of this agenda are as follows. Decision makers appear more risk tolerant for events in the more distant future. The decision making process, for instance, whether dated lotteries are reduced in one go or sequentially reduced, influences choices. The timing of the resolution of uncertainty matters too. The extent of discounting depends on the degree of riskiness of lotteries. Finally, behavior differs whether lotteries are reduced first in the time dimension or the risk dimension. Suppose that an observer observes the choices of a decision maker when outcomes are delayed, and when the probability that they will materialize, falls over time. Sections 2.12.4 and 2.12.5 consider the resulting effects on the observed probability weighting function in terms of factors such as its elevation, subproportionality, and elasticity (Epper and Fehr-Duda, 2014b).

2.2 Probability weighting functions

Under EU, decision makers weight probabilities linearly (see Remark 1.1). In contrast, empirical evidence suggests non-linear weighting of probabilities. There is fairly widespread agreement

in the empirical literature on the shape of the non-linear weighting for probabilities that are bounded away from the end points of the interval $[0, 1]$. However, there are unresolved issues about the precise shape of non-linear weighting close to the end points of the probability interval $[0, 1]$, an issue that only the more recent literature has focused on. To separate these issues, and based on the empirical evidence, it is useful to consider the following two hypotheses, H1 and H2. Most behavioral decision theory proceeds under the assumption of H1. However, a more nuanced picture is given in H2.

H1: Decision makers overweight small probabilities and underweight large probabilities, no matter how small or how large they are.⁷

H2: There are two kinds of decision makers:

(H2a) A fraction $\mu \in [0, 1]$ of decision makers (i) ignore events of extremely low probability and, (ii) treat extremely high probability events as certain.⁸ For all other (non-extreme) probabilities they behave as in H1, i.e., they overweight small probabilities and underweight large ones.

(H2b) A fraction $1 - \mu$ of the decision makers behave as in H1 for all levels of probabilities.

Classical non-EU theories largely subscribe to H1 (or assume that $\mu = 0$ in hypothesis H2). In contrast, hypothesis H2 has been largely ignored despite a compelling case for it in Kahneman and Tversky's (1979) original prospect theory, and in the *bimodal perception of risks* model (Viscusi, 1998). We follow the chronological order of developments so, for the moment, we focus only on H1. In Section 2.11, we examine the evidence for H2 and outline al-Nowaihi and Dhami's (2010a) *composite prospect theory* (CPT) that is able to account for H2.

Recall that we have already conjectured that the Allais paradox can be resolved under non-linear probability weighting. As a compelling illustration of the importance of non-linear probability weighting, consider the following example from Kahneman and Tversky (1979 p. 283). Suppose that one is compelled to play Russian roulette using a revolver that can potentially fire six rounds, but all rounds are not loaded.⁹ One would be willing to pay much more to reduce the number of bullets from one to zero (elimination of risk) than from four to three (reduction, but not elimination of risk). However, in each case, the reduction in the probability of a bullet firing is $1/6$ and, so, under EU, the decision maker should be willing to pay the same amount. This suggests non-linear weighting of probabilities.

For any lottery L , let $E(L)$ be the expected value of the lottery and let C_L be the certainty equivalent. Then, we can define the *relative risk premium* as

$$RRP = \frac{E(L) - C_L}{|E(L)|}. \quad (2.1)$$

⁷ For the evidence see Kahneman and Tversky (2000), Starmer (2000), and Appendix A in Wakker (2001). For the necessary and sufficient conditions required for inverse S-shaped probability weighting functions, see Tversky and Wakker (1995). There is also emerging evidence of the neuro-biological foundations for such behavior (Berns et al., 2008); see Part 9 for a more detailed discussion.

⁸ In the context of the take-up of insurance for low probability natural hazards, the results from one set of experiments by Kunreuther et al. (1978) are consistent with $\mu = 0.8$.

⁹ Readers may remember the game of Russian roulette from the 1978 film, *The Deer Hunter*. In this potentially lethal game, fewer than 6 rounds in a revolver are loaded, the cylinder is spun, and the player places the muzzle against his/her head, and pulls the trigger.

Figure 2.1 Relative risk premium for the Student and the Representative population.

Source: Reproduced with permission of *Annual Review of Economics*, Volume 4, Helga Fehr-Duda and Thomas Epper, "Probability and risk: foundations and economic implications of probability-dependent risk preferences," © 2012 by Annual Reviews <http://www.annualreviews.org>

There are three possibilities: Risk aversion corresponds to $RRP > 0$, risk neutrality to $RRP = 0$, and risk seeking/loving to $RRP < 0$. Fehr-Duda and Epper (2012) compute the RRP for a student population recruited from two major Swiss Universities in 2006, and a representative population of Swiss German-speaking adults. Lotteries of the form $(x_1, 1 - p; x_2, p)$ are used, where $0 \leq x_1 < x_2$. The results are shown in Figure 2.1; relative risk premium, RRP , is plotted on the vertical axis and the probability of the highest outcome, p , is plotted on the horizontal axis. Clearly, the RRP is probability dependent. Thus, risk preferences of the decision maker depend on probabilities. This is inconsistent with EU because under EU, risk preferences arise solely through the shape of the utility function.

Definition 2.19 (*Probability weighting function*): By a probability weighting function, we mean a strictly increasing function $w : [0, 1] \xrightarrow{\text{onto}} [0, 1]$.

To fix ideas, readers may, for the moment, consider $w(p)$ as the subjective weight placed by decision makers on the objective probability, p (these ideas carry over to non-negative subjective probabilities that sum up to 1). The proof of the next proposition is left as an exercise.

Proposition 2.8 A probability weighting function has the following properties:

(a) $w(0) = 0$, $w(1) = 1$. (b) w has a unique inverse, w^{-1} , and w^{-1} is also a strictly increasing function from $[0, 1]$ onto $[0, 1]$. (c) w and w^{-1} are continuous.

In order to distinguish between the hypotheses H1 and H2, we will need to look at the behavior of alternative probability weighting functions for probabilities close to the endpoints of $[0, 1]$. In particular, we need to speak meaningfully about the steepness of the probability weighting function around $p = 0$ and $p = 1$. The next two definitions introduce the relevant concepts.

Figure 2.2 Non-parametrically estimated probability weighting functions for the Student and Representative population based on aggregate data.

Source: Reproduced with permission of *Annual Review of Economics*, Volume 4, Helga Fehr-Duda and Thomas Epper, "Probability and risk: foundations and economic implications of probability-dependent risk preferences," © 2012 by Annual Reviews <http://www.annualreviews.org>

Definition 2.20 (al-Nowaihi and Dhami, 2010a): A probability weighting function, $w(p)$, (i) infinitely overweights infinitesimal probabilities, if for $\gamma > 0$, $\lim_{p \rightarrow 0} \frac{w(p)}{p^\gamma} = \infty$, and (ii) infinitely underweights near-one probabilities if $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = \infty$.¹⁰

Definition 2.21 (al-Nowaihi and Dhami, 2010a): A probability weighting function, $w(p)$, (i) zero-underweights infinitesimal probabilities, if for $\gamma > 0$, $\lim_{p \rightarrow 0} \frac{w(p)}{p^\gamma} = 0$, and (ii) zero-overweights near-one probabilities in the sense that $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = 0$.

For aggregate data (and for non-extreme probabilities), the data typically suggests an *inverse S-shaped probability weighting function*. Figure 2.2 shows the estimated probability weighting function using non-parametric estimates corresponding to the data in Figure 2.1.

2.2.1 Prelec's probability weighting function

A large number of probability weighting functions have been proposed in the literature. The most popular of these functions is the Prelec (1998) function. The Prelec function is parsimonious, tractable, and has axiomatic foundations. Depending on parameter values, we will see that it is either consistent with H1 or the special case of H2 with $\mu = 1$. We now turn to a detailed

¹⁰ In particular, for $\gamma = 1$, Definition 2.20(i) implies that $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$.

examination of the Prelec weighting function, reminding readers that the comments we make here apply to most probability weighting functions (the so-called *standard weighting functions*, which we define, below).¹¹ Furthermore, an understanding of the Prelec function will be critical to appreciating the recent developments that take account of hypothesis H2; see Section 2.11.3.

Definition 2.22 (Prelec, 1998): By the *Prelec function*, we mean the probability weighting function $w(p) : [0, 1] \rightarrow [0, 1]$ given by

$$w(0) = 0, w(1) = 1, \quad (2.2)$$

$$w(p) = e^{-\beta(-\ln p)^\alpha}, 0 < p \leq 1, \alpha > 0, \beta > 0. \quad (2.3)$$

Sometimes the special case of $\beta = 1$ is known as *Prelec-I* and the case of $\beta \neq 1$ is known as *Prelec-II* to distinguish between the one-parameter and the two-parameter family of distributions.

The Prelec function only requires that $\alpha > 0, \beta > 0$. In order to distinguish between H1 and H2, it is critical whether α is smaller or larger than 1. For this reason, we make a distinction between the *Prelec function* and the *standard Prelec function*; Prelec (1998) prefers the latter for reasons we give below.

Definition 2.23 (Standard Prelec function): By the *standard Prelec probability weighting function*, we mean the Prelec function, defined in (2.2) and (2.3), but with $0 < \alpha < 1$.

Remark 2.2 For $\alpha = \beta = 1$ we get $w(p) = p$ as in EU. Since an infinite number of α, β values are possible and just one pair of values coincides with the special case of EU, it would be quite remarkable if human behavior could be represented by just that one pair of values. Indeed, the evidence clearly rules out this possibility. It is even more remarkable that many economists still stubbornly wish to cling on to EU.

A simple proof that is omitted gives rise to the following result.

Proposition 2.9 The Prelec function (Definition 2.22) satisfies the properties listed in Proposition 2.8.

The roles of α, β in the Prelec weighting function are highlighted next.

1. (Role of α) The parameter α controls the convexity/concavity of the Prelec function. If $\alpha < 1$, then the Prelec function is strictly concave for low probabilities but strictly convex for high probabilities. In this case, it is *inverse S-shaped*, as in the curve $w(p) = e^{-(-\ln p)^{0.5}}$ (i.e., $\alpha = 0.5, \beta = 1$), which is sketched as the *thick curve* in Figure 2.3. The converse holds if $\alpha > 1$, in which case the Prelec function is *S-shaped*. An example is the curve $w(p) = e^{-(-\ln p)^2}$ ($\alpha = 2, \beta = 1$), sketched in Figure 2.3 as the *light curve*. The straight line in Figure 2.3 is the 45° line $w(p) = p$ ($\alpha = \beta = 1$) corresponding to the case of EU.
2. (Role of β) Between the region of strict convexity ($w'' > 0$) and the region of strict concavity ($w'' < 0$), there is a point of inflexion ($w'' = 0$). The parameter β controls the location of the inflexion point, relative to the 45° line. Thus, for $\beta = 1$, the point of inflexion is at $p = e^{-1}$ and lies on the 45° line, as in Figure 2.3. However, if $\beta < 1$, then the point of inflexion lies above the 45° line, as in the curve $w(p) = e^{-0.5(-\ln p)^2}$ ($\alpha = 2, \beta = 0.5$).

¹¹ The interested reader can also consult al-Nowaihi and Dhami (2011) for more details.

Figure 2.3 Plots of $w(p) = e^{-(\ln p)^{0.5}}$ and $w(p) = e^{-(\ln p)^2}$.

For this example, the fixed point, $w(p^*) = p^*$, is at $p^* \simeq 0.14$ but the point of inflexion, $w''(\tilde{p}) = 0$, is at $\tilde{p} \simeq 0.20$.

Some useful results about the Prelec function are given next. The reader is asked to prove them in the exercises.

Proposition 2.10 For $\alpha = 1$, the Prelec probability weighting function (Definition 2.22) takes the form $w(p) = p^\beta$, is strictly concave if $\beta < 1$, but strictly convex if $\beta > 1$. In particular, for $\alpha = \beta = 1$, $w(p) = p$ (as under EU).

Proposition 2.11 (al-Nowaihi and Dhami, 2010a): Suppose that $\alpha \neq 1$. Then, the Prelec function has the following properties.

- (a) It has exactly three fixed points: 0, $p^* = e^{-\left(\frac{1}{\beta}\right)^{\frac{1}{\alpha-1}}}$, and 1. For $\beta = 1$, $p^* = e^{-1}$.
- (b) It has a unique inflexion point, $\tilde{p} \in (0, 1)$ at which $w''(\tilde{p}) = 0$.
- (c) If $\alpha < 1$, it is strictly concave for $p < \tilde{p}$ and strictly convex for $p > \tilde{p}$ (inverse S-shaped).
- (d) If $\alpha > 1$, it is strictly convex for $p < \tilde{p}$ and strictly concave for $p > \tilde{p}$ (S-shaped).
- (e) The inflexion point, $\tilde{p}$, lies above, on, or below, the 45° line, respectively, if β is less than, equal to, or greater than one.

Table 2.1, graphs the Prelec function $w(p) = e^{-\beta(-\ln p)^\alpha}$, for various values of α, β .

Corollary 2.1

- (i) Suppose that $\alpha \neq 1$. Then $\tilde{p} = p^* = e^{-1}$ (i.e., the point of inflexion, $\tilde{p}$, and the fixed point, p^* , coincide) if, and only if, $\beta = 1$.
- (ii) If $\beta = 1$, then:
 - (a) If $\alpha < 1$, then w is strictly concave for $p < e^{-1}$ and strictly convex for $p > e^{-1}$ (inverse S-shape; see the thick curve in Figure 2.3).
 - (b) If $\alpha > 1$, then w is strictly convex for $p < e^{-1}$ and strictly concave for $p > e^{-1}$ (S-shape; see the light curve in Figure 2.3).

For the thick curve in Figure 2.3 (and first row in Table 2.1), where $\alpha < 1$, the slope of $w(p)$ becomes very steep near $p = 0$. By contrast, for the thin curve in Figure 2.3 (and last row in Table 2.1), where $\alpha > 1$, the slope of $w(p)$ becomes shallow near $p = 0$; in this case low

Table 2.1 Representative graphs of the Prelec function.

	$\beta = \frac{1}{2}$	$\beta = 1$	$\beta = 2$
$\alpha = \frac{1}{2}$	 $w(p) = e^{-\frac{1}{2}(-\ln p)^{\frac{1}{2}}}$	 $w(p) = e^{-(-\ln p)^{\frac{1}{2}}}$	 $w(p) = e^{-2(-\ln p)^{\frac{1}{2}}}$
$\alpha = 1$	 $w(p) = p^{\frac{1}{2}}$	 $w(p) = p$	 $w(p) = p^2$
$\alpha = 2$	 $w(p) = e^{-\frac{1}{2}(-\ln p)^2}$	 $w(p) = e^{-(-\ln p)^2}$	 $w(p) = e^{-2(-\ln p)^2}$

Source: al-Nowaihi and Dhami (2011).

probabilities are underweighted. We now tie these observations with the notion of steepness of a probability weighting function at extreme probabilities (Definitions 2.20, 2.21).

Proposition 2.12

- (a) For $\alpha < 1$ and $\gamma > 0$, the Prelec (1998) function: (i) infinitely overweights infinitesimal probabilities, i.e., $\lim_{p \rightarrow 0} \frac{w(p)}{p^\gamma} = \infty$, and (ii) infinitely underweights near-one probabilities, i.e., $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = \infty$.
- (b) For $\alpha > 1$ and $\gamma > 0$, the Prelec function: (i) zero-underweights infinitesimal probabilities, i.e., $\lim_{p \rightarrow 0} \frac{w(p)}{p^\gamma} = 0$, and (ii) zero-overweights near-one probabilities, i.e., $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = 0$.

We have made a distinction between the *Prelec function* ($\alpha > 0$) and the *standard Prelec function* ($0 < \alpha < 1$). Prelec (1998) himself favors the case $0 < \alpha < 1$, and it is this case which is standard in non-EU theories such as rank dependent utility and prospect theory. According to Prelec (1998, p. 505), for the case $\gamma = 1$, the infinite limit in Proposition 2.12(a) captures the qualitative change as we move from impossibility to improbability. On the other hand, this contradicts hypothesis H2a, i.e., the observed behavior that many people simply ignore events of very low probability. These problems are avoided for $\alpha > 1$. However, for $\alpha > 1$, the Prelec function is S-shaped, see Proposition 2.11(d) and Figure 2.3, which conflicts with hypotheses H1

and H2b. This suggests that we need a richer account of decision making under risk for events when near-zero and near-one probabilities are involved; *composite prospect theory*, outlined in Section 2.11.3, is one attempt to give such an account.

When aggregate data is taken into account, most weighting functions appear to be inverse S-shaped. However, there is substantial heterogeneity at the individual level with the two most common shapes being convex and inverse S-shape.¹² Fehr-Duda and Epper (2012) give estimates of the Prelec function for two different populations—a student population and a representative population (see description, above). For the student population, $\alpha = 0.513$ and $\beta = 0.958$, and for the representative population, $\alpha = 0.423$ and $\beta = 0.868$.

Definition 2.24 (*Subproportionality and certainty effect*): A feature of most probability weighting functions, at least over a range $[\hat{p}, 1]$, $\hat{p} \geq 0$, is subproportionality, i.e.,

$$\frac{w(p)}{w(q)} > \frac{w(\lambda p)}{w(\lambda q)}, 0 < \lambda < 1, \hat{p} \leq q < p \leq 1. \quad (2.4)$$

If $\hat{p} = 0$ and $0 < q$, then w is subproportional over the entire probability range. The certainty effect arises when $p = 1$. In this case, we have

$$w(\lambda q) > w(\lambda)w(q).$$

Probability weighting functions that have the feature of subproportionality, can typically explain the common ratio effect. In addition, inverse S-shaped probability weighting functions that cut the diagonal from above can explain the common consequence effect and the simultaneous existence of insurance and gambling.¹³

There are other probability weighting functions also; we now briefly consider the main ones.

OTHER PROBABILITY WEIGHTING FUNCTIONS

1. The Tversky and Kahneman (1992) probability weighting function is

$$w(p) = \frac{p^\tau}{[p^\tau + (1-p)^\tau]^{\frac{1}{\tau}}}, 0.279 < \tau < 1. \quad (2.5)$$

This probability weighting function is not subproportional for small values of p , hence, it cannot account for the common ratio effect for small probabilities. A smaller value of τ induces a more pronounced departure from linearity. One potential drawback of this function is that the point of intersection with the diagonal is not independent of the curvature parameter, τ (recall that this problem does not arise with the Prelec function).

2. Karmakar (1979) proposed the following weighting function

$$w(p) = \frac{p^\tau}{p^\tau + (1-p)^\tau}, 0 < \tau < 1. \quad (2.6)$$

This function is not subproportional for low values of p but it intersects the diagonal at $p = 0.5$, which is independent of τ (unlike the Tversky–Kahneman function).

¹² See, for instance, Stott (2006), Gonzalez and Wu (1999), van de Kuilen and Wakker (2011), Fehr-Duda and Epper (2012).

¹³ Friedman and Savage (1948) proposed a utility function with concave and convex segments to explain the simultaneous occurrence of insurance and gambling but this does not explain why risk preferences of individuals are sensitive to probabilities at fairly different levels of payoffs.

3. The Goldstein and Einhorn (1987) linear-in-log-odds probability weighting function is given by

$$w(p) = \frac{\delta p^\eta}{\delta p^\eta + (1-p)^\eta}, p \in [0, 1], \delta \geq 0, \eta \geq 0. \quad (2.7)$$

In this specification, η is responsible for the curvature and a smaller value of η induces a more pronounced departure from the EU case, $w(p) = p$. The parameter δ controls elevation; an increase in δ increases the elevation of the weighting function. The standard EU case corresponds to $\delta = \eta = 1$.

Fehr-Duda and Epper (2012) argue that the one parameter weighting functions do not fit the data as well as the two-parameter family of functions. Gonzalez and Wu (1999) show that the Prelec function in (2.3) and the Goldstein–Einhorn function in (2.7) fit the data equally well.

2.2.2 Stochastic dominance under non-linear probability weighting

If hypotheses H1 and H2 are important, then it may seem natural to replace the linear weighting under EU with non-linear weighting. However, the next example shows that this is not straightforward.

Example 2.6 (Simple non-linear probability weighting): One alternative to EU is the decision weighted form of utility in which we define:

$$W(x_1, p_1; \dots; x_n, p_n) = \sum_{i=1}^n w(p_i) u(x_i), \quad (2.8)$$

where $w(p_i)$ is the probability weight of outcome x_i . Early attempts at formulating these kinds of utility functions include Edwards (1954, 1962) and Handa (1977). One problem with this utility function is that the choices generated by it might be stochastically dominated. This is shown in Example 2.7 (Fishburn, 1978).

Example 2.7 (Problems with non-linear weighting of probabilities): Consider the lottery $L = (x, p; y, 1-p)$, $0 < p < 1$. Let $w : [0, 1] \rightarrow [0, 1]$ be a probability weighting function. Let u be a utility function for sure outcomes and let $\tilde{U}$ be the utility function in (2.8). By definition,

$$\tilde{U}(L) = w(p) u(x) + w(1-p) u(y).$$

Let preferences induced by $\tilde{U}$ be denoted by $\prec_{\tilde{U}}$

- (a) For the special case, $x = y$, we get $\tilde{U} = [w(p) + w(1-p)] u(x)$. In general, for non-EU theories, $w(p) + w(1-p) \neq 1$. For probabilities bounded away from the end points of the interval $[0, 1]$, we typically have $w(p) + w(1-p) < 1$.¹⁴ Hence, $(x, p; x, 1-p) \prec_{\tilde{U}} (x, 1)$. But any “sensible” theory of risk should give $(x, p; x, 1-p) \sim_{\tilde{U}} (x; 1)$.
- (b) Take $y = x + \epsilon$, $\epsilon > 0$. Then, first order stochastic dominance for discrete outcomes (Definition 2.9) implies that $(x, 1) \prec_1 (x, p; x + \epsilon, 1-p)$. Now, $\tilde{U}(x, p; x + \epsilon, 1-p) = w(p) u(x) + w(1-p) u(x + \epsilon)$. Assuming u is continuous and $w(p) + w(1-p) < 1$, we get

¹⁴ For instance, for the Prelec probability weighting function, and for values of the parameters $\alpha = 0.5$ and $\beta = 1$ the statement $w(p) + w(1-p) < 1$ is true for all probabilities in the range $[0.03, 0.97]$.

$$\begin{aligned}\lim_{\epsilon \rightarrow 0} \tilde{U}(x, p; x + \epsilon, 1 - p) &= w(p) u(x) + w(1 - p) u(x) \\ &= [w(p) + w(1 - p)] u(x) < \tilde{U}(x).\end{aligned}$$

Hence, for sufficiently small $\epsilon > 0$, $\tilde{U}(x, p; x + \epsilon, 1 - p) < \tilde{U}(x)$. Thus, we have that $(x, 1) \prec_1 (x, p; x + \epsilon, 1 - p)$ but $\tilde{U}(x, p; x + \epsilon, 1 - p) < \tilde{U}(x, 1)$. Hence, first order stochastic dominance is violated. We discuss the approaches taken to deal with this problem in various non-EU theories, below.

2.3 Rank dependent utility theory (RDU)

To summarize the story so far, that is relevant for this section: Hypothesis H1, above, highlighted the tendency for decision makers to overweight small probabilities and underweight large probabilities. EU is unable to take account of H1 because it weights probabilities in a linear manner. Example 2.7 captures the early attempts to introduce non-linear weighting, by transformation of *point probabilities*. However, decision makers could choose stochastically dominated options in these theories, which was not attractive.

Rank dependent utility theory (RDU), relying on the work of Quiggin (1982, 1993), proposed the first satisfactory solution to the problem of non-linear probability weighting. Unlike Example 2.7, Quiggin suggested transformation of *cumulative probabilities*. EU and RDU are otherwise similar, except for cumulatively transformed probabilities. This was a major advance over EU, because it could resolve several paradoxes of EU, e.g., the Allais paradox. Further, decision makers who use RDU do not choose stochastically dominated options.

We now introduce *decision weights* that play a key role in most non-EU theories.

Definition 2.25 (*Decision weights*): Consider the lottery $(x_1, p_1; x_2, p_2; \dots; x_n, p_n)$, where $x_1 < x_2 < \dots < x_n$.¹⁵ Let w be the probability weighting function. For RDU, the decision weights, π_i , are defined as follows.

$$\begin{aligned}\pi_n &= w(p_n), \\ \pi_{n-1} &= w(p_{n-1} + p_n) - w(p_n), \\ &\dots \\ \pi_i &= w\left(\sum_{j=i}^n p_j\right) - w\left(\sum_{j=i+1}^n p_j\right), \\ &\dots \\ \pi_1 &= w\left(\sum_{j=1}^n p_j\right) - w\left(\sum_{j=2}^n p_j\right) = w(1) - w\left(\sum_{j=2}^n p_j\right) = 1 - w\left(\sum_{j=2}^n p_j\right).\end{aligned}$$

From Definition 2.25, we get that,

$$\pi_j \geq 0 \text{ and } \sum_{j=1}^n \pi_j = 1. \quad (2.9)$$

The logic and intuition for decision weights in Definition 2.25 is made clear later in this section.

Definition 2.26 Consider the lottery $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$, where $x_1 < x_2 < \dots < x_n$. Let w be the probability weighting function. Let π_i , $i = 1, 2, \dots, n$, be given by Definition 2.25. The decision maker's rank dependent utility from L , is given by

¹⁵ If any outcomes in the original lottery are equal, we sum up the associated probabilities and write lotteries in this format. For instance, the lottery $L = (4, 0.3; 4, 0.4; 6, 0.3)$ is equivalent to the lottery $(4, 0.7; 6, 0.3)$. If all outcomes are equal then $n = 1$.

$$RDU(L) = \sum_{i=1}^n \pi_i u(x_i). \quad (2.10)$$

From (2.10), an implication of models of RDU is that two outcomes that differ in rank but have the same probability will typically have different decision weights assigned to them.

2.3.1 Attitudes to risk under RDU

Under EU, attitudes to risk are captured by the shape of the utility function. For instance, a concave utility function implies and is implied by risk aversion. Typically, for psychologists, and many economists, the notion that risk is captured by the shape of the utility function alone, does not seem a palatable one. Indeed, it seems natural to associate the notion of riskiness also with probabilities. An important implication of RDU is that the utility function and the decision maker's perception of objective probabilities jointly determine attitudes to risk.¹⁶

Example 2.8 Suppose that a decision maker is offered the lottery $L = (0, 1 - p; 1, p)$, $0 < p < 1$, so the expected value is $EL = p$. Suppose that the decision maker follows RDU, the weighting function is convex, say, $w(p) = p^2$, and the utility function is linear, i.e., $u(x) = x$. Under EU, such a decision maker is risk neutral. Using Definition 2.26, under RDU, $RDU(L) = w(p) = p^2$. Since, $u(x) = x$, the certainty equivalent of the lottery under RDU, C_L , equals p^2 . Risk aversion requires that the certainty equivalent of a lottery is lower than the expected value of the lottery for all lotteries, hence,

$$C_L < EL \Leftrightarrow p^2 < p \Leftrightarrow p < 1,$$

which is true. In other words, the finding of risk aversion can equally well be explained by a linear utility function and a convex probability weighting function. In this example, the decision maker would be risk loving if $w(p) = \sqrt{p}$, which illustrates the importance of the probability weighting function in determining risk attitudes under RDU.

The discussion, below, shows that decision weights in Definition 2.25 have a simple, intuitive, explanation.

Example 2.9 (Curvature of weighting function and optimism, pessimism): The curvature of w is also sometimes interpreted in terms of the optimism or pessimism of the decision maker; these terms have no natural analogue in EU. To see this, assume that w is convex throughout. Suppose that we have the balanced risk lottery $L = (x_1, 0.5; x_2, 0.5)$; $x_1 < x_2$. Using Definition 2.26, under RDU

$$RDU(L) = u(x_1) [1 - w(0.5)] + u(x_2) w(0.5). \quad (2.11)$$

Since $w(0) = 0$, $w(1) = 1$ (see Definition 2.19) and w is assumed to be convex throughout, so $w(0.5) < 0.5$. Thus, in (2.11), the weight on $u(x_1)$ is higher than the weight on $u(x_2)$ despite identical objective probabilities. In other words, the decision maker is pessimistic in placing a higher weight on the lower outcome. The converse (optimism) would apply if w were concave throughout; in this case, the decision maker puts a higher decision weight on the higher outcome, despite both outcomes being equiprobable.

¹⁶ See Chateaufneuf and Cohen (1994) for an early theoretical demonstration of this idea.

Figure 2.4 An illustration of optimism and pessimism as the shape of the probability weighting function varies.

Let us delve a bit further into the relation between decision weights and probability weights. Consider the lottery $(30, 1/3; 60, 1/3; 90, 1/3)$. Using Definition 2.25, the decision weights corresponding to the three outcomes are

$$\pi(30) = 1 - w(2/3); \pi(60) = w(2/3) - w(1/3); \pi(90) = w(1/3). \quad (2.12)$$

Figure 2.4 plots a convex weighting function (LHS panel) and a concave weighting function (RHS panel). The magnitudes of the decision weights corresponding to each of the three outcomes, as calculated in (2.12), are marked on the vertical axis. For the convex case, the magnitudes of the decision weights decrease as the outcome increases, $\pi(90) < \pi(60) < \pi(30)$; this reflects *pessimism*. If such a weighting function is combined with a concave utility function, it enhances risk aversion. The converse happens when the weighting function is concave. Here larger outcomes are given greater decision weights, $\pi(90) > \pi(60) > \pi(30)$; this reflects *optimism*. Combined with a concave utility function, optimism reduces risk aversion.

Example 2.10 (*Elevation of probability weighting function and optimism*): Consider a decrease in the elevation of the probability weighting function, e.g., an increase in β in the Prelec function (Definition 2.22). This change is associated with a lower degree of optimism. To see this, consider the lottery $L = (x_1, 1 - p; x_2, p)$, $x_1 < x_2$. The rank dependent utility of this lottery is given by

$$RDU(L) = w(p) [u(x_2) - u(x_1)] + u(x_1).$$

Following a decrease in elevation, $w(p)$ decreases, which reduces RDU by reducing the decision weight that the decision maker puts on the higher outcome. A similar insight holds under prospect theory if all outcomes are in the domain of gains.

What is the shape of decision weights when there are several outcomes and we have an inverse S-shaped probability weighting function? Following simulations reported in Fehr-Duda and Epper (2012), the typical shape is shown in Figure 2.5. We have 21 ranked outcomes with a uniform probability distribution over them, plotted for two weighting functions—the Prelec-II function

Figure 2.5 Shapes of decision weights when there are multiple outcomes under RDU. Panel (a) shows the Prelec-II function and Panel (b) shows the Goldstein–Einhorn function. + denotes the uniform objective probability distribution. ● denotes the case $\alpha = \eta = 0.2$, $\beta = \delta = 1$. ▲ denotes the case $\alpha = \eta = 0.9$, $\beta = \delta = 1$. ■ denotes the case $\alpha = \eta = 0.2$, $\beta = \delta = 0.3$.

and the Goldstein–Einhorn function (see Definition 2.22 and (2.7)); recall that $0 < \alpha < 1$ gives the inverse S-shape under the Prelec function, and a similar role is played by the parameter η in the Goldstein–Einhorn function. Extreme outcomes are accorded extreme decision weights, while the intermediate outcomes are accorded relatively flat weights. This enhances the salience of extreme outcomes, a feature that explains several puzzles in finance (see Section 3.9).

Remark 2.3 Several axiomatizations of RDU allow for additive separability between terms that multiply utility with probability weights, e.g., Abdellaoui (2002) and Wakker (1994). In order to ensure concavity or convexity of the weighting function, these contributions introduce additional global auxiliary conditions such as probabilistic risk aversion. See in particular, Wakker (2001) who allows for a preference axiomatization of convex capacities. This allows for a weighting function that is either concave or convex throughout. Diecidue et al. (2009) introduce local conditions that allow for probabilistic risk aversion to vary over the probability interval $[0, 1]$. For one set of parameter values, they can address hypothesis H1, while for the complementary set of parameter values, they can address hypothesis H2a. However, their proposal was not designed with a view to simultaneously addressing H1 and H2.

A decision maker who follows RDU never chooses stochastically dominated lotteries. We state here the formal result without proof.¹⁷ Let $x_1 < x_2 < \dots < x_n$ be a set of outcomes. Consider two lotteries, L_p, L_q , corresponding to two different distribution functions P, Q over the outcomes,

$$L_p = (x_1, p_1; x_2, p_2; \dots; x_n, p_n), \quad L_q = (x_1, q_1; x_2, q_2; \dots; x_n, q_n).$$

¹⁷ Formal proofs are surprisingly hard to find. The formal results below draw on unpublished joint research conducted by Ali al-Nowaihi and Sanjit Dhami.

Suppose that the decision weights (Definition 2.25) for the lotteries L_p, L_q are denoted respectively by π_{p_i} and π_{q_i} , $i = 1, 2, \dots, n$.

Let W be the set of probability weighting functions, i.e.,

$$W = \{w : [0, 1] \rightarrow [0, 1], w(0) = 0, w(1) = 1, w \text{ is non-decreasing}\}. \quad (2.13)$$

Definition 2.27 Under RDU, the lottery, L_p , is preferred to another lottery, L_q , written $L_q \preceq_{RDU} L_p$, if and only if

$$\sum_{i=1}^n \pi_{q_i} u(x_i) \leq \sum_{i=1}^n \pi_{p_i} u(x_i), \text{ for all } u \in \mathbf{u} \text{ and for all } w \in W,$$

where $\mathbf{u}$ is the class of all non-decreasing utility functions. If, in addition, the inequality is strict for some $u \in \mathbf{u}$, then we say that L_p is strictly preferred to L_q under RDU. This is written as $L_q \prec_{RDU} L_p$.

Definition 2.28 We define first order stochastic dominance under RDU, $\preceq_1^{RDU}$, as follows.

$$Q \preceq_1^{RDU} P \Leftrightarrow \text{for all } u \in \mathbf{u} \text{ and all } w \in W, L_q \preceq_{RDU} L_p. \quad (2.14)$$

Proposition 2.13 (a) $Q \preceq_1^{RDU} P \Leftrightarrow P_i \leq Q_i$, for all $i = 1, 2, \dots, n$.

(b) $Q \preceq_1^{RDU} P \Leftrightarrow Q \preceq_1^{EU} P$, where $\preceq_1^{EU}$ is the analogue of the first order stochastic dominance relation in Definition 2.28 when the decision maker follows expected utility.

2.3.2 RDU under uncertainty

Recall our discussion of subjective expected utility (SEU) under uncertainty in Section 1.3. We now consider RDU under uncertainty. Consider the Savage act (see Section 1.3 for the definition),

$$f = (E_1, x_1; E_2, x_2; \dots; E_n, x_n),$$

where $\cup_{i=1}^n E_i = S$, the sample space. Suppose also that the outcomes are ordered as $x_1 < x_2 < \dots < x_n$. We briefly describe how Schmeidler (1989) formulated a more general rank dependent theory to deal with uncertainty (and not just risk, which was Quiggin's (1982) contribution).

Definition 2.29 A subjective probability weighting function (or event weighting function), $\tilde{w} : E \rightarrow \mathbb{R}$ where $E \subseteq S$; $\tilde{w}$ has the following properties:

- (1) $\tilde{w}(\emptyset) = 0$, where $\emptyset$ is the empty set.
- (2) If $E_i \subset E_j$, then $\tilde{w}(E_i) \leq \tilde{w}(E_j)$.
- (3) $\tilde{w}(S) = 1$.

$\tilde{w}$ need not be additive, i.e., for mutually exclusive sets E_i, E_j , $\tilde{w}(E_i \cup E_j)$ need not equal $\tilde{w}(E_i) + \tilde{w}(E_j)$.

The objective function for rank dependent utility under uncertainty is defined as:

$$U(f) = \sum_{j=1}^n \pi_j u(x_j).$$

The decision weights under uncertainty, π_j , are defined as follows:

$$\pi_j = \tilde{w}(E_j \cup E_{j+1} \cup \dots \cup E_n) - \tilde{w}(E_{j+1} \cup E_{j+2} \cup \dots \cup E_n).$$

RDU under risk is a special case of Schmeidler's (1989) framework when the probability of event E_j equals its objective probability and probabilistic sophistication (Definition 2.13) holds.

The Ellsberg paradox (see Chapter 4) can be explained under RDU if one relaxes the assumption of probabilistic sophistication. The assumption of probabilistic sophistication allows us to write

$$\tilde{w}(E) = w(p(E)), \quad (2.15)$$

where w is the probability weighting function under risk and $p(E)$ denotes the objective probability of event E . The non-linearity of $\tilde{w}$ can now be seen immediately. Let E_i, E_j be mutually exclusive events, then, under probabilistic sophistication:

$$\begin{aligned} \tilde{w}(E_i \cup E_j) &= w(p(E_i \cup E_j)) \\ &= w(p_i + p_j) \\ &\neq w(p_i) + w(p_j) = \tilde{w}(E_i) + \tilde{w}(E_j). \end{aligned}$$

The first line is true by definition, the second follows because E_i and E_j are mutually exclusive events and the third because w is non-linear. In the discussion of RDU under risk, we showed how various shapes of the probability weighting function, w , can denote optimism or pessimism. Similar notions hold for the event weighting function, $\tilde{w}$. For instance, pessimism can be shown to be equivalent to the inequality $\tilde{w}(E_i \cup E_j) \geq \tilde{w}(E_i) + \tilde{w}(E_j)$ (see exercise 10.4.2 in Wakker, 2010).

The most interesting aspect of the formulation of rank dependent utility under uncertainty, aside from its generality, is that the empirical evidence on the shape of w carries over to the shape of $\tilde{w}$. Indeed, the inverse S-shape is even more vivid under $\tilde{w}$. We omit a discussion of the empirical findings. The interested reader can consult Hogarth and Kunreuther (1989), Kilka and Weber (2001), and Abdellaoui et al. (2005).

2.3.3 Drawbacks of RDU

RDU offers a distinct improvement over EU. Since EU is a special case of RDU when $w(p) = p$, RDU explains everything that EU does but the converse is false. RDU is able to explain the Allais paradoxes. An exercise asks you to do the relevant calculations. However, RDU cannot explain all the facts, as the next example shows.

Example 2.11 (A refutation of both EU and RDU): Consider Problems 11 and 12 from Kahneman and Tversky (1979).

Problem 11. In addition to whatever you own (x_0), you have been given 1000. You are now asked to choose between

$$A = (x_0 + 1000, 0.5; x_0 + 2000, 0.5) \text{ and } B = (x_0 + 1000, 0; x_0 + 1500, 1).$$

A is chosen by 16%, while B is chosen by 84%. Using Definition 2.26, under RDU, the evidence, thus, suggests that for most subjects,

$$w(0.5)u(x_0 + 2000) + [1 - w(0.5)]u(x_0 + 1000) < u(x_0 + 1500). \quad (2.16)$$

Problem 12: In addition to whatever you own (x_0), you have been given 2000. You are now asked to choose between

$$C = (x_0 + 1000, 0.5; x_0 + 2000, 0.5) \text{ and } D = (x_0 + 1500, 1; x_0 + 2000, 0)$$

C is chosen by 69% of the subjects, while *D* is chosen by 31%. Using Definition 2.26, under RDU, the empirical evidence indicates that for most subjects,

$$w(0.5)u(x_0 + 2000) + [1 - w(0.5)]u(x_0 + 1000) > u(x_0 + 1500). \quad (2.17)$$

Clearly, (2.16) contradicts (2.17), violating RDU. The main reason for this violation is that RDU does not take account of shifts in the “reference point” of the decision maker, when the endowment changes from $x_0 + 1000$ to $x_0 + 2000$. We shall see below in Example 2.14 that prospect theory, which takes account of such changes in reference points, can account for this puzzle.

RDU is unable to explain many important phenomena, whose explanation rests on features that are central to prospect theory such as *loss aversion* and *reference dependence*. Examples include explanations of the equity premium puzzle, tax evasion puzzles, disposition effect, backward bending labor supply curve, endowment effect, asymmetric price elasticities, and exchange asymmetries. These stylized facts are amenable to explanation based on prospect theory.

2.4 Prospect theory (PT)

Remark 1.1, above, listed the two main features of EU: linearity in probabilities and utility that does not differ in the domain of gains and losses. RDU relaxed the first feature by introducing non-linear probability weighting. Prospect theory goes a step further and relaxes both features of EU. There are two main versions of prospect theory.¹⁸ *Original prospect theory* (OPT) is due to Kahneman and Tversky (1979) and *cumulative prospect theory*, or simply *prospect theory* (PT) is due to Tversky and Kahneman (1992).¹⁹ Our focus here will be on PT. Section 2.11.1, below, gives a brief treatment of OPT.

Under PT (and OPT), the carriers of utility are not final levels of wealth, but deviations of actual wealth levels from a *reference point*, an idea that is well established in psychology. Evidence indicates that when exposed to external stimuli, such as temperature, brightness, and pain, individuals are more sensitive to *changes* rather than *levels* (Helson, 1964). In order to fix ideas on reference dependence, consider the following well-known experiment: Put your right hand in cold water and your left hand in warm water until both hands have had time to adjust to the temperature. Then, simultaneously take out both hands and dip them in lukewarm water. Although both hands experience the identical lukewarm temperature, the right hand feels warm and the left hand feels cold.

Strictly speaking, the view that the reference point is exogenous under PT needs to be qualified. Kahneman and Tversky were fully aware that the *status-quo* turns out to be a useful reference point in many applications. Other possible choices could be an *expected outcome*, a *fair outcome*, or a *legal entitlement*; clearly the context dictates the appropriate reference point. The reference point could also be state-dependent wealth, average wealth, desired wealth, or it could even be

¹⁸ See also *third generation prospect theory* in Section 2.7, and *composite prospect theory* in Section 2.11.3.

¹⁹ Starmer and Sugden (1989b) also introduced non-linear probability weights in a prospect theory framework. Although this is rarely mentioned, Tversky and Kahneman (1992) also extend prospect theory to ambiguity, using the framework suggested by Schmeidler (1989).

made endogenous by using the rational expectations of future wealth (see Section 2.8). For a discussion, see Kahneman and Tversky (2000), Köszegi and Rabin (2006), and Schmidt et al. (2008). Abeler et al. (2011) find that expectations of income serve as reference points and determine effort provision. Falk and Knell (2004) show how individuals might attempt to endogenize their reference points with a view to taking account of self-improvement and self-enhancement.

If the outcome turns out to be better (respectively worse) as compared to the reference point, then the decision maker is said to be in the *domain of gains* (respectively *losses*). Experimental and field evidence suggests that utility is evaluated differently in the domain of gains and losses. For instance, Example 1.5, due to Tversky and Kahneman (1981), demonstrated that decision makers are risk averse in the domain of gains and risk loving in the domain of losses. Using Australian data, Page et al. (2012) showed that following a natural disaster (floods), individuals who suffer a loss of at least 50% of their property values are more likely to accept risky gambles.

Extensive evidence, that we review below, also indicates that losses bite more than equivalent gains. This phenomenon, known as *loss aversion*, accounts for a large number of puzzles that could not be explained using EU and RDU. Finally, under PT (but not under OPT), decision makers transform probabilities non-linearly, in a manner similar to RDU, to produce decision weights. The difference from RDU is that, under PT, these transformations are applied separately in the domain of gains and losses.

We now give a more formal treatment of PT.²⁰ To take account of reference dependence, we first define lotteries in *incremental form*.

Definition 2.30 (*Lotteries in incremental form or prospects*) We say that a lottery is presented in incremental form if it is represented as:

$$L = (y_1, p_1; y_2, p_2; \dots; y_n, p_n), \quad (2.18)$$

where

$$y_i = x_i - x_0, \quad i = 1, 2, \dots, n, \quad (2.19)$$

is the increment (positive, negative, or zero) in wealth relative to reference wealth, x_0 . The reference wealth may be fixed at some given level, e.g., when wealth is simply the status-quo level, or it may be stochastic, as in the models described below in Sections 2.7 and 2.8. Lotteries represented in the incremental form are sometimes also known as “prospects.”

In PT, the *utility function* is termed as a *value function*. However, we speak of utility under PT in the normal sense that readers would understand the term in EU and RDU, and reserve the term value function for the objective function under PT.

Definition 2.31 (*Utility function under PT; Tversky and Kahneman, 1979*). Let $Y \subset \mathbb{R}$ be the set of wealth levels relative to a reference point, as in (2.19). A utility function, v , is a mapping $v : Y \rightarrow \mathbb{R}$ that satisfies the following:

1. v is continuous.
2. v is strictly increasing.
3. $v(0) = 0$ (reference dependence).
4. v is concave for $y \geq 0$ (declining sensitivity for gains).

²⁰ A feature of the ideas in OPT/PT is that they may appear self-evident. For an interesting account of the application of these ideas to Greek mythology, see Orwin (1994) and Ober (2012).

5. v is convex for $y \leq 0$ (declining sensitivity for losses).
6. $-v(-y) > v(y)$ for $y > 0$ (loss aversion).²¹

There are several alternative concepts of loss aversion in PT; these are discussed in Section 2.5.2. Tversky and Kahneman (1992) propose the following power form of the utility function.²²

$$v(y) = \begin{cases} y^\gamma & \text{if } y \geq 0 \\ -\lambda(-y)^\gamma & \text{if } y < 0 \end{cases}, \quad (2.20)$$

where γ and λ are constants such that $0 < \gamma < 1$, and $\lambda > 1$ is known as the *coefficient of loss aversion*. One may also impose separate powers in the domain of gains and losses, respectively, γ^+ and γ^- . Tversky and Kahneman (1992) estimated that $\gamma^+ \simeq \gamma^- = \gamma = 0.88$ and $\lambda \simeq 2.25$.

The properties in Definition 2.31, are illustrated in Figure 2.6, which is a plot of (2.20) for $\lambda = 2.5$, $\gamma = 0.5$.

Suppose that we have a total of $m + 1 + n$ outcomes such that there are m distinct outcomes in the domain of losses, n distinct outcomes in the domain of gains, and there is 1 reference outcome. Consider the following lottery in incremental form (Definition 2.30) that represents these outcomes and the associated probabilities

$$L = (y_{-m}, p_{-m}; y_{-m+1}, p_{-m+1}; \dots; y_{-1}, p_{-1}; y_0, p_0; y_1, p_1; y_2, p_2; \dots; y_n, p_n), \quad (2.21)$$

where y_i is defined in (2.19). The restriction on probabilities is given by

$$\sum_{i=-m}^n p_i = 1, p_i \geq 0, i = -m, -m+1, \dots, n. \quad (2.22)$$

Figure 2.6 The utility function under prospect theory.

²¹ Notice that this formulation makes sense because of properties 2 and 3 of the utility function.

²² For the axiomatic foundations of this utility function, see Section 2.6 below.

It is pedagogically more convenient to refer to the y_i values as “outcomes” rather than using the more cumbersome but accurate expression “outcomes relative to the reference point.” We shall follow this convention, below. The restriction on outcomes is given by

$$y_{-m} < y_{-m+1} < \dots < y_{-1} < y_0 = 0 < y_1 < y_2 < \dots < y_n, \quad (2.23)$$

where $y_0 = 0$ is the *reference outcome* (the reference point is x_0). Thus, in PT, outcomes are ordered from worst (y_{-m}) to best (y_n).

Definition 2.32 (*Set of lotteries*): Denote by $\mathcal{L}_P$, the set of all lotteries of the form given in (2.21), subject to the restrictions (2.22), (2.23).

In order to compute the decision weights for gains under PT, we apply the usual RDU calculations, as in Definition 2.25, starting at the positive extreme and using a probability weighting function, w^+ , for the domain of gains. However, for losses, we start at the negative extreme, and use a probability weighting function, w^- , for the domain of losses.

Remark 2.4 Abdellaoui (2000) and Abdellaoui et al. (2005) find that there is no significant difference in the curvature of the weighting function for gains and losses. For the Prelec function (see Definition 2.22), we know that the parameter α controls the curvature. However, the elevation (which in the Prelec function is controlled by the parameter β) can be different in the domain of gains and losses.

Definition 2.33 (Tversky and Kahneman, 1992). For PT, the decision weights, π_i , are defined as follows:

$$\begin{aligned} \pi_n &= w^+(p_n) \\ \pi_{n-1} &= w^+(p_{n-1} + p_n) - w^+(p_n) \dots \\ \pi_i &= w^+\left(\sum_{j=i}^n p_j\right) - w^+\left(\sum_{j=i+1}^n p_j\right) \dots \\ \pi_1 &= w^+\left(\sum_{j=1}^n p_j\right) - w^+\left(\sum_{j=2}^n p_j\right) \\ \pi_{-m} &= w^-(p_{-m}) \\ \pi_{-m+1} &= w^-(p_{-m} + p_{-m+1}) - w^-(p_{-m}) \dots \\ \pi_{-j} &= w^-\left(\sum_{i=-m}^{-j} p_i\right) - w^-\left(\sum_{i=-m}^{-j-1} p_i\right) \dots \\ \pi_{-1} &= w^-\left(\sum_{i=-m}^{-1} p_i\right) - w^-\left(\sum_{i=-m}^{-2} p_i\right) \end{aligned}$$

We now define the objective function of a decision maker who follows PT. This objective function is called the *value function*.

Definition 2.34 (*The value function*; Starmer and Sugden, 1989a; Tversky and Kahneman, 1992): The value of the lottery $L \in \mathcal{L}_P$ to the decision maker is given by

$$V(L) = \sum_{i=-m}^n \pi_i v(y_i). \quad (2.24)$$

Recall that under RDU, there is no notion of the domain of gains and losses, and the decision weights add up to one (see (2.9)). However, under PT this result may no longer hold. This is stated in the next proposition, which the reader is asked to prove.

Proposition 2.14 Under PT, if all outcomes are in the domain of gains or in the domain of losses, then the decision weights add up to one, otherwise they do not.

In most examples in this section, the Prelec (1998) probability weighting function will be used because it appears to be the one with the strongest empirical support. To quote from Stott (2006, p. 102): “the most predictive version of [cumulative prospect theory] has a power value curve, a single parameter risky weighting function due to Prelec (1998) and a Logit stochastic process.” Under PT, w^+ and w^- are allowed to differ, however, we will typically make the simplifying assumption that $w^+ = w^- = w$; see Prelec (1998).

2.4.1 A brief note on PT under uncertainty

PT can be easily extended to uncertainty along the lines described in Section 2.3.2, so we shall be brief. The main difference is that we need to work with lotteries in incremental form. Consider the following Savage act

$$L = (E_{-m}, y_{-m}; \dots; E_{-1}, y_{-1}; E_0, y_0; E_1, y_1; \dots; E_n, y_n), \quad (2.25)$$

where (2.23) holds, $y_0 = 0$ is the outcome relative to the reference point, and $E_{-m}, \dots, E_0, \dots, E_n$ are $m+n$ disjoint events whose union forms the sample space. Denote by $\bar{\mathcal{L}}_P$ the set of all lotteries of the form given in (2.25). Denote the event weighting function (Definition 2.29) for gains by $\tilde{w}^+$ and that for losses by $\tilde{w}^-$.

Definition 2.35 For PT under uncertainty, the decision weights, π_i , are defined as follows:

$$\begin{aligned} \pi_n &= \tilde{w}^+(E_n) \\ \pi_{n-1} &= \tilde{w}^+(E_{n-1} \cup E_n) - \tilde{w}^+(E_n) \dots \\ \pi_i &= \tilde{w}^+\left(\bigcup_{j=i}^n E_j\right) - \tilde{w}^+\left(\bigcup_{j=i+1}^n E_j\right) \dots \\ \pi_1 &= \tilde{w}^+\left(\bigcup_{j=1}^n E_j\right) - \tilde{w}^+\left(\bigcup_{j=2}^n E_j\right) \\ \pi_{-m} &= \tilde{w}^-(E_{-m}) \\ \pi_{-m+1} &= \tilde{w}^-(E_{-m} \cup E_{-m+1}) - \tilde{w}^-(E_{-m}) \dots \\ \pi_j &= \tilde{w}^-\left(\bigcup_{i=-m}^j E_i\right) - \tilde{w}^-\left(\bigcup_{i=-m}^{j-1} E_i\right) \dots \\ \pi_{-1} &= \tilde{w}^-\left(\bigcup_{i=-m}^{-1} E_i\right) - \tilde{w}^-\left(\bigcup_{i=-m}^{-2} E_i\right) \end{aligned}$$

As in the case under risk, since $v(y_0) = v(0) = 0$, the decision weight corresponding to the reference outcome, π_0 , can be chosen arbitrarily.

The objective function of the decision maker who uses PT under uncertainty is defined next.

Definition 2.36 (The value function): The value of the lottery $L \in \bar{\mathcal{L}}_P$ to the decision maker is given by

$$V(L) = \sum_{i=-m}^n \pi_i v(y_i). \quad (2.26)$$

2.4.2 Attitudes to risk under prospect theory

Under EU, $w(p) = p$, so the attitudes to risk are completely determined by the shape of the utility function. Under PT (and OPT), the utility function is concave in the domain of gains and convex in the domain of losses. From this, it might be tempting to conclude that a decision maker who uses PT is risk averse in the domain of gains and risk loving in the domain of losses. Such an inference would be incorrect. The reason is that in PT (and in most non-EU theories), attitudes

to risk are determined not only by the shape of the utility function but also by the shape of the probability weighting function, $w(p)$.

Example 2.12 Suppose that a decision maker who uses PT faces the lottery $L = (0, 1 - p; y, p)$ in incremental form, where $y > 0$. Using Definition 2.31, $v(0) = 0$. Let the utility function be given by $v(y) = \sqrt{y}$ and let the weighting function be the Prelec function, $w(p) = e^{-\beta(-\ln p)^\alpha}$, with $\alpha = 0.5$, $\beta = 1$. Using Definition 2.34,

$$V(L) = [1 - w(p)]\sqrt{0} + w(p)\sqrt{y} = w(p)\sqrt{y}.$$

The expected value of the lottery is $EL = py$. The certainty equivalent of the lottery, C_L , can be calculated as follows:

$$\begin{aligned} w(p)\sqrt{y} &= \sqrt{C_L}, \\ \Rightarrow C_L &= yw(p)^2. \end{aligned}$$

The decision maker is risk loving if $C_L > EL$ and risk averse if $C_L < EL$.

$$C_L \gtrless EL \Leftrightarrow yw(p)^2 \gtrless py \Leftrightarrow w(p)^2 \gtrless p. \quad (2.27)$$

For the special case of EU, $w(p) = p$. Since $p \in [0, 1]$, for EU, $w(p)^2 \leq p$ and so $C_L \leq E$. Thus, assuming a concave utility function under EU (in this case, $v(y) = \sqrt{y}$) is sufficient to guarantee risk aversion. However, for PT and for the Prelec function, $w(p)^2 > p$ for low p and $w(p)^2 < p$ for high p . In particular, for the parameter values chosen in this example,

$$w(p)^2 \gtrless p \Leftrightarrow -2(-\ln p)^{0.5} - \ln p \gtrless 0.$$

Thus, for $p^* = 0.0183$, $w(p^*)^2 = p^*$, for $p < 0.0183$, $w(p)^2 > p$ (i.e., the decision maker is risk loving despite a concave utility function), and for $p > 0.0183$, $w(p)^2 < p$ (i.e., the decision maker is risk averse).

The result in Example 2.12 is more general, and stated in the next remark.

Remark 2.5 Under PT, the decision maker has a strictly concave utility function in the domain of gains (see Definition 2.31). Nevertheless, for small probabilities in the domain of gains, the decision maker is risk loving, while for higher probabilities, the decision maker is risk averse.

We leave it to the reader to construct an analogous example in the domain of losses to illustrate the following more general remark.

Table 2.2 The fourfold classification of risk attitudes under prospect theory.

Probability	Domain of gains	Domain of losses
Low	$(100, 0.05; 0, 0.95)$	$(-100, 0.05; 0, 0.95)$
	$C = 14, E = 5$	$C = -8, E = -5$
High	$(100, 0.95; 0, 0.05)$	$(-100, 0.95; 0, 0.05)$
	$C = 78, E = 95$	$C = -84, E = -95$

Remark 2.6 *Despite having a convex utility function (see Definition 2.31) in the domain of losses, the decision maker is risk averse for low probabilities and risk loving for higher probabilities.*

The next example presents some experimental evidence supporting Remarks 2.5, 2.6. Put together, these remarks leads to a *fourfold classification of risk attitudes* under PT, which is one of the salient contributions of PT.

Example 2.13 *(The fourfold pattern of attitudes to risk; Tversky and Kahneman, 1992): Let C , E denote the certainty equivalent and the expected value, respectively of an associated lottery.*

Table 2.2 shows values of C , E for lotteries of the form $(x, p; 0, 1 - p)$, i.e., win $x > 0$ with probability p or 0 with probability $1 - p$ for low and high p in the domain of gains and losses. Comparing the values of C and E , we see that for low probabilities, there is risk seeking in the domain of gains but risk aversion in the domain of losses. For moderate or high probabilities, we see risk aversion in the domain of gains but risk seeking in the domain of losses. This pattern is hard to explain under EU or RDU, but is easily explained by PT. Thus, the attitudes to risk in PT are much richer than under EU or RDU.

In subsequent studies the fourfold pattern of risk has been tested using two kinds of methods. The first method is a *choice-based elicitation procedure* in which subjects are directly asked to choose between the lottery and its expected value. A risk averse decision maker should prefer the expected value to the lottery and a risk seeking decision maker should prefer to play the lottery. The second method is a *price based elicitation procedure* in which subjects are asked to state their maximum willingness to pay for the lottery if all outcomes are in gains and maximum willingness to pay to avoid playing the lottery if all outcomes are in the domain of losses. Harbaugh et al. (2002) and Harbaugh et al. (2010) use this method for a particularly simple class of lotteries of the form $L = (x, p)$. They find evidence for the fourfold classification of risk in the price based elicitation procedure but not in the choice-based task, where subjects appear to be risk neutral.

Fehr-Duda and Epper (2012) raise the following three objections about the findings in Harbaugh et al. (2010) that are more widely applicable.

1. They are skeptical about the findings of approximate risk neutrality in the choice-based tasks. They argue (p. 583) that these findings are not surprising: “Because it is so obvious that expected value equals outcome times probability, people may interpret the experiment as a test of their intelligence or numeracy rather than as a preference elicitation task.” For instance, an experimental subject, when asked for a choice between the lottery $(50, 0.10)$ and the expected value of the lottery, 5, may choose indifference between the two options.
2. A second issue they raise about the findings from lotteries of the form $L = (x, p)$ is that one cannot separately disentangle the parameters of the probability weighting function and the utility function, unless specific functional forms are used. They conclude (p. 583) with a cautionary note for experimental economists: “Therefore, we strongly recommend using multi-outcome prospects, with more than one nonzero outcome, over a wide range of probabilities to be able to generate a sufficiently rich database.”
3. Finally, the lotteries used in Harbaugh et al. (2010) deal with probabilities in the set $\{0.1, 0.4, 0.8\}$. We know from our discussion in Section 1.5 that violations of EU are more pronounced along the boundaries of the probability triangle. Indeed, in the interior of a probability triangle for, say, RDU, the indifference curves appear approximately linear. Figure 2.7 illustrates the situation for a three outcome lottery—the horizontal axis shows

Figure 2.7 Indifference curves under RDU over the full range of probabilities (left panel) and with the boundaries truncated (right panel).

Source: Reproduced with Permission of *Annual Review of Economics*, Volume 4, Helga Fehr-duda and Thomas Epper, “Probability and risk: foundations and economics implications of Probability-appendent risk preferences,” © 2012 by Annual Reviews <http://www.annualreviews.org>

the probability, p_3 , of the worst outcome and the vertical axis, the probability, p_1 , of the best outcome.²³ The indifference curves in the probability triangle are for RDU. In the left panel the indifference curves are drawn over the entire relevant space. The right panel shows the same indifference curves but the boundaries have been truncated; the indifference curves in the interior are now approximately linear.

Rieger et al. (2014) compare risk attitudes in 53 countries. They calculate the relative risk premium for gains and losses. There is strong support for risk aversion in gains and risk seeking in losses. The average relative risk premium in gains is 0.70 (risk aversion) and, in losses it is -0.46 (risk seeking). Individuals in richer countries are more risk averse in gains but also more risk seeking in losses. There are also gender effects—women are more risk averse in gains but they are also more risk seeking in losses.

We also consider the evidence on the fourfold classification of risk elsewhere in Part I; see, for instance, Section 2.9.3 and Figure 2.13 for confirmatory evidence.

2.4.3 A violation of EU and RDU that can be explained by PT

Recall Example 2.11 for which EU and RDU were both refuted. We now show that this example is consistent with PT because PT takes account of changes in the reference point, which EU and RDU cannot.

Example 2.14 (Support for PT against EU and RDU). Suppose that the decision maker has the utility function $v(y) = (y)^{0.6}$ and uses the Prelec probability weighting function $w(p) = e^{-(-\ln p)^{0.65}}$. Consider Example 2.11 that constituted a refutation of EU and RDU. Problem 11 in Example 2.11 involved the following choice

$$A = (x_0 + 1000, 0.5; x_0 + 2000, 0.5) \text{ versus } B = (x_0 + 1000, 0; x_0 + 1500, 1).$$

²³ Unlike our notational convention in Part I, here the three outcomes are ordered as $x_3 < x_2 < x_1$.

Let us take a status-quo interpretation of reference points. Thus, for Problem 11, the reference point is the endowment point, $x_0 + 1000$ and so $y = x - (x_0 + 1000)$. Thus, the value function for each of these lotteries is given, respectively, by

$$V(A) = 1000^{0.6} e^{-(\ln 0.5)^{0.65}} = 28.692.$$

$$V(B) = 500^{0.6} = 41.628.$$

PT predicts that lottery B is preferred over lottery A, which is true for most subjects. Problem 12 in Example 2.11 considered the following choice,

$$C = (x_0 + 1000, 0.5; x_0 + 2000, 0.5) \text{ versus } D = (x_0 + 1500, 1; x_0 + 2000, 0).$$

In this case, the reference point is $x_0 + 2000$ and so $y = x - (x_0 + 2000)$. Thus, the value function corresponding to each of these lotteries is

$$V(C) = -2.25 (1000)^{0.6} e^{-(\ln 0.5)^{0.65}} = -64.558.$$

$$V(D) = -2.25 (500)^{0.6} = -93.662.$$

PT predicts that C should be chosen over D, which is true for a majority of the subjects.

2.4.4 Some erroneous criticisms of PT

We now consider some of the common criticisms of PT that are either misplaced or overstated.

1. *PT is only an “as if” theory:* All the mainstream decision theories that we have looked at, EU/RDU/PT, are ‘as if’ theories. Each of these theories involves a relatively high degree of cognitive sophistication. There is no supposition that the mental processes of decision makers mirror closely any of these theories, and the theories make no assumptions about cognitive processes either. However, evidence from neuroeconomics confirms various aspects of PT, such as reference dependence, loss aversion, and non-linear probability weighting (see Part 9 for details).

So why does PT explain the evidence from many diverse problems so well, even if it is an “as if” theory? The answer probably lies in the individual components of PT that have strong empirical support. These components include reference dependence, loss aversion, diminished sensitivity to gains and losses, shape of the utility functions in the domain of gains and losses, and inverse S-shaped probability weighting functions. Thus, in many cases, the “as if” assumption actually turns out to be justified when one uses PT. By contrast, the empirically observed violations of EU, considered above, show that the “as if” supposition does not often hold in the case of EU.

2. *PT performs better only because it has additional parameters:* Another commonly heard criticism of PT is that “these theories have more parameters than EU and RDU, so it is ‘no surprise’ that they have greater explanatory power.”

Proponents of EU who make this criticism will find that EU is subjected to a similar criticism. EU has more parameters than expected value maximization (EV), so if the “no surprise” argument has any intrinsic merit, it would also apply to the better explanatory power of EU relative to EV (e.g., the St. Petersburg paradox). It is in the nature of scientific progress that one discovers new anomalies that existing theory cannot explain. One then needs to construct a new theory that explains everything that the old theory can explain, and also has the ability to explain the new anomalies. It is often unavoidable that the new theory has

a larger number of parameters. The intellectual victory of EU over EV when the St. Petersburg paradox arose is a good example. A trivial example can also be used to make the same point. Suppose that one observes a scatter of points that is unmistakably quadratic. Then fitting a straight line rather than a curve through the points may be parsimonious, yet hardly satisfactory.

The “no surprise” argument would have intellectual merit if the new theory explains less than the old theory particularly out-of-sample, is intractable, and lacks parsimony. This is not the case with PT. PT is elegant, tractable, based on robust psychological foundations, and relatively parsimonious. It explains everything that EU and RDU can explain; the converse is false.

A theory with more parameters may explain better the in-sample data but not necessarily the out-of-sample data. Indeed, one can use statistical tests that allow us to trade off greater explanatory power against the larger number of parameters (e.g., the Akaike information criterion and the Bayesian information criterion). This methodology is routinely used to test alternative models of learning (see Part 5 of the book). We have already discussed in the introductory chapter that PT does not predict better than the alternative theories, just because it has a larger number of parameters.

One can separately elicit the parameters of the utility and the weighting functions, parametrically or non-parametrically, under PT; Section 2.5 is devoted to this endeavor. The results strongly support the functional forms under PT. Mixture models that allow for the presence of both EU and PT decision makers find that the vast majority of subjects (80% in the study of Bruhin et al. (2010) reviewed in Section 2.9.4) follow PT. On these grounds, EU is simply a mis-specified theory for most decision makers and the extra parameters under PT are supported by the empirical evidence.

3. *PT has an arbitrary reference point, which makes it vacuous:* Not only is it difficult to specify a universal reference point, it might not be desirable to do so.
 - (a) PT is not unique among mainstream theories in not being able to strictly specify all components. For instance, Bayesian statistics does not specify a prior distribution but teaches us a method of updating a prior to a posterior distribution. This inability to specify a prior is not taken as a fatal shortcoming. Another example is that the predictions of neo-classical theory are often very sparse unless one is willing to specify explicitly, preferences and technology. A good example is general equilibrium theory; see, for instance, section 17E in Mas-Collel et al. (1995) titled “Anything goes . . .”. Indeed, the real bite in the predictions from many models comes from actually specifying preferences and technology. This is hardly considered to be fatal for neoclassical economics.
 - (b) What if human behavior is actually “sufficiently rich” in terms of the reference point? “Sufficiently rich” does not imply infinitely rich or random. Indeed, many candidates for a reference point seem very salient across many problems and contexts. Of these, the *status quo* or a fair/just entitlement (even if the fairness is subjective) is one of the most salient. In actual applications, this is often able to guide the researcher to a suitable reference point. In many contexts, a natural reference point arises on closer examination. For instance, in their explanation of the tax evasion puzzles (see Section 3.5 below), Dharmi and al-Nowaihi (2007, 2010b) assume the “legal after-tax liabilities” to be the reference point for a potential tax evader; this has the flavor of a status-quo point. Their calibrated results, based on this suggestion match closely the data from the problem.
 - (c) There has been progress in endogenous specifications of the reference point; see, for instance, the discussion in Section 2.8 on the Köszegi–Rabin framework. In this framework,

the reference point is determined within the model, in a manner that is consistent with rational expectations. The advantage is that this framework is not subject to the potential criticism of an arbitrary reference point. The disadvantage is that the required cognitive sophistication of the decision makers is very high.

A more serious criticism of PT comes from the evidence on human behavior for events of very low and very high probabilities. This is dealt with in Section 2.11.3 below. Indeed, newer theories that are able to handle events of very low and very high probabilities, such as *composite prospect theory* (see Section 2.11.3), rely heavily on the insights of PT because PT captures fundamentally important insights about human behavior. Other serious criticisms are discussed in Section 2.9. These have to do with the evidence from configural weights models, violations of gain–loss separability, the absence of “regret” in PT, and the interaction between probability weights and stake size.

2.5 Elicitation of utility and probability weighting functions in PT

In this section, we briefly consider some of the methods of elicitation under PT as well as some of the parameter estimates in the literature; for a more detailed discussion, see Wakker (2010).

2.5.1 Elicitation of the utility function under PT

In order to elicit the utility function under PT, let us suppose that the reference point is zero and proceed in the four steps suggested in Abdellaoui et al. (2007).

I. Determining probabilities p_l, p_g : $w^-(p_l) = \frac{1}{2}$ and $w^+(p_g) = \frac{1}{2}$, where w^- and w^+ are, respectively, probability weighting functions in the domain of losses and gains.

Suppose that, relative to the reference point, we are given (i) three outcomes in the loss domain, $l_0 < l < l^*$, and (ii) some level of probability p . Now we elicit two levels of outcomes in the loss domain, l_1 and l_2 , such that $l_2 < l_1 < l_0 < l < l^*$. We first find the utility midpoints using the method of Abdellaoui (2000) and Köbberling and Wakker (2003).

Suppose that the following indifferences hold

$$(l_1, p; l^*, 1 - p) \sim (l_0, p; l, 1 - p). \quad (2.28)$$

$$(l_2, p; l^*, 1 - p) \sim (l_1, p; l, 1 - p). \quad (2.29)$$

Under PT, for $i = 0, 1$, $(l_{i+1}, p; l^*, 1 - p) \sim (l_i, p; l, 1 - p)$ implies that

$$w^-(p)v(l_{i+1}) + (1 - w^-(p))v(l^*) = w^-(p)v(l_i) + (1 - w^-(p))v(l), \quad (2.30)$$

where v is the utility function under PT. Rewriting (2.30),

$$v(l_i) - v(l_{i+1}) = \frac{1 - w^-(p)}{w^-(p)} (v(l^*) - v(l)). \quad (2.31)$$

The right hand side is independent of the indices, $i, i + 1$, thus, for $i = 0, 1$, and using (2.28), (2.29), we have

$$v(l_0) - v(l_1) = v(l_1) - v(l_2). \quad (2.32)$$

Thus,

$$v(l_1) = \frac{1}{2} [v(l_0) + v(l_2)], \quad (2.33)$$

is the utility midpoint of $v(l_0)$ and $v(l_2)$. Once the values l_1 and l_2 are elicited, then we find the probability p_l such that $(l_1, 1) \sim (l_2, p_l; l_0, 1 - p_l)$. This indifference implies that

$$v(l_1) = w^-(p_l)v(l_2) + (1 - w^-(p_l))v(l_0). \quad (2.34)$$

Substituting (2.33) into (2.34) we get the required value

$$w^-(p_l) = \frac{1}{2}. \quad (2.35)$$

We now proceed to the domain of gains. We begin with a probability p and three outcomes in the domain of gains $g_0 > g > g^*$. Now we elicit two levels of gains g_1 and g_2 such that $g_2 > g_1 > g_0 > g > g^*$. Suppose that the following indifferences hold

$$(g^*, 1 - p; g_1, p) \sim (g, 1 - p; g_0, p). \quad (2.36)$$

$$(g^*, 1 - p; g_2, p) \sim (g, 1 - p; g_1, p). \quad (2.37)$$

Having elicited g_1 and g_2 we can now proceed analogously to the domain of losses to find a probability p_g such that

$$w^+(p_g) = \frac{1}{2}. \quad (2.38)$$

II. Eliciting utility in the loss domain.

Pick an outcome y_l in the domain of losses and normalize $v(y_l) = -1$. We now elicit the outcome $l_{0.5}$ in the domain of losses such that $(l_{0.5}, 1) \sim (y_l, p_l; 0, 1 - p_l)$, where p_l is found in (2.35). Under PT, this indifference implies that

$$v(l_{0.5}) = w^-(p_l)v(y_l).$$

Substituting (2.35) and $v(y_l) = -1$ we get

$$v(l_{0.5}) = -\frac{1}{2}.$$

We can now proceed to elicit the utility function in the interval $[y_l, 0]$. For instance, elicit an outcome $l_{0.25}$ such that $(l_{0.25}, 1) \sim (l_{0.5}, p_l; 0, 1 - p_l)$. This indifference implies that

$$v(l_{0.25}) = w^-(p_l)v(l_{0.5}) = -\frac{1}{4}.$$

Similarly we can find $l_{0.125}$ such that $(l_{0.125}, 1) \sim (l_{0.25}, p_l; 0, 1 - p_l)$, so $v(l_{0.125}) = w^-(p_l)v(l_{0.25}) = -\frac{1}{8}$, and so on.

III. Linking utility in the loss domain with utility in the gain domain.

We now relate utility in the loss domain from Step II with utility in the gain domain. This is an important step in the framework of Abdellaoui et al. (2007), which allows for the measurement of loss aversion.²⁴ We consider three indifferences.

(a) Consider one of the elicited outcomes in the interval $[y_l, 0]$ in Step II, say, l_s with the corresponding utility function $v(l_s) = -s$ (e.g., $v(l_{0.25}) = -0.25$). We now find an outcome l in the loss domain such that $(l_s, 1) \sim (l, 0.5; 0, 0.5)$. This implies that $v(l_s) = w^-(0.5)v(l)$, so

$$-s = w^-(0.5)v(l). \quad (2.39)$$

(b) Now elicit an outcome in the domain of gains, g , such that $(0, 1) \sim (l, 0.5; g, 0.5)$. This implies that $0 = w^-(0.5)v(l) + w^+(0.5)v(g)$. Using (2.39) we get

$$w^+(0.5)v(g) = s. \quad (2.40)$$

(c) Elicit the outcome g_s in the domain of gains so that $(g_s, 1) \sim (g, 0.5; 0, 0.5)$. This implies that $v(g_s) = w^+(0.5)v(g)$. Using (2.40), we get that $v(g_s) = s$. Thus, in terms of utility, the outcome g_s in the domain of gains is the mirror image of the outcome l_s in the domain of loss.

IV. Eliciting utility in the gain domain.

We now determine utility in the gain domain in the interval $[0, g_s]$, where g_s was determined in Step III. We elicit $g_{0.5} \in [0, g_s]$ such that $(g_{0.5}, 1) \sim (0, 1 - p_g, g_s, p_g)$. This gives rise to the condition $v(g_{0.5}) = w^+(p_g)v(g_s)$. Using (2.38) and $v(g_s) = s$ we get $v(g_{0.5}) = \frac{s}{2}$. Proceeding in an analogous manner, we can generate utility in the gains domain for other values in the interval $[0, g_s]$ such as $g_{0.25}, g_{0.125}$.

Figure 2.8 shows a non-parametric utility function fitted to the data from Abdellaoui et al. (2007) for EU and for PT. The non-parametric curve is concave in gains and convex in losses.²⁵ The degree of concavity and convexity is more pronounced relative to several other studies.²⁶ At the individual level, the most common pattern was an S-shaped utility function. Only one individual out of 48 behaved in a manner consistent with the typical assumption in EU of a concave utility function throughout. Similar results are obtained by Abdellaoui et al. (2013) when they elicit the preferences of private bankers and fund managers. This serves to contribute towards the external validity of lab experiments in such domains.

Figure 2.9 shows a fit of the power form of utility in (2.20) to the same data. The coefficient γ in the domain of gains is 0.75 and in the domain of loss it is 0.74. The curve has an extremely good fit and most points lie very close to the fitted curve.

One disadvantage of non-parametric estimation is that there might be substantial error propagation. Further, the procedure is not very efficient in the sense that too many iterations are needed, imposing greater cognitive requirements on the subjects. In response to these concerns, Abdellaoui et al. (2008) propose a parametric estimation method with the power form of utility. They

²⁴ In the trade-off method of Wakker and Deneffe (1996), one cannot measure simultaneously the utility in the domain of gains and losses, thus making it difficult to measure loss aversion.

²⁵ Notice that if we restricted attention only to EU, then the finding of risk seeking behavior in the domain of losses does not allow us to conclude that the utility function is convex. This is because risk seeking in the domain of losses might also arise due to the shape of the probability weighting function; see Abdellaoui et al. (2007).

²⁶ For instance, Tversky and Kahneman (1992), Fennema and van Assen (1998), Abdellaoui (2000), and Schunk and Betsch (2006).

Figure 2.8 Non-parametric estimates of utility for gains and losses under PT and EU based on median data.

confirm all the individual features of prospect theory: Concavity of utility in the domain of gains, convexity in the domain of losses, loss aversion, and inverse S-shaped probability weighting.

2.5.2 Elicitation of loss aversion under PT

There are many different definitions of loss aversion.²⁷ However, these definitions typically rely on the utility function and not on the probability weighting function. Hence, the elicitation of the utility function in Section 2.5.1 sets the stage for the elicitation of loss aversion.

The original definition of loss aversion, due to Kahneman and Tversky (1979), is given in Definition 2.31, i.e.,

$$\frac{-v(-y)}{v(y)} > 1; y > 0.$$

When the utility function takes the power form in (2.20), loss aversion is simply

$$\lambda = \frac{-v(-1)}{v(1)}.$$

²⁷ For some work on the behavioral foundations of loss aversion, see Peters (2012).

Figure 2.9 Parametric estimates of the power form of utility for gains and losses under PT based on median data.

Source: Abdellaoui et al. (2007). Reproduced with permission. Copyright, INFORMS, <http://www.informs.org>

Köbberling and Wakker (2005) consider the implications of an alternative definition of loss aversion. In this definition, suggested originally but informally by Benartzi and Thaler (1995), for a general utility function v ,

$$\lambda = \frac{v'_{\uparrow}(0)}{v'_{\downarrow}(0)}, \quad (2.41)$$

where $v'_{\uparrow}(0)$ and $v'_{\downarrow}(0)$ are, respectively, the left hand side and the right hand side limits around 0.

The Wakker and Tversky (1993) definition of loss aversion requires a greater slope of the utility function at any loss outcome relative to the slope at the absolute value of the loss, i.e.,

$$v'(-y) > v'(y), \forall y > 0.$$

Neilson (2002) proposed the following requirement for a loss averse decision maker

$$\frac{v(-x)}{-x} \geq \frac{v(y)}{y}, x > 0, y > 0.$$

Once the utility function has been estimated using the technique in Section 2.5.1, then any of these definitions can be applied to estimate loss aversion.

There are also some definitions of loss aversion that rely on the probability weighting function.

Definition 2.37 (Kahneman and Tversky, 1979): Let $\prec$ be a binary preference relation over lotteries. An individual is loss averse if $(y, 0.5; -y, 0.5) \prec (z, 0.5; -z, 0.5)$ where $y > z \geq 0$.

In OPT, Kahneman and Tversky (1979) defined loss aversion as the tendency of people to reject symmetric 50–50 bets (set $z = 0$ in Definition 2.37). Schmidt and Zank (2005) extend Definition 2.37 to the concept of *strong loss aversion*. As one might expect from Definition 2.37, in a comparison of the lotteries $(y, 0.5; -y, 0.5)$ and $(z, 0.5; -z, 0.5)$ under prospect theory, the weighting function plays a critical role. Thus, loss aversion, in this definition, involves a condition between changes in utility and the magnitude of probability weights.

Abdellaoui et al. (2007) summarize some of the estimates of loss aversion, based on aggregate data from previous studies; see, Table 2.3. The estimates from separate studies are sometimes not comparable because some report median values, while others report mean values.²⁸ Based on this small set of results, the Tversky and Kahneman (1992) estimate of 2.25 is quite representative. The estimates in Table 2.3 are for aggregate data. Abdellaoui et al. (2007) also report their own estimates from individual data, based on various definitions of loss aversion.²⁹ Using the Kahneman and Tversky (1979) definition, they detect the presence of loss aversion at the aggregate and the individual level; 39 out of 47 subjects are loss averse. Using the Wakker and Tversky (1993) definition, 30 out of 36 are loss averse. In the Köbberling and Wakker (2005) definition, 35 out of 47 subjects are loss averse. The mean estimates of loss aversion for these three studies are, respectively, 2.04, 1.71, and 8.27.

A large number of estimates of loss aversion have come from studies that examine exchange disparities. We consider these estimates separately in Section 3.2.1. Section 3.4 considers the concept of *myopic loss aversion*.

Table 2.3 Estimates of loss aversion in various studies. The two estimates in Bleichrodt et al. (2001) are based on two different datasets. The two estimates in Booij and van de Kuilen (2009) are based on high and low monetary amounts.

Study	Definition of loss aversion	Estimate
Fishburn and Kochenberger (1979)	$\frac{v'(-y)}{v'(y)}$	4.8
Tversky and Kahneman (1992)	$\frac{-v(-1)}{v(1)}$	2.25
Bleichrodt et al. (2001)	$\frac{v(-y)}{v(y)}$	2.17, 3.06
Schmidt and Traub (2002)	$\frac{v'(-y)}{v'(y)}$	1.43
Pennings and Smidts (2003)	$\frac{v'(-y)}{v'(y)}$	1.81
Booij and van de Kuilen (2009)	$\frac{v'_\uparrow(-y)}{v'_\downarrow(y)}$	1.79, 1.74

Source: Abdellaoui et al. (2007).

²⁸ In Table 2.3, median values are reported by Fishburn and Kochenberger (1979), Tversky and Kahneman (1992), and Bleichrodt et al. (2001).

²⁹ Estimates of loss aversion at the individual level are also provided in Schmidt and Traub (2002) and Bleichrodt and Pinto (2002) although these studies find a lower proportion of loss averse subjects.

2.5.3 Elicitation of the probability weighting function under PT

One can either estimate the probability weighting function parametrically or non-parametrically. Table 2.4 shows some parameter estimates reported in Bleichrodt and Pinto (2000) for three main probability weighting functions.

For several reasons, one might be interested in non-parametric estimation of the probability weighting function. Consider the trade-off method proposed by Wakker and Deneffe (1996). Suppose that we begin with three outcomes in the domain of gains, $R > r > x_0$ such that $(R, 1) \succeq (x_0, 1)$. The outcome x_1 is then elicited such that

$$(x_0, 1 - p; R, p) \sim (x_1, 1 - p; r, p). \quad (2.42)$$

Under PT, the indifference in (2.42) implies that

$$w(p)v(R) + (1 - w(p))v(x_0) = w(p)v(r) + (1 - w(p))v(x_1). \quad (2.43)$$

Now the outcome x_2 is elicited such that

$$(x_1, 1 - p; R, p) \sim (x_2, 1 - p; r, p)$$

which implies that

$$w(p)v(R) + (1 - w(p))v(x_1) = w(p)v(r) + (1 - w(p))v(x_2). \quad (2.44)$$

From (2.43) and (2.44)

$$(1 - w(p))(v(x_2) - v(x_1)) = w(p)(v(R) - v(r)). \quad (2.45)$$

Table 2.4 Estimates of the parameters of various probability weighting functions.

Probability weighting function	Parameter estimates
Tversky–Kahneman (1992)	Tversky–Kahneman (1992): $\tau = 0.61$ (gains), $\tau = 0.69$ (losses)
$w(p) = \frac{p^\tau}{[p^\tau + (1-p)^\tau]^{\frac{1}{\tau}}}$	Camerer and Ho (1994): $\tau = 0.56$ (gains)
	Wu and Gonzalez (1996): $\tau = 0.71$ (gains)
	Abdellaoui (2000): $\tau = 0.60$ (gains), $\tau = 0.70$ (losses)
	Wu and Gonzalez (1996): $\delta = 0.84$, $\eta = 0.68$ (gains)
Goldstein–Einhorn (1987)	Gonzalez and Wu (1999): $\delta = 0.77$, $\eta = 0.44$ (gains)
$w(p) = \frac{\delta p^\eta}{\delta p^\eta + (1-p)^\eta}$	Tversky and Fox (1995): $\delta = 0.77$, $\eta = 0.69$ (gains)
	Abdellaoui (2000): $\delta = 0.65$, $\eta = 0.60$ (gains)
	Abdellaoui (2000): $\delta = 0.84$, $\eta = 0.65$ (losses)
Prelec (1998)	
$w(p) = e^{-(-\ln p)^\alpha}$	Wu and Gonzalez (1996): $\alpha = 0.74$ (gains)

Source: Bleichrodt and Pinto (2000).

Notice that the RHS is independent of x_1 and x_2 . One can now continue these iterations of indifferences. For instance, the next stage would be to find an x_3 such that $(x_2, 1 - p; R, p) \sim (x_3, 1 - p; r, p)$. In general, for any x_i and x_{i-1} , the analogue of (2.45) is

$$(1 - w(p)) (v(x_i) - v(x_{i-1})) = w(p) (v(R) - v(r)). \quad (2.46)$$

Since the RHS is independent of x_i and x_{i-1} , iterating the process k times, we get

$$v(x_1) - v(x_0) = v(x_2) - v(x_1) = v(x_3) - v(x_2) = \dots = v(x_k) - v(x_{k-1}). \quad (2.47)$$

Normalize $v(x_0) = 0$ and $v(x_k) = 1$. From the first equality in (2.47), we get $v(x_1) = \frac{1}{2}v(x_2)$. From the second equality, we get $v(x_2) = \frac{2}{3}v(x_3)$. In general, for the j th equality, we get $v(x_j) = \frac{j}{j+1}v(x_{j+1})$, and from the last equality, we get $v(x_{k-1}) = \frac{k-1}{k}v(x_k) = \frac{k-1}{k}$. Rolling back the iterations, we get $v(x_{k-2}) = \frac{k-2}{k-1}v(x_{k-1}) = \frac{k-2}{k-1} \frac{k-1}{k} = \frac{k-2}{k}$. This establishes the pattern of recursion, so that we have

$$v(x_j) = \frac{j}{k}, j = 1, 2, \dots, k. \quad (2.48)$$

Once we obtain the utility function in this manner (or in the manner suggested in Section 2.5.1), we can follow Abdellaoui (2000). Choose any $x_j \in \{x_0, x_1, \dots, x_k\}$ (these are the first stage elicited values), and then elicit the probability q such that

$$(x_0, 1 - q; x_k, q) \sim (x_j, 1),$$

which implies that

$$w(q)v(x_k) + (1 - w(q))v(x_0) = v(x_j)$$

Using $v(x_k) = 1$, $v(x_0) = 0$, and $v(x_j) = j/k$, we get

$$w(q) = \frac{j}{k}.$$

Now we select another element from $\{x_0, x_1, \dots, x_k\}$ and repeat the procedure to get the probability weight associated with another probability value and so on for each point in $\{x_0, x_1, \dots, x_k\}$. Bleichrodt and Pinto (2000) apply this procedure to health outcomes (rather than monetary prizes). They find strong evidence of an inverse S-shaped probability weighting function at the individual and the aggregate levels. As to the shapes of the weighting function at the individual level, they find that 10.9% of the subjects had a concave weighting function, 0% had a linear weighting function, 4.4% had a convex weighting function, and 83.7% had an inverse S-shaped weighting function.

2.6 The axiomatic foundations of PT

We briefly consider the preference foundations of various elements of PT in this section. The interested reader can consult Wakker (2010) for a comprehensive treatment. Since the Prelec (1998) probability weighting function (see Definition 2.22) and the power form of utility (see Equation 2.20) are used extensively in Part 1, the reader is specifically given a flavor of their preference foundations.

2.6.1 Foundations of PT in terms of the trade-off consistency method

In this section we consider the preference foundations of PT based on the *trade-off consistency method* (Chateauneuf and Wakker, 1999; Köbberling and Wakker, 2003).³⁰ This method gives the preference foundations for EU, RDU, and PT under *risk* as well as under *uncertainty*. Our presentation here is based on Chateauneuf and Wakker (1999).³¹

For pedagogical simplicity, let $X = \mathbb{R}$ be the set of monetary outcomes.³² The reference point is normalized to 0. A typical prospect is given by $L = (y_1, p_1; y_2, p_2; \dots; y_n, p_n)$ (see Definition 2.30, with $x_0 = 0$), where $y_1 < y_2 < \dots < y_n$ are outcomes in X and $p_1, p_2, \dots, p_n$ are probabilities such that $p_i \geq 0$ and $\sum_i p_i = 1$. Let $\mathcal{L}_P$ be the set of all such prospects.

Let $\succeq$ be a preference relation over $\mathcal{L}_P$ and let $\succ$ and $\sim$ be the strict preference and indifference relations. Sure outcomes y_i are equivalent to the prospect $(y_i, 1)$. An outcome $y_i \succ 0$ is a gain, while $y_i < 0$ is a loss. Since we have assumed that X is the set of monetary outcomes, so for sure outcomes, $\succeq$ corresponds in a natural way with $\geq$.

If $\succeq$ is a *weak order* (i.e., complete and transitive), then we can find a preference representation such that for any two prospects $L_1, L_2 \in \mathcal{L}_P$ we have $L_1 \succeq L_2 \Leftrightarrow V(L_1) \geq V(L_2)$. Let $x = (x_1, x_2, \dots, x_n) \in X^n$ and fix the prospect $L_1 = (y_1, p_1; \dots; y_n, p_n)$. Preferences $\succeq$ are *continuous* if for all $x \in X^n$ and fixed probabilities $p_1, p_2, \dots, p_n$, the following two sets are closed

$$\{x : (x_1, p_1; \dots; x_n, p_n) \succeq L_1\}, \{x : (x_1, p_1; \dots; x_n, p_n) \leq L_1\}.$$

Let $L_1 = (y_1, p_1; \dots; y_n, p_n)$ and $L_2 = (x_1, p_1; \dots; x_n, p_n)$. Then, $\succeq$ satisfies *stochastic dominance* if $x_i \geq y_i$ for $i = 1, 2, \dots, n$ implies $L_2 \succeq L_1$ and if, in addition, $x_i \succ y_i$ for at least one i we have $L_2 \succ L_1$ (see Definition 1.9 and note that $x_i \geq y_i \Leftrightarrow x_i \succeq y_i$).

Suppose that we are given an arbitrary prospect $L = (y_1, p_1; \dots; y_n, p_n)$. Then, we define a new prospect $\alpha_j L$ which replaces the j th outcome in L , y_j , by α_j , i.e.,

³⁰ On the penultimate line of the second paragraph on p. 94 of his book, Wakker (2010) credits Pfanzagl (1968, Remark 9.4.5) with the recommendation of the trade-off tool. The interested reader can consult Wakker (2010) for a detailed statement of the relevant theorems and the references. For the preference foundations of PT in the continuous case, see Kothiyal et al. (2011).

³¹ For other axiomatizations of prospect theory, see Tversky and Kahneman (1992), Wakker and Tversky (1993), Chateauneuf and Wakker (1999), Zank (2001), Wakker and Zank (2002), Köbberling and Wakker (2003), Schmidt (2003), Schmidt and Zank (2007, 2008). All these axiomatizations assumed an exogenous reference point. For axiomatizations of the rank dependent model, see Quiggin (1981, 1982), Yaari (1987), Schmeidler (1989), Luce (1991), Abdellaoui (2002), Luce and Marley (2005), and Luce and Fishburn (1991). For axiomatic extensions of the RDU model see Green and Jullien (1988), Chew and Epstein (1989a), and Segal (1989, 1993). These sets of papers provide links between EU and RDU as well as showing the connection between RDU and the betweenness axiom.

³² The framework can be extended to more general spaces that do not restrict attention to monetary outcomes and higher dimensional spaces such as $\mathbb{R}^m$ where elements of X are m dimensional bundles of goods, etc.

$$\alpha_j L = (y_1, p_1; \dots; y_{j-1}, p_{j-1}; \alpha_j, p_j; y_{j+1}, p_{j+1}; \dots; y_n, p_n); y_{j-1} < \alpha_j < y_{j+1}.$$

Definition 2.38 Let there be four outcomes (all in gains or all on losses) a, b, c, d . Consider the preference relation $\succ^*$ such that $ab \succ^* cd$ (also written as $[a; b] \succ^* [c; d]$) if there exist prospects $L_1 = (y_1, p_1; y_2, p_2; \dots; y_n, p_n)$, $L_2 = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$ (with identical probabilities) and an index $j = 1, \dots, n$, such that

$$a_j L_1 \succeq b_j L_2 \text{ and } c_j L_1 \prec d_j L_2.$$

Example 2.15 Suppose that $L_1 = (80, 0.3; y_2, 0.7)$ and $L_2 = (90, 0.3; x_2, 0.7)$. Then, using Definition 2.38, $[1; 0] \succ^* [9; 8]$ if

$$(80, 0.3; 1, 0.7) \succeq (90, 0.3; 0, 0.7) \text{ and } (80, 0.3; 9, 0.7) \prec (90, 0.3; 8, 0.7).$$

Recall that v is the utility function under PT (Definition 2.31). The next lemma illustrates the usefulness of the preference relation $\succ^*$ for utility differences.

Lemma 2.1 Suppose that the decision maker follows PT. Then

$$[a; b] \succ^* [c; d] \Rightarrow v(a) - v(b) > v(c) - v(d).$$

Proof: Given Definition 2.38, the decision weights in each pair of prospects $(a_j L_1, b_j L_2)$ and $(c_j L_1, d_j L_2)$ only differ at the j th place; denote this decision weight by π_j . Then $a_j L_1 \succeq b_j L_2 \Leftrightarrow V(a_j L_1) \geq V(b_j L_2)$ or (using Definition 2.34)

$$\pi_j(v(a) - v(b)) \geq \sum_{i \neq j} \pi_i v(x_i) - \sum_{i \neq j} \pi_i v(y_i). \quad (2.49)$$

Analogously $c_j L_1 \prec d_j L_2$ implies that

$$\pi_j(v(c) - v(d)) < \sum_{i \neq j} \pi_i v(x_i) - \sum_{i \neq j} \pi_i v(y_i). \quad (2.50)$$

Using (2.49), (2.50) we get

$$v(a) - v(b) > v(c) - v(d).$$

The second inequality in the statement of the proposition can be derived analogously, so we omit it. ■

In the elicitation of the utility function under PT, see (2.48), notice that the elicited utility differences are constant. This is an implication of Lemma 2.1. To see this, the procedure elicits values $x_0, x_1, x_2, \dots$ such that $[x_{j+1}; x_j] \sim^* [x_1; x_0]$ so $[x_{j+1}; x_j] \succeq^* [x_1; x_0]$ and $[x_{j+1}; x_j] \preceq^* [x_1; x_0]$, which implies, from Lemma 2.1, that $v(x_{j+1}) - v(x_j) > v(x_1) - v(x_0)$, as claimed.

In order to ensure that this elicitation process does not run into contradictions, we impose the next condition.

Definition 2.39 (*Trade-off consistency*³³): Under trade-off consistency there cannot exist outcomes a, b, c, d such that $[a; b] \succ^* [c; d]$ and $[c; d] \succeq^* [a; b]$.

The main result is given in the next proposition.

Proposition 2.15 (*Chateauneuf and Wakker, 1999*): Assuming trade-off consistency, the following two statements are equivalent.

- (i) Cumulative prospect theory holds with a continuous utility function.
- (ii) The preference relation $\succeq$ satisfies the following conditions.
 - (a) Weak ordering.
 - (b) Continuity.
 - (c) Stochastic dominance.
 - (d) Trade-off consistency.

For an extension of this framework under risk to issues of uncertainty, a richer set of results, and a discussion of the related literature, see Köbberling and Wakker (2003), and Wakker (2010). The existing axiomatizations listed above, presuppose a reference point. Schmidt and Zank (2012) propose an alternative set of axioms to get a PT representation that does not impose a reference point. They rely on the idea of diminishing sensitivity around a reference point to endogenously identify a reference point.

2.6.2 Foundations of the Prelec weighting function

Under EU, one can use the reduction axiom to reduce compound lotteries to simple lotteries by using the product rule of probabilities. Under non-linear probability weighting, this method no longer works and we need something to replace the product rule of probabilities. Alternative preference foundations of the Prelec function propose different forms of the product rule.

Let X be the set of *outcomes*. Since outcomes are monetary losses or gains in all our applications, we may take X to be the set of real numbers, R .³⁴ We assume that the preferences of the decision maker are described by a real-valued function $u : X \rightarrow R$; $y \in X$ being preferred to $x \in X$ if, and only if, $u(y) \geq u(x)$. Three axiomatizations of the Prelec (1998) probability weighting function (see Definition 2.22) have been proposed. These are by Prelec (1998), Luce (2001), and al-Nowaihi and Dhami (2006). The main results are stated below to give readers a flavor of the literature.

We shall find it convenient to use the following notation: $(x; p_1, p_2)$ is the lottery (x, p_1) received with probability p_2 . It is straightforward to extend this notation, iteratively to $(x; p_1, p_2, p_3)$.

Definition 2.40 (*Reduction invariance; Luce, 2001*): The probability weighting function, w , satisfies reduction invariance if, for all $x \in X$, $p_1, p_2, q \in [0, 1]$, $\lambda > 0$, $(x; p_1, p_2) \sim (x; q) \Rightarrow (x; p_1^\lambda, p_2^\lambda) \sim (x; q^\lambda)$.

Theorem 2.1 (*Luce, 2001*): The probability weighting function, w , satisfies reduction invariance if, and only if, it is the Prelec function.

Definition 2.41 (*Power invariance, al-Nowaihi and Dhami, 2006*): The probability weighting function w satisfies power invariance if, for all $x \in X$, $p, q \in [0, 1]$, $\lambda > 0$,

³³ This condition is referred to as sign-comonotonic trade-off consistency in Wakker and Tversky (1993).

³⁴ If outcomes are bundles of goods, then X can be taken to be a subset of R^n . For more complex outcomes, X can be taken to be an appropriate topological vector space.

$$(x; p, p) \sim (x; q) \Rightarrow (x; p^\lambda, p^\lambda) \sim (x; q^\lambda) \text{ and } (x; p, p, p) \sim (x; q) \Rightarrow (x; p^\lambda, p^\lambda, p^\lambda) \sim (x; q^\lambda).$$

Comparing Definitions 2.40 and 2.41, we see that *power invariance* is simpler in that it requires two probabilities (p, q) instead of three (p_1, p_2, q) . On the other hand, *power invariance* requires two stages of compounding, instead of the single stage of *reduction invariance*. By contrast, *compound invariance* of Prelec (1998) involves no compounding but four probabilities and four outcomes.³⁵ We thus have a menu of testing options.

Theorem 2.2 (*al-Nowaihi and Dhami, 2006*): *The probability weighting function, w , satisfies power invariance if, and only if, it is the Prelec function.*

Corollary 2.2 (*al-Nowaihi and Dhami, 2006*): *Power invariance is equivalent to reduction invariance of Luce (2001) and compound invariance of Prelec (1998).*

2.6.3 Foundations of the power form of utility

Recall the power form of utility given in (2.20). We now discuss the preference foundations of this utility function due to al-Nowaihi et al. (2008).

Let $(x; p)$ stand for the *simple lottery* that pays $x \in R$ with probability $p \in [0, 1]$ and 0 otherwise. Let us use slightly different notation for lotteries in incremental form (Definition 2.30). Let

$$(\mathbf{x}; \mathbf{p}) = (x_{-m}, x_{-m+1}, \dots, x_0, x_1, \dots, x_n; p_{-m}, p_{-m+1}, \dots, p_0, p_1, \dots, p_n)$$

stand for the lottery that pays $x_i \in R$ with probability $p_i \in [0, 1]$, where $\sum_{i=-m}^n p_i = 1$ and $x_{-m} \leq x_{-m+1} \leq \dots \leq x_{-1} \leq x_0 = 0 \leq x_1 \leq x_2 \leq \dots \leq x_n$. If $\mathbf{x} = (x_1, x_2, \dots, x_n)$, then $-\mathbf{x} = (-x_1, -x_2, \dots, -x_n)$ and $\mathbf{x}^r = (x_n, x_{n-1}, \dots, x_1)$. Thus $(-\mathbf{x}^r; \mathbf{p}^r)$ stands for the lottery that pays $-x_i$ with probability p_i . If each $x_i \geq 0$ and, for some i , $p_i x_i > 0$, then we call $(\mathbf{x}; \mathbf{p})$ a *positive lottery*. For instance, if $(\mathbf{x}; \mathbf{p}) = (-7, 0, 4; 0.2, 0.5, 0.3)$, then $(-\mathbf{x}; \mathbf{p}) = (7, 0, -4; 0.2, 0.5, 0.3)$ and $(-\mathbf{x}^r; \mathbf{p}) = (-4, 0, 7; 0.3, 0.5, 0.2)$.

Definition 2.42 (*Tversky and Kahneman, 1992*): *The decision maker exhibits preference homogeneity if, for all lotteries $(\mathbf{x}; \mathbf{p})$, if c is the certainty equivalent of $(\mathbf{x}; \mathbf{p})$, then, for all $k \in R_+$, kc is the certainty equivalent of $(k\mathbf{x}; \mathbf{p})$.*

Definition 2.43 below, is an attempt to extend Tversky and Kahneman's (1992) concept of loss aversion to more general lotteries.

Definition 2.43 *Loss aversion holds for positive lotteries if, for some $\lambda > 1$, $\frac{|V(-\mathbf{x}^r; \mathbf{p}^r)|}{V(\mathbf{x}; \mathbf{p})} = \lambda$, for all positive lotteries, where V is the value function in prospect theory, given in (2.24). We call λ the coefficient of loss aversion.*

In the extreme case, where all outcomes are in gains, $V(-\mathbf{x}^r; \mathbf{p}^r)$ flips all outcomes to the domain of losses. The ratio $\frac{|V(-\mathbf{x}^r; \mathbf{p}^r)|}{V(\mathbf{x}; \mathbf{p})}$ captures the loss to gain utility under PT, which is a more general measure of loss aversion. In applications of PT and empirical implementations of PT, it is common to assume that in the power form of utility (see (2.20)), $\gamma^+ = \gamma^-$ and that the weighting

³⁵ Compound invariance of Prelec (1998) is as follows. For all outcomes $x, y, x', y' \in X$, probabilities $p, q, r, s \in [0, 1]$ and compounding integers $n \geq 1$: If $(x, p) \sim (y, q)$ and $(x, r) \sim (y, s)$; then $(x', p^n) \sim (y', q^n)$ implies $(x', r^n) \sim (y', s^n)$.

function is identical in the domain of gains and losses ($w^- = w^+$). The next theorem provides the necessary justification.

Theorem 2.3 (*al-Nowaihi et al., 2008*): (a) If preference homogeneity holds for simple lotteries, then the utility function for riskless outcomes, v , takes the form given in (2.20):

$$v(x) = x^{\gamma^+}, \text{ for } x \geq 0, v(x) = -\lambda (-x)^{\gamma^-}, \text{ for } x < 0, \text{ where } \gamma^+ > 0, \gamma^- > 0, \lambda > 0. \quad (2.51)$$

Conversely, if the value function for riskless outcomes takes the form (2.51), then preference homogeneity holds for all lotteries.

(b) If the utility function (2.51) for riskless outcomes exhibits loss aversion, then $\lambda > 1$ and $\gamma^+ = \gamma^-$.

(c) If preference homogeneity and loss aversion both hold for simple lotteries, then the utility function for riskless outcomes takes the form (2.51) with $\lambda > 1$, $\gamma^+ = \gamma^-$, and $w^- = w^+$. Conversely, if the utility function for riskless outcomes takes the form (2.51) with $\lambda > 1$, $\gamma^+ = \gamma^-$, and $w^- = w^+$, then preference homogeneity holds for all lotteries and loss aversion holds for all positive lotteries.

2.7 Third generation PT and stochastic reference points

Schmidt et al. (2008) propose an extension of PT to the case of stochastic reference points. They call their descriptive theory of decision making, *third generation prospect theory*, or PT³. Their framework addresses situations where individuals are endowed with a lottery and must choose between alternative actions that typically induce different probability distributions over outcomes. For instance, the decision maker who buys a house has an endowment in which his house may suffer harm due to fire or other natural hazards with some probability. His choice of action, for instance, to buy insurance induces another probability distribution over the relevant outcomes.

Consider a set of states of nature $S = \{s_1, s_2, \dots, s_m\}$. State $s_i \in S$ has an objective probability of occurrence, $0 \leq p_i \leq 1$ such that $\sum_{i=1}^m p_i = 1$. There is a set of state-contingent consequences from one's chosen action. The consequences, in any state, lie in the compact set $X = [a, b] \in \mathbb{R}$. To fix ideas, consider each of these consequences as terminal wealth. Suppose that F is the set of all *Savage acts*, where any $f \in F$ is a mapping $f : S \rightarrow X^m$; so $f(s_i) \in X$ is the outcome received by the decision maker when the state is s_i (see Section 1.3 for *Savage acts*).

Suppose that $r \in X^m$ is some *reference Savage act*; think of the reference act as the *state-wise entitlement* expected by the decision maker. Then, for $f, g \in F$, $f \succeq_r g$ denotes the preference of the decision maker for f over g when his reference act is r . In contrast to this *state-contingent reference act*, PT considers the special case when r is a *constant act*, i.e., $r(s_i) = r(s_j)$ for any $s_i, s_j \in S$.

Schmidt et al. (2008) propose the following preference representation. Suppose that a decision maker has the reference act r and wishes to compute his utility from the act f . Let

$$v(f(s_i), r(s_i)) = v(f(s_i) - r(s_i))$$

denote the utility in state s_i under the act f when the reference act is r . The function v is given in Definition 2.31, and a parametric form is given in (2.20). Thus, v is increasing and $v(r(s_i), r(s_i)) = 0$. Order the states in S in such a way that $f(s_i) - r(s_i)$ is increasing. Let S^+ be

the set of states for which $f(s_i) - r(s_i) \geq 0$ and S^- be the set of states for which $f(s_i) - r(s_i) < 0$. Then the utility of the decision maker from the act f when his reference act is r is given by

$$V(f, r) = \sum_{s_i \in S^-} \pi(s_i; f, r) v(f(s_i), r(s_i)) + \sum_{s_i \in S^+} \pi(s_i; f, r) v(f(s_i), r(s_i)), \quad (2.52)$$

where $\pi(s_i; f, r)$ is the decision weight corresponding to the state s_i . The decision weights are constructed as in Definition 2.33, separately cumulated in the domain of gains (S^+) and losses (S^-). The utility function V represents preferences in the sense that $f \succeq_r g \Leftrightarrow V(f, r) \geq V(g, r)$. As under PT, a decision maker who has these preferences does not choose stochastically dominated options. This implies that if for $f, g \in F$, $f(s_i) \geq g(s_i)$ for all $s_i \in S$, with strict inequality in at least one state, then $V(f, r) > V(g, r)$. EU, RDU, PT are all special cases of this framework. Sugden's (2003) *reference dependent subjective expected utility theory* (RDSEU) is also a special case when $\pi(s_i; f, r) = p_i$.

Schmidt et al. (2008) suggest the following parametric form. For the utility function, v , they suggest the parametric form in (2.20) and for the probability weighting function (that feeds into the calculations of decision weights) they propose the Tversky and Kahneman (1992) probability weighting function given in (2.5) with an identical weighting function in the domain of gains and losses. As parameter values they suggest the following. The parameter of loss aversion, $\lambda \in [1, 2.5]$, the utility function parameter in (2.20), $\gamma \in [0.5, 1]$, and the weighting function parameter in (2.5), $\tau \in [0.5, 1]$.

This framework can explain (i) the WTA/WTP disparity (see Section 3.2), provided the coefficient of loss aversion, $\lambda > 1$, and (ii) preference reversals (Section 1.5.6). Let us consider the WTA/WTP disparity. We first define *non-reversible preferences*. These preferences imply that if one prefers the act f over g when the reference act is g , one must continue to do so even if the reference act is altered to f .

Definition 2.44 *The preferences of a decision maker are said to be non-reversible if $f \succeq_g g \Rightarrow f \succeq_f g$. Preferences are said to be strictly non-reversible if $f \succeq_g g \Rightarrow f \succ_f g$, where $\succ$ is the strict preference relation.*

Proposition 2.16 (Schmidt et al., 2008): (a) *Strict non-reversibility implies the WTA/WTP disparity.*

(b) *The parameterized version of PT³ satisfies strict non-reversibility if the parameter of loss aversion $\lambda > 1$.*

Proof: In this case, the reference act is the constant act (e.g., possession or non-possession of a mug in all states). Let r be a constant act such that $r(s_i) = z$ for all $s_i \in S$ and let $r \sim_g g$. Clearly z is the WTA of the act g . Now suppose that r' is another constant act such that $r'(s_i) = z'$ for all $s_i \in S$ and let $r' \sim_{r'} g$. A moment's reflection reveals that z' is the WTP for the act g . Suppose preferences are strictly non-reversible. Then $r \sim_g g \Rightarrow r \succeq_g g$ and $g \succeq_g r$. But due to strict non-reversibility, $r \succeq_g g \Rightarrow r \succ_r g$. So $r \succ_r g \sim_{r'} r'$, thus, $\text{WTA} > \text{WTP}$.

(b) Left to the reader as an exercise. ■

2.8 Stochastic reference points in PT under rational expectations

Kőszegi and Rabin (2006) argue that existing evidence in support of the status quo as a reference point comes from experiments where the status quo is expected to remain unchanged in the

future. However, when future values of the relevant variables of interest, say, income or wealth, are uncertain, then expectations about the future may be critical in the formation of the reference point. Recent evidence supports the idea that expectations can influence reference points (Ericson and Fuster, 2011). In one set of experiments, they endowed subjects with a mug and then probabilistically offered them a chance of exchanging the mug with a second object, a pen. When the probability of exchanging the mug for the pen was low, they found that subjects were less willing to exchange their mugs when they had an opportunity to do so.

We now explain the basic framework in Köszegi and Rabin (2006). Suppose that $c \in \mathbb{R}$ is the level of consumption. Different values of consumption could correspond to, say, dated values of consumption or to the levels of consumption in different states of the world. Let $r \in \mathbb{R}$ be a reference point.

Suppose that the actions of a decision maker lead to stochastic draws of consumption c with some distribution function F . Define the expected utility of the decision maker, conditional on a fixed reference point r as

$$U(F | r) = E_c u = \int u(c | r) dF(c), \quad (2.53)$$

where u is a utility function of consumption, conditional on the reference point, and F is induced by a particular action of the decision maker.

The reference point r captures the beliefs of the decision maker about the possible outcomes, hence, a fixed reference point may not be reasonable. Since the consumption outcomes are stochastic, the reference point, r , may also be thought of as stochastic (as in Section 2.7) with a distribution function, G . The reference point reflects the decision maker's most recent beliefs about future outcomes. To quote from Köszegi and Rabin (2006): "Specifically, a person's reference point is her probabilistic beliefs about the impending outcome between the time she first focused on a decision and shortly before the time of consumption."

The expected utility of the decision maker when the reference point is stochastic is given by

$$U(F | G) = E_c E_r u = \int \left[\int u(c | r) dG(r) \right] dF(c). \quad (2.54)$$

This approach is similar to theories of disappointment aversion (Bell, 1985; Loomes and Sugden, 1986; Gul 1991; see Section 2.10.2). In these theories, one compares the consumption outcomes with a reference lottery that equals the certainty equivalent of the lottery. By contrast, in the Köszegi–Rabin framework, we compare each consumption outcome with each possible element of the reference lottery as in (2.54).

In PT, the utility function depends only on *gain-loss utility*, i.e., the utility of an outcome relative to the reference point. By contrast, in the Köszegi–Rabin framework, the conditional utility, u , depends on (i) the absolute level of *consumption utility*, and (ii) *gain-loss utility*, in the following manner.

$$u(c | r) = m(c) + l(c | r). \quad (2.55)$$

Remark 2.7 In a more general model, one may consider an N -dimensional vector of consumption, $c = (c_1, c_2, \dots, c_N) \in \mathbb{R}^N$ and an N -dimensional vector of reference points, $r = (r_1, r_2, \dots, r_N) \in \mathbb{R}^N$. The analogue of (2.55) in this case is given by:

$$m(c) = \sum_{j=1}^N m_j(c_j) \text{ and } l(c | r) = \sum_{j=1}^N l_j(c_j | r_j), \quad (2.56)$$

where m_j and l_j denote, respectively, consumption utility and gain-loss utility. For $j = 1, 2, \dots, N$, each m_j is a differentiable and strictly increasing function. Both components of utility, m and l , are additively separable across the N dimensions. The gain-loss utility across each dimension is assumed identical, and it has the following form

$$l_j(c_j | r_j) = \mu (m_j(c_j) - m_j(r_j)). \quad (2.57)$$

However, for the case of (2.55) we have

$$l(c | r) = \mu (m(c) - m(r)). \quad (2.58)$$

Example 2.16 John faces the consumption lottery $(c_1, p_1; c_2, p_2)$, where $c_1 < c_2$ and $p_1 + p_2 = 1$. Denote the probability distribution over these consumption levels by F . In theories of disappointment aversion, the reference point r is given by $\bar{r}$, the certainty equivalent, hence, the distribution G is degenerate at $\bar{r}$. The decision maker's utility in this case is given by

$$U = \sum_{i=1}^2 p_i v(c_i | \bar{r}),$$

where v is the standard utility function under PT (see Definition 2.31).

However, in the Köszegi–Rabin framework, uncertainty about the future induces a stochastic reference point. Suppose that the reference point r has the distribution G , such that $r = r_1$ with probability q_1 and $r = r_2$ with probability q_2 and $q_1 + q_2 = 1$. Then John's expected utility in (2.54) is given by

$$U(F | G) = p_1 \left[\sum_{j=1}^2 q_j u(c_1 | r_j) \right] + p_2 \left[\sum_{j=1}^2 q_j u(c_2 | r_j) \right]. \quad (2.59)$$

Substituting (2.55) and (2.58) in (2.59) we get

$$\begin{aligned} U(F | G) = & \sum_{i=1}^2 p_i m(c_i) + p_1 \left[\sum_{j=1}^2 q_j \mu (m(c_1) - m(r_j)) \right] \\ & + p_2 \left[\sum_{j=1}^2 q_j \mu (m(c_2) - m(r_j)) \right]. \end{aligned} \quad (2.60)$$

The first term in (2.60) is standard expected utility and the next two terms capture gain-loss utility for each realization of the consumption level, weighted by the probability of its occurrence. For instance, in the second term in (2.60), when the realized consumption level is c_1 , John compares his consumption with both possible realizations of the stochastic reference point; it is possible that he is elated in one of the comparisons and disappointed in the other. He performs a similar comparison in the third term when realized consumption is c_2 . Notice that in this approach, probability is weighted linearly, as under expected utility theory. This assumption is contrary to the strong evidence on non-linear probability weighting that we review extensively in Part 1 (Fehr-Duda and Epper, 2012).

The properties of gain-loss utility, μ , are as follows.

Definition 2.45 The gain-loss utility, $\mu(x)$, is continuous, differentiable for all $x \neq 0$, and strictly increasing. It has the following properties.

- (i) (Reference dependence) $\mu(0) = 0$.

- (ii) (Large stakes loss aversion) For $0 < x < y$, $\mu(y) - \mu(x) < \mu(-x) - \mu(-y)$.³⁶
- (iii) (Small stakes loss aversion) Let $\mu'_+(0) = \lim_{x \rightarrow 0^+} \mu'(x)$ and $\mu'_-(0) = \lim_{x \rightarrow 0^-} \mu'(x)$. Then $\frac{\mu'_-(0)}{\mu'_+(0)} = \lambda > 1$, where λ is the parameter of loss aversion.
- (iv) (Diminishing sensitivity) For $x > 0$, $\mu''(x) \leq 0$ and for $x < 0$, $\mu''(x) \geq 0$.

The properties listed in Definition 2.45 are similar to those in Definition 2.31, except for the difference between small and large stakes loss aversion. For alternative definitions of loss aversion, see Section 2.5.2. For small stakes gambles, it is assumed that μ is linear,

$$\mu(y) = \begin{cases} \eta y & \text{if } y \geq 0 \\ \eta \lambda y & \text{if } y < 0 \end{cases}, \quad \eta > 0, \lambda > 1. \quad (2.61)$$

In applying (2.54), one has to specify how the expectations about the reference point are formed. While the appropriate specification of a reference point is ultimately an empirical question, as a first pass, Köszegi and Rabin make the extreme assumption that the expectations of the decision maker are fully consistent with rational expectations in a manner that we specify below.

The next proposition formalizes two intuitive ideas that follow from Definition 2.45. First, if one's reference point is low, then most realized outcomes are in the domain of gains, hence, the decision maker's utility will be higher. Since the reference point is stochastic, a natural formalization of a "lower reference point" is to compare two distributions of reference points in which one distribution first order stochastically dominates the other. The dominated distribution gives a higher probability of lower reference points, hence, this should be the one that the decision maker should prefer. Second, individuals have a status-quo bias in the following sense. If a decision maker prefers the consumption bundle c to c' , when the reference point is c' , then the decision maker also prefers c to c' if the reference point is c . This is related to the idea of non-reversible preferences in Definition 2.44.

Proposition 2.17 (Köszegi and Rabin, 2006): Let μ satisfy the conditions in Definition 2.45.

- (i) Suppose that the distribution of consumption is given by F . Consider two distributions of the reference point, G and G' , such that G' first order stochastically dominates G . Then $U(F | G) \leq U(F | G')$, where U is defined in (2.54).
- (ii) Suppose that $c, c' \in \mathbb{R}$ and $c \neq c'$. Then

$$u(c | c') \geq u(c' | c') \Rightarrow u(c | c) \geq u(c' | c). \quad (2.62)$$

The next example illustrates Proposition 2.17.

Example 2.17 Suppose that in Example 2.16, $c_1 = 0$, $c_2 = 1$, $p_1 = p_2 = 0.5$. Let the reference point be $r_1 = 0$ with probability q_1 and $r_2 = 1$ with probability q_2 . Suppose that μ is linear as in (2.61) and $m(x) = x$, then, from (2.60), the utility function of the decision maker is

$$U(F | G) = \frac{1}{2} + \frac{1}{2} \eta (q_1 - q_2 \lambda).$$

Now consider another distribution of reference points, G' that dominates G . Under G' , the probability of reference point $r = 1$ is $q'_2 > q_2$ and $r = 0$ is $q'_1 < q_1$. Then $U(F | G) - U(F | G') = \frac{1}{2} \eta [(q_1 - q'_1) + \lambda (q'_2 - q_2)] > 0$, as predicted by Proposition 2.17(i).

³⁶ Suppose that μ is linear such that $\mu(x) = x$ for $x > 0$ and $\mu(x) = 2x$ for $x < 0$. Let $x = 5$ and $y = 10$ then $\mu(y) - \mu(x) = 5$ and $\mu(-x) - \mu(-y) = 10$.

The proof of Proposition 2.17(ii) is relatively straightforward. Let $u(c \mid c') \geq u(c' \mid c')$ and suppose that $u(c \mid c) < u(c' \mid c)$. Then, a few simple calculations show that substituting the values of $u(c \mid c)$, $u(c' \mid c)$ lead to a contradiction.

From (2.55), $u(c \mid r) = m(c) + l(c \mid r)$. Thus, the utility function in the Köszegi–Rabin framework differs from the standard PT utility function in having the first term, $m(c)$, that depends on the absolute level of consumption. When large stakes are involved, then changes in utility are driven more by the first term, i.e., changes in marginal utility that economists are typically used to thinking about. However, when small stakes are involved, m is likely to be linear, so one may wonder if the Köszegi–Rabin utility function $u(c \mid r)$ behaves in a manner that is similar to gain–loss utility in prospect theory. This is formalized in the next result.

Proposition 2.18 (Köszegi and Rabin, 2006): Suppose that stakes are small so that consumption utility, m , is linear and gain–loss utility μ satisfies the conditions in Definition 2.45. Then, there exists a utility function v that also satisfies the conditions in Definition 2.45 such that for all $c \in \mathbb{R}$ and $r \in \mathbb{R}$ we have³⁷

$$u(c \mid r) - u(r \mid r) = v(c - r).$$

However, for large stakes, when m is non-linear, Proposition 2.18 does not hold.

A choice set, D_k , $k = 1, 2, \dots$ is a set of probability distributions over $\mathbb{R}$ (possibly degenerate), so $D_k \in \Delta\mathbb{R}$. Suppose that the decision maker expects to choose $F_k^* \in D_k$. The decision maker's beliefs are represented by a distribution Q over the choice sets $\{D_k\}_{k \in \mathbb{N}}$ such that q_k is the probability that choice set D_k occurs and F_k^* is chosen.³⁸ Thus, the decision maker's expected choice, prior to the resolution of uncertainty is

$$\sum_{j \in \mathbb{N}} q_j F_j^*.$$

We now define three different kinds of equilibrium concepts, depending on how far in advance of the resolution of uncertainty, the decision maker makes his choice. But first it is worth going through an example that clarifies the various constructions involved.

Example 2.18 Consider the example shown in Figure 2.10. In this case, there are two choice sets, D_1 and D_2 . Each choice set is a degenerate probability distribution over meals.³⁹ Choice set D_1 gives a choice of eating out at one of two restaurants A or B. Choice set D_2 gives a choice of two takeaway meals to be eaten at home—C or D. In richer descriptions, each choice could be a probability distribution over a set of restaurants or a set of takeaway meals. Suppose that the decision maker knows that if he eats out (the choice set D_1), he prefers restaurant B (decision F_1^*), and if he eats at home (the choice set D_2), he prefers takeaway C (decision F_2^*). The decision maker's beliefs are represented by a distribution Q over the choice sets $\{D_1, D_2\}$, such that D_1 and D_2 are believed to occur with respective probabilities q and $1 - q$.

³⁷ When the consumption and the reference point are drawn from $\mathbb{R}^N$ then under the conditions of Proposition 2.18, there exist utility functions $(v_1, v_2, \dots, v_N) \in \mathbb{R}^N$ that also satisfy the conditions in Definition 2.45 such that for all $c = (c_1, c_2, \dots, c_N) \in \mathbb{R}^N$ and $r = (r_1, r_2, \dots, r_N) \in \mathbb{R}^N$ we have $u(c \mid r) - u(r \mid r) = \sum_{j=1}^N v_j(c_j - r_j)$.

³⁸ We consider here the case where the decision sets are sequences, $\{D_k\}_{k \in \mathbb{N}}$. For an extension to the continuous case, $\{D_k\}_{k \in \mathbb{R}}$, see Köszegi and Rabin (2006, 2007).

³⁹ We assume that the meals can be translated into some units on the real line.

Figure 2.10 The case of two choice sets.

Consider first, situations where decisions are made sufficiently in advance of the actual outcomes, such as in insurance decisions. In this case, the individual gets enough time to be *acclimated* to the decision. If $\{F_k^* \in D_k\}_{k \in \mathbb{N}}$ are the choices, then the individual regards $\sum_{j \in \mathbb{N}} q_j F_j^*$ as the reference point (or reference distribution). In this case, the relevant equilibrium is a *choice acclimating personal equilibrium* (CPE).

Definition 2.46 (Kőszegi and Rabin, 2007, p. 1058) Suppose that $\{D_k\}_{k \in \mathbb{N}}$ is a sequence of choice sets. Then $\{F_k^* \in D_k\}_{k \in \mathbb{N}}$ is choice acclimating personal equilibrium (CPE) if for each D_k ,

$$U\left(F_k^* \mid \sum_{j \in \mathbb{N}} q_j F_j^*\right) \geq U\left(F'_k \mid q_k F'_k + \sum_{j \in \mathbb{N}/k} q_j F_j^*\right) \text{ for all } F'_k \in D_k.$$

Thus, once the decision made by the decision maker becomes the reference point, then, in a CPE, for each choice set, no other decision in the choice set can make the decision maker better off. This is the sense in which rational expectations are used to close the model. In particular, the decision maker correctly forecasts the economic environment and his own reaction in each possible state of the environment and then maximizes utility conditional on these “correct” expectations. We give several applications of a CPE below, but first, let us continue with Example 2.18 for a simple illustration of Definition 2.46.

Example 2.19 Consider Example 2.18. The selection $\{F_1 = B, F_2 = C\}$ described in Example 2.18 is a CPE if the following two conditions are met.

$$U(B \mid qB + (1-q)C) \geq U(A \mid qA + (1-q)C). \quad (2.63)$$

$$U(C \mid qB + (1-q)C) \geq U(D \mid qB + (1-q)D). \quad (2.64)$$

Notice that in each of (2.63) and (2.64), if the decision maker deviates from one of the planned choices, then the new choice becomes a part of the stochastic reference point. This is a central feature of a CPE.

In contrast to a CPE, a second possibility is that the decision maker makes his decision too close to the actual resolution of uncertainty (e.g., buying insurance for a travel plan in order to take advantage of some last minute travel deals). In this case, the relevant equilibrium notion is one of an *unacclimating personal equilibrium* (UPE).

Definition 2.47 (Kőszegi and Rabin, 2007, p. 1056) Suppose that $\{D_k\}_{k \in \mathbb{N}}$ is a sequence of choice sets. Then $\{F_k^* \in D_k\}_{k \in \mathbb{N}}$ is an unacclimating personal equilibrium (UPE) if for each D_k ,

$$U\left(F_k^* \mid \sum_{j \in \mathbb{N}} q_j F_j^*\right) \geq U\left(F'_k \mid \sum_{j \in \mathbb{N}} q_j F_j^*\right) \text{ for all } F'_k \in D_k.$$

In Köszegi and Rabin (2006, p. 1143) a UPE is simply described as a “personal equilibrium” (PE).

In Definition 2.47, the decision maker expects to choose $\{F_k^* \in D_k\}_{k \in \mathbb{N}}$ and his beliefs about the distribution of the relevant choice sets are given by Q . Taking these expectations as the reference point, in a UPE, the decision maker indeed finds it optimal to choose $F_k^* \in D_k, k \in \mathbb{N}$.

Example 2.20 Consider Example 2.18. The selection $\{F_1 = B, F_2 = C\}$ described in Example 2.18 is a UPE, if the following two conditions are met.

$$U(B \mid qB + (1 - q)C) \geq U(A \mid qB + (1 - q)C). \quad (2.65)$$

$$U(C \mid qB + (1 - q)C) \geq U(D \mid qB + (1 - q)C). \quad (2.66)$$

The main difference from the conditions in (2.63) and (2.64) is that the reference point is now attuned only to the choices $F_1 = B$ and $F_2 = C$ that occur with respective probabilities q and $1 - q$.

What is the relevant equilibrium concept when a UPE leads to multiple equilibria? Unlike cases of multiple equilibria in strategic interaction, the setting of a game against nature is much simpler. The relevant refinement, embodied in a *preferred personal equilibrium* (PPE), is that restricting to the set of UPE, the decision maker picks the sequence $\{F_k\}_{k \in \mathbb{N}}$ that gives him the highest ex-ante expected utility.

Definition 2.48 (Köszegi and Rabin, 2006, p. 1144) Suppose that $\{D_k\}_{k \in \mathbb{N}}$ is a sequence of choice sets. Then $\{F_k \in D_k\}_{k \in \mathbb{N}}$ is a preferred personal equilibrium (PPE) if $\{F_k \in D_k\}_{k \in \mathbb{N}}$ is a UPE and for all UPE sequences $\{F'_k \in D_k\}_{k \in \mathbb{N}}$ we have that

$$U\left(\sum_{j \in \mathbb{N}} q_j F_j \mid \sum_{j \in \mathbb{N}} q_j F_j\right) \geq U\left(\sum_{j \in \mathbb{N}} q_j F'_j \mid \sum_{j \in \mathbb{N}} q_j F'_j\right).$$

Let us now consider a simple example that illustrates the difference between a CPE and a UPE.

Example 2.21 Suppose that a decision maker has current wealth w and he faces the lottery $L = (w - 100, 0.5; w, 0.5)$, thus, with probability 0.5, the decision maker faces a potentially large loss. The decision maker can pay an insurance premium of 55 and obtain, instead, the lottery $L' = (w - 55, 1)$. Denote the probability distributions over outcomes in the lotteries L and L' by respectively, F and F' . Should the decision maker buy insurance?

- (a) Consider first a CPE. In this case, there is significant time between the actual decision and the resolution of uncertainty. So, if the decision maker does not buy insurance, his reference point is the lottery L and if he buys insurance, the reference point is the lottery L' . In a CPE, it is profitable to buy insurance if

$$U(F \mid F) \leq U(F' \mid F'), \quad (2.67)$$

where U is defined in (2.54) to (2.58). Let consumption utility be linear, so $m(x) = x$ and let μ be given by (2.61). Then, (2.67) can be written as

$$\frac{1}{2} \left[(w - 100) + \frac{1}{2} \eta \lambda (-100) \right] + \frac{1}{2} \left[w + \frac{1}{2} \eta (100) \right] \leq w - 55, \quad (2.68)$$

where the LHS and RHS of (2.68) give, respectively, $U(F | F)$ and $U(F' | F')$. In computing $U(F' | F')$, note that the outcome under the lottery F' is a certain outcome so there is no gain-loss utility. However, gain-loss utility plays a critical role in the computation of $U(F | F)$. When the outcome is $w - 100$, the decision maker suffers a loss relative to the reference outcome w . Analogously, when the outcome is w , there is a feeling of gain relative to the reference outcome $w - 100$.

- (b) Consider now the case of a UPE. Buying insurance is a UPE, if having initially planned to buy the insurance, the individual finds it optimal to carry out the initial plan to buy rather than not buy insurance. Hence, in a UPE, it is profitable to buy insurance if

$$U(F | F') \leq U(F' | F'). \quad (2.69)$$

$U(F' | F')$ is already given by the RHS of (2.68). However, $U(F | F')$ is 2.22 given by

$$U(F | F') = \frac{1}{2} [w - 100 - 45\eta\lambda] + \frac{1}{2} [w + 55\eta]. \quad (2.70)$$

If we are now willing to specify the values of λ and η , then we can carry out the relevant comparisons for each of the two equilibria.

Example 2.22 (Stochastic dominance and CPE⁴⁰): One undesirable feature of a CPE is that the decision maker may choose stochastically dominated options. Let us use the gain-loss function of the form given in (2.61):

$$\mu(y) = \begin{cases} 0 & \text{if } y \geq 0 \\ \hat{\lambda}y & \text{if } y < 0 \end{cases}, \hat{\lambda} = \eta(\lambda - 1) \geq 0.$$

The decision maker is loss averse if $\hat{\lambda} > 0$ and loss neutral if $\hat{\lambda} = 0$. Consider the following two lotteries

$$A = (10, p; 20, 1 - p); B = (10, 1), 0 < p < 1.$$

Clearly, lottery A first order stochastically dominates B (the distribution function for lottery A lies everywhere below that for B). In a CPE, using a condition analogous to (2.67), the decision maker prefers lottery B to lottery A if

$$p10 + (1 - p)20 - p(1 - p)\eta(\lambda - 1)10 < 10$$

or, $B \succ A$ is equivalent to

$$\frac{1}{p} < \eta(\lambda - 1).$$

The LHS attains a minimum value of 1. Thus, if $\hat{\lambda} = \eta(\lambda - 1) < 1$, then the preference for the stochastically dominated option ($B \succ A$) can never arise for any p . For this reason, applications of this framework often make such an assumption. On the other hand, if

⁴⁰ I am grateful to Fabian Herweg for suggesting this example.

$\hat{\lambda} = \eta(\lambda - 1) > 1$, then for some values of p , a decision maker chooses the stochastically dominated option in a CPE.⁴¹

What is the relation between the Köszegi–Rabin framework and PT³? Schmidt et al. (2008, p. 207) argue that when the Köszegi–Rabin framework is recast in terms of Savage acts, it has an undesirable implication. It is possible that for two acts f and g , the probabilities of each state are the same but for at least some $s_i \in S$ it is the case that $f(s_i) \neq g(s_i)$. Since the probabilities are identical across all states, the Köszegi and Rabin framework would treat these two acts as identical, yet under PT³ these acts are not identical (see (2.52)).

There are at least two issues for applied economists in testing the Köszegi and Rabin framework. First, it is not clear how much time should elapse before the decision maker has become acclimatized to his decision, hence, the choice between a CPE and a UPE can be unclear. Since the predictions of a CPE and a UPE may be different, this is an important consideration in making the theory falsifiable. A second issue is the “strength” of empirical tests. Empirical tests that simply demonstrate “expectations driven reference points” are consistent with the Köszegi and Rabin framework, but not stringent enough to reject it. For instance, such tests may not be able to distinguish between the Köszegi–Rabin framework and theories of disappointment aversion. A stringent test must, therefore, incorporate the rational expectations built into the Köszegi and Rabin framework. It is worth bearing this in mind when you read Section 2.8.3.

In the remaining subsections we give examples of a CPE and a UPE as well as the empirical evidence for this class of models.

2.8.1 An example of a choice acclimating equilibrium (CPE): The newsvendor problem

We now consider an example of a CPE in a newsvendor problem, due to Herweg (2013). At the beginning of a *trading period* (say, a day) a newsvendor orders a quantity $q \geq 0$ of newspapers at a unit wholesale price, w ; this is the only decision made by the newsvendor. The vendor is uncertain about the demand for newspapers, x , which is known to be distributed over the interval $[x, \bar{x}]$ with density f and distribution F . The retail price of newspapers is $p \geq 0$ per unit. During the trading period, the ordered quantity q cannot be replenished. Any unsold newspapers, $q - x$, are sold at a scrap price of $s \geq 0$ per unit. We assume that

$$0 \leq s < w < p. \quad (2.71)$$

Thus, the vendor always makes a profit on any newspapers that are sold and a loss on any newspapers that are unsold. This allows gain–loss utility to play an important role in the vendor’s decisions. The ex-post state-dependent profits of the vendor are

$$\pi(q, x) = \begin{cases} \pi_L(q, x) = (p - w)x + (q - x)(s - w) & \text{if } x < q \\ \pi_H(q, x) = (p - w)q & \text{if } x \geq q \end{cases}. \quad (2.72)$$

Ex-ante, the newsvendor cannot know for certain what his profits will be. However, using the distribution of possible demand levels, F , and (2.72), the expected profit of the newsvendor is

⁴¹ This may create technical problems. For instance, non-concavities of the target function (Herweg, 2013) or non-existence of a contract that implements certain actions (Herweg et al., 2010).

$E\pi(q, x) = \int_{\underline{x}}^q \pi_L(q, x) dF(x) + \int_q^{\bar{x}} \pi_H(q, x) dF(x)$. From (2.72)

$$\pi_L = (p - s)x - (w - s)q, \quad (2.73)$$

hence, we can rewrite expected profits as

$$E\pi(q, x) = \left[-(w - s)qF(q) + (p - s) \int_{\underline{x}}^q x dF(x) \right] + (p - w)q(1 - F(q)). \quad (2.74)$$

The classical solution maximizes $E\pi(q, x)$ by a suitable choice of q . The first order condition is sufficient because the objective function is strictly concave. The solution, $q = q^*$, is given by

$$F(q^*) = \frac{p - w}{p - s} \in (0, 1). \quad (2.75)$$

Suppose now that the newsvendor has the Köszegi–Rabin utility, U , defined in (2.54) to (2.58). Thus, the ex-post utility of the newsvendor for a fixed q, x, r is given by

$$U = \pi(q, x) + \mu(\pi(q, x) - r), \quad (2.76)$$

where r is the reference point and the gain–loss utility is assumed to take the particularly simple form

$$\mu(y) = \begin{cases} 0 & \text{if } y \geq 0 \\ \lambda y & \text{if } y < 0 \end{cases}, \quad \lambda \in [0, 1]. \quad (2.77)$$

The restriction $\lambda \in [0, 1]$ ensures that the newsvendor's objective function is concave. The reference point itself is determined as in the Köszegi–Rabin framework. We assume that the choices are made sufficiently in advance of the outcome so that the concept of the choice acclimating personal equilibrium (CPE) in Definition 2.46 applies.

Suppose that the newsvendor has ordered some quantity, q , and a particular level of demand x has materialized. If the decision maker has acclimatized with the decision (CPE), the reference point, r , in (2.76) is $\pi(q, z)$ where z has the distribution function $F(z)$. Thus, conditional on given levels of q, x , the utility of the newsvendor is

$$U = \pi(q, x) + \int_{\underline{x}}^{\bar{x}} \mu(\pi(q, x) - \pi(q, z)) dF(z), \quad (2.78)$$

where μ is defined in (2.77). There are two possibilities.

I. ($x < q$): For any particular choice of q , followed by any realization of demand such that $x < q$, the material utility of the newsvendor is $\pi_L(q, x) = [(p - s)x - (w - s)q]$ defined in (2.73). The reference point is given by $\pi(q, z)$ and z has the distribution function $F(z)$. There are two subcases to consider: $z < q$ and $z \geq q$. When $z < q$, μ is defined on the term $\pi_L(q, x) - \pi_L(q, z) = (p - s)(x - z)$. For any $z \geq q$, μ is defined on the term $\pi_L(q, x) - \pi_H(q, z) = (p - s)(x - q) < 0$. Thus, the gain–loss utility (second term in (2.78)) is

$$\int_{\underline{x}}^x \mu((p-s)(x-z)) dF(z) + \int_x^q \mu((p-s)(x-z)) dF(z) + \int_q^{\bar{x}} \mu((p-s)(x-q)) dF(z). \quad (2.79)$$

Using the first row of (2.77), the first term in (2.79) is zero. Using the second row in (2.77), the second term equals $-\lambda(p-s) \int_x^q (z-x) dF(z)$ and the third equals $-\lambda(p-s)(q-x)(1-F(q))$. Hence, the Köszegi–Rabin utility of the newsvendor for a particular realization of x , when $x < q$ is given by

$$U^-(q, x) = [(p-s)x - (w-s)q] - \lambda(p-s) \int_x^q (z-x) dF(z) - \lambda(p-s)(q-x)(1-F(q)). \quad (2.80)$$

II. ($x \geq q$): In this case, the realized demand exceeds the ordered supply. From (2.77), gain–loss utility $\mu(y) = 0$ if $y \geq 0$. Hence, the vendor will be able to sell his entire stock, q at a price p per unit. Thus, his material utility is given by $\pi_H = (p-w)q$ (see (2.72)) and there is no gain–loss utility. Thus, his Köszegi–Rabin utility for a particular realization of x , when $x \geq q$ is given by

$$U^+(q, x) = (p-w)q. \quad (2.81)$$

The utility levels in (2.80), (2.81) are for fixed levels of x (either side of q). However, ex ante, the newsvendor does not know the realization of x . Thus, his expected utility is $EU(q) = \int_{\underline{x}}^q U^-(q, x) dF(x) + \int_q^{\bar{x}} U^+(q, x) dF(x)$. Substituting U^- and U^+ from (2.80), (2.81), we get

$$\begin{aligned} EU(q) &= \int_{\underline{x}}^q [(p-s)x - (w-s)q - \lambda(p-s) \int_x^q (z-x) dF(z) \\ &\quad - \lambda(p-s)(q-x)(1-F(q))] dF(x) + (p-w)q(1-F(q)). \end{aligned} \quad (2.82)$$

The vendor with Köszegi–Rabin preferences chooses q in order to maximize $EU(q)$ in (2.82).⁴² Since $0 \leq \lambda \leq 1$, $EU(q)$ is strictly concave. The reader can also check that corner solutions can be ruled out. This leaves only an interior solution $q = \hat{q}$, given by the solution to the first order condition.

$$EU'(\hat{q}) = 0 \Rightarrow (p-w) - (p-s)F(\hat{q}) - \lambda(p-s)F(\hat{q})(1-F(\hat{q})) = 0. \quad (2.83)$$

Evaluating the first order condition (2.83) at $q = q^*$, where q^* is given in (2.75), we get

$$EU'(q^*) = -\lambda(p-w) \left(\frac{w-s}{p-s} \right) < 0. \quad (2.84)$$

Since $EU(q)$ is strictly concave ($EU''(q) < 0$), we get from (2.84) that $\hat{q} < q^*$, i.e., a newsvendor with Köszegi–Rabin preferences finds it optimal to order a lower quantity. This reduction in the optimal quantity is driven by the loss aversion of the newsvendor. To see this, implicitly differentiate (2.83) with respect to λ to get

⁴² When $\lambda = 0$, the solution is given by (2.75).

$$\frac{\partial \hat{q}}{\partial \lambda} = \frac{(p-s)F(\hat{q})(1-F(\hat{q}))}{EU''(\hat{q})} < 0.$$

A loss averse newsvendor hedges his bet in the face of demand uncertainty by lowering the ordered amount, q , relative to the case where no loss aversion exists. If the actual demand turns out to be lower than expected, then with a lower q , a loss averse newsvendor suffers a smaller loss in utility on account of loss aversion.

2.8.2 An example of an unacclimating personal equilibrium (UPE): The taxi drivers' problem

We consider the phenomenon of the backward bending labor supply of New York cab drivers in Chapter 3. Here, we consider a stylized model of such a situation.⁴³ A taxi driver has the material utility

$$m(w, e) = we - \frac{1}{2}e^2, \quad (2.85)$$

where w is the market determined wage level, and $e \in [0, \bar{e}]$ is the taxi driver's effort level, measured in terms of number of hours worked. For any realization of the wage level, w , the taxi driver maximizes his material utility by a suitable choice of e . Since this is a strictly concave problem over a compact domain, the solution is given by

$$e^*(w) = w.$$

Thus, the labour supply curve is upward sloping.⁴⁴

Now suppose that the taxi driver has the Köszegi–Rabin utility in which the gain–loss utility applies to the income dimension as well as to the effort dimension. Thus, we need to use Remark 2.7 for the case $N = 2$. Suppose that in the optimal solution, the driver expects to put in effort $e_H \geq 0$ when the wage is w_H , and effort $e_L \geq 0$ when the wage is w_L . We also assume that the decision is made sufficiently close to the actual realization of the outcomes, so that the relevant solution concept is an unacclimating personal equilibrium, UPE (Definition 2.47).

Definition 2.49 *The taxi driver has an income target, $\bar{w}$, if $w_H e_H = w_L e_L = \bar{w}$.*

Let us assume that the taxi driver has an income target, as specified in Definition 2.49. Since $w_H > w_L$, one implication of having an income target is that $e_H < e_L$. So the driver works less when the wage is higher.

Since the driver plans to exert effort level e_j when wage is w_j , $j = H, L$, his stochastic reference point for income is

$$r_I = \begin{cases} w_H e_H & \text{with probability } p \\ w_L e_L & \text{with probability } 1 - p \end{cases},$$

⁴³ We present a simplified version of the taxi driver problem using the unpublished notes of Fabian Herweg. See also Köszegi and Rabin (2006) for a related application.

⁴⁴ In a more general model under EU, there are well-known opposing income and substitution effects such that the labor supply can be upward or downward sloping.

and the *reference point for cost of effort* is

$$r_C = \begin{cases} \frac{1}{2}e_H^2 & \text{with probability } p \\ \frac{1}{2}e_L^2 & \text{with probability } 1 - p \end{cases}.$$

Suppose that the realized wage is w , and the driver exerts the effort level e . Then, the Köszegi–Rabin utility of the driver is:⁴⁵

$$\begin{aligned} V(e \mid w, r_I, r_C) = & \left[we - \frac{1}{2}e^2 \right] + [p\mu(we - w_H e_H) + (1-p)\mu(we - w_L e_L)] \\ & + \left[p\mu\left(-\frac{1}{2}e^2 + \frac{1}{2}e_H^2\right) + (1-p)\mu\left(-\frac{1}{2}e^2 + \frac{1}{2}e_L^2\right) \right]. \end{aligned} \quad (2.86)$$

The first term in (2.86) is material utility $m(w, e)$. The second term is gain–loss utility from income. The actual income we is compared to the reference income $w_H e_H$ with probability p , and to the reference income $w_L e_L$ with probability $1 - p$. The third term is gain–loss utility from the effort level. The actual cost of effort $\frac{1}{2}e^2$ is compared to the reference cost $\frac{1}{2}e_H^2$ with probability p , and to the reference cost $\frac{1}{2}e_L^2$ with probability $1 - p$.

In a UPE, the planned choices of the driver are consistent with actual choices. Hence, we now check if the driver would like to carry out the planned choices in each state. Suppose that the driver exerts the effort level e . Then there are three cases to consider.

- C1. $e \leq e_H < e_L$. In terms of gain–loss utility, the driver is in the gain dimension with respect to effort in both states.
- C2. $e_H < e \leq e_L$. The driver is in the gain dimension with respect to the low wage state and in the loss dimension with respect to the high wage state.
- C3. $e_H < e_L \leq e$. The driver is in the loss dimension in both states.

The second dimension of gain–loss utility arises with respect to the income level, so we need to check actual income against reference income, i.e., $w_i e \gtrless \bar{w}$, $i = H, L$. We consider the various cases separately and assume that gain–loss utility, μ , takes the linear form, given in (2.61) with $\eta = 1$.

Case I. The high wage state, w_H : Suppose that the realized wage is w_H . We need to consider each of the subcases, C1, C2, and C3.

C1. $e \leq e_H < e_L$: In this case, since actual effort is lower than both levels of planned effort, so $w_i e < \bar{w}$ for $i = H, L$. Thus, the driver is in the loss dimension with respect to income and in the gain dimension with respect to effort. Using $w_H e_H = w_L e_L = \bar{w}$, the Köszegi–Rabin utility in (2.86) is

$$\begin{aligned} V(e \mid w_H, r_I, r_C) = & \left[w_H e - \frac{1}{2}e^2 \right] + [-\lambda p(\bar{w} - w_H e) - \lambda(1-p)(\bar{w} - w_H e)] \\ & + \left[\frac{p}{2}(e_H^2 - e^2) + \frac{(1-p)}{2}(e_L^2 - e^2) \right]. \end{aligned} \quad (2.87)$$

⁴⁵ It is more convenient in this example to replace the notation for the utility function U in the Köszegi–Rabin framework with the new notation V that keeps track of the effort level and the wage level in each case.

The first term is material utility, the second is gain–loss utility in the income domain, and the third is gain–loss utility in the effort domain. From (2.87), the first and second order derivatives with respect to e are: $V' = w_H(1 + \lambda) - 2e$ and $V'' = -2 < 0$. Since this is a high wage state, w_H , a UPE requires that the driver does wish to carry out his original plan of working at least e_H hours. Since $V'' < 0$, and $V' > 0$ for small values of e , a sufficient condition for ruling out the case $e < e_H$ is that $V' |_{e=e_H} \geq 0$ or $w_H(1 + \lambda) - 2e_H \geq 0$. Also $w_H e_H = \bar{w}$, so $e_H = \bar{w}/w_H$. In conjunction, these conditions imply that a sufficient condition for ruling out $e < e_H$ is

$$V' |_{e=e_H} \geq 0 \Leftrightarrow \bar{w} \leq \frac{1 + \lambda}{2} w_H^2. \quad (2.88)$$

Higher loss aversion, λ , is more conducive to the satisfaction of (2.88).

C2. $e_H < e \leq e_L$: In this case, $\bar{w} = w_H e_H < w_H e$ and $w_H e \leq w_H e_L = \bar{w}$. Thus, in the income dimension, the driver is in the domain of gains when wage is high and in the domain of losses when wage is low. In the effort dimension, the driver is in gains with respect to the low wage reference state and in losses with respect to the high wage reference state. Thus, using $w_H e_H = w_L e_L = \bar{w}$, the analogue of (2.87) is

$$\begin{aligned} V(e | w_H, r_I, r_C) = & \left[w_H e - \frac{1}{2} e^2 \right] + [p(w_H e - \bar{w}) - \lambda(1 - p)(\bar{w} - w_H e)] \\ & + \left[-\lambda \frac{p}{2} (e^2 - e_H^2) + \frac{1 - p}{2} (e_L^2 - e^2) \right]. \end{aligned} \quad (2.89)$$

In this case, one can check that $V' = w_H[1 + \lambda - p(\lambda - 1)] - e[2 + p(\lambda - 1)]$ and $V'' < 0$. In this case, $e_H < e$, so to rule it out we require $V' |_{e=e_H} \leq 0$. A simple calculation shows that if the following condition holds, then we cannot have $e_H < e$:

$$V' |_{e=e_H} \leq 0 \Leftrightarrow \bar{w} \geq \frac{w_H^2(1 + \lambda - p(\lambda - 1))}{2 + p(\lambda - 1)}. \quad (2.90)$$

C3. ($e_H < e_L \leq e$). In this case, the driver is in the domain of gains with respect to income and in the domain of losses with respect to cost of effort in both reference states. Thus, his Köszegi–Rabin utility is

$$\begin{aligned} V(e | w_H, r_I, r_C) = & \left[w_H e - \frac{1}{2} e^2 \right] + [p(w_H e - \bar{w}) + (1 - p)(w_H e - \bar{w})] \\ & - \left[\lambda \frac{p}{2} (e^2 - e_H^2) + \lambda \frac{1 - p}{2} (e^2 - e_L^2) \right]. \end{aligned} \quad (2.91)$$

A simple calculation shows that $V' = 2w_H - e(1 + \lambda)$, $V'_{e=0} > 0$, and $V'' < 0$. Using $e_H = \bar{w}/w_H$, and in order to keep to the planned effort levels (i.e., effort e_H when wage is w_H), we require that

$$V' |_{e=e_H} \leq 0 \Leftrightarrow \bar{w} \geq \frac{2w_H^2}{1 + \lambda}. \quad (2.92)$$

However, if (2.90) holds, then so too does (2.92) because with $\lambda > 1$, $\min \left\{ \frac{2}{1+\lambda}, \frac{(1+\lambda-p(\lambda-1))}{2+p(\lambda-1)} \right\} = \frac{2}{1+\lambda}$. Hence, we can rule out any departure from the planned effort level in the high wage state by using (2.88) and (2.90). The result can be summarized as follows.

Proposition 2.19 *There exists a reference income, $\bar{w}$, satisfying*

$$w_H^2 \frac{2}{1+\lambda} \leq \bar{w} \leq \frac{1+\lambda}{2} w_H^2 \quad (2.93)$$

such that the taxi driver finds it optimal to carry out his planned effort level in the high wage state.

Case II. The low wage state, w_L .

In the low wage state, w_L , one needs to check, analogously to Case I, all three subcases in C1, C2 and C3. The analogue of Proposition 2.19 in this case is given next.

Proposition 2.20 *There exists a reference income $\bar{w}$ and functions $a(w_L, \lambda)$ and $b(w_L, \lambda)$ satisfying*

$$a(w_L, \lambda) \leq \bar{w} \leq b(w_L, \lambda), \quad (2.94)$$

such that the taxi driver finds it optimal to carry out his planned effort level in the low wage state.

We leave the proof of Proposition 2.20 to the reader. Putting Propositions 2.19 and 2.20 together we get the final result.

Proposition 2.21 *There exists a UPE with an income target, $\bar{w}$, if the target jointly satisfies (2.93) and (2.94). The state-contingent effort levels are $e_i = \bar{w}/w_i$, $i = L, H$.*

We have derived in this example the conditions under which a wage target is justified. But we have not derived the optimal wage target from the set of all wage targets. In order to compute the optimal wage target, one may proceed as suggested in the definition of a PPE (Definition 2.48). For each wage target, compute the utility from the wage target, and then choose the target that maximizes this utility.⁴⁶

2.8.3 Some empirical evidence for Köszegi–Rabin preferences

In Abeler et al. (2011), subjects perform a repetitive and tedious task that has no intrinsic value to the experimenter. They count the number of zeros in a table of 150 randomly ordered digits that are either 1 or 0. In the first stage, subjects were paid a piece rate of 10 cents for each correct table; the payment was received with probability 1. In the second task, they could decide how long they wanted to work, up to a maximum allowed time of 60 minutes.

Subjects in the second task received their accumulated earnings at the piece rate of 20 cents per correct table. However, the payment was received with probability 0.5, and with probability 0.5, they received a fixed payment, $f > 0$. In the LO treatment, $f = f_{LO} = 3$ euros and in the HI treatment, $f = f_{HI} = 7$ euros. Let w be the piece rate per correct table, e the number of correct

⁴⁶ In personal communication, Fabian Herweg points out that there exist also other UPEs that are not income target effort plans. It may well be that the PPE is one of these non-target UPEs.

tables (proxy for effort), and $\phi(e)$ the cost of effort function, such that $\phi' > 0$ and $\phi'' > 0$. Consider the predictions of three different classes of model.

1. Absence of a reference point: Consider the canonical textbook model and the following additively separable utility function

$$U(e, f, w) = [0.5u(we) + 0.5u(f)] - \phi(e),$$

where u is a continuous, differentiable, strictly increasing, and concave utility function. Individuals choose e to maximize U , given w, f . The first order condition $wu'(we) = 2\phi'(e)$ is independent of f and it can be solved for the optimal effort level, e^* , which is predicted to be independent of f . In particular, when $u(x) = x$, the solution is given by

$$\phi'(e^*) = \frac{w}{2}, \quad (2.95)$$

where the LHS is the marginal cost of effort and the RHS is the marginal benefit.

2. Exogenous reference point: Suppose that there is no reference point for effort,⁴⁷ linear weighting of probabilities for simplicity, and the reference wage is exogenously given at w_r . Then, under prospect theory,

$$V(e, f, w) = [0.5v(we - w_re) + 0.5v(f - w_r)] - \phi(e).$$

The first order condition is $(w - w_r)v' = 2\phi'(e)$. The optimal effort level is predicted to be independent of f .

3. Endogenous reference: Suppose that the reference point is given as in the Köszegi–Rabin framework, so that the utility function is defined in (2.54) to (2.58). In particular, let us restrict to the linear case, so $m(c) = c$, and gain–loss utility is also linear as in (2.61). We assume that the relevant equilibrium concept is a CPE (Definition 2.46). We also assume that there is no reference point for effort but there is a reference point for wage income. There are two cases:
 - 3.1 The decision maker chooses e such that $we < f$. Prior to the resolution of uncertainty about the state, the consumption utility is $m(we) = we$ with probability 0.5 and $m(f) = f$ with probability 0.5. Each of these possible levels of consumption with the associated probabilities also serve as the reference points.

$$r = \begin{cases} we & \text{with probability 0.5} \\ f & \text{with probability 0.5} \end{cases}.$$

Each consumption level must now be compared with this stochastic reference point, and then we must aggregate over all consumption levels (see (2.54)). Denoting the Köszegi–Rabin utility in this case by U^- , we have

$$U^-(e | r) = \frac{1}{2} \left[we - \phi(e) + \frac{1}{2}\eta\lambda (we - f) \right] + \frac{1}{2} \left[f - \phi(e) + \frac{1}{2}\eta(f - we) \right]. \quad (2.96)$$

⁴⁷ This result is unchanged even if there is a positive but exogenous reference point for effort.

In the first term in (2.96), the realization of consumption utility is we . Relative to the reference point we , the decision maker experiences no gain or loss. However, relative to the reference point f , the decision maker experiences a loss. In the second term, the realization of consumption utility is f . In this case, the decision maker feels a gain relative to the potential consumption level we , and no gain or loss relative to the consumption level, f . Let $\hat{e}_-$ be the optimal consumption level when $we < f$. The first order condition, which is sufficient, is given by

$$\phi'(\hat{e}_-) = \frac{w}{2} + \frac{w}{4}\eta(\lambda - 1) = \phi'(e^*) + \frac{w}{4}\eta(\lambda - 1), \quad (2.97)$$

where e^* is the optimal effort in the absence of a reference point, see (2.95). From (2.97), if there were no loss aversion, $\lambda = 1$, then $\phi'(\hat{e}_-) = \phi'(e^*)$. Recall from (2.61) that $\lambda > 1$, so in the presence of loss aversion, $\phi'(\hat{e}_-) > \phi'(e^*)$, thus, given $\phi'' > 0$, we have $\hat{e}_- > e^*$. By implication, $we^* < f$.

- 3.2 The decision maker chooses e such that $we > f$. Denoting the Köszegi–Rabin utility in this case by U^+ , the expression analogous to (2.96) is given by

$$U^+(e | r) = \frac{1}{2} \left[we - \phi(e) + \frac{1}{2}\eta(we - f) \right] + \frac{1}{2} \left[f - \phi(e) + \frac{1}{2}\eta\lambda(f - we) \right].$$

The optimal effort level, in this case, $\hat{e}_+$, is given by the solution to the following first order condition

$$\phi'(\hat{e}_+) = \frac{w}{2} - \frac{w}{4}\eta(\lambda - 1) = \phi'(e^*) - \frac{w}{4}\eta(\lambda - 1). \quad (2.98)$$

In this case, the marginal benefit of effort at the optimal point is lower relative to the canonical model; $\phi'(\hat{e}_+) < \phi'(e^*)$, so $\hat{e}_+ < e^*$. Thus, if e^* is high enough, so that $we^* > f$, then loss aversion serves to reduce effort below e^* . By implication, $we^* > f$.

Thus, once we allow for an endogenous reference point, the fixed payment f has an effect on effort, while in the other cases it has no effect. As f increases to a high enough level as in case 3.1, so $we^* < f$, we should, on average, observe an increase in effort under endogenous reference point. An increase in f increases the loss-aversion adjusted cost of falling behind ($we < f$), hence, individuals exert more effort. This can be stated as a testable hypothesis:

H1: Average effort is higher when $f = f_H$, relative to the case $f = f_L$.

A second implication is as follows. The presence of gain–loss utility increases effort by increasing the marginal benefit of effort if $we < f$. The magnitude of this increase depends on the strength of loss aversion, λ . Gain–loss utility also reduces the marginal utility of effort when $we > f$ and, so, reduces optimal effort. In sum, loss aversion pushes effort in the direction of $we = f$. In the limit, as $\lambda \rightarrow \infty$, the first order conditions give $w\hat{e}_- = w\hat{e}_+ = f$; thus it is always optimal for the decision maker to stop exerting effort as soon as wage income equals f . Thus, f has the most powerful effect on effort in this case. This gives rise to the second testable hypothesis.

- H2:** The probability of stopping at $we = f_{LO}$ is higher when $f = f_{LO}$ relative to the case $f = f_{HI}$. Similarly, the probability of stopping at $we = f_{HI}$ is higher when $f = f_{HI}$ relative to the case $f = f_{LO}$. These effects are enhanced by an increase in loss aversion.

Figure 2.11 Histogram of accumulated earnings (in euros) at which a subject stopped.

Source: Abeler et al. (2011), with permission from the American Economic Association.

Figure 2.11 shows the histogram of earnings at which individuals stopped for two different treatments, $f_{LO} = 3$ and $f_{HI} = 7$. Individuals make fairly dispersed choices. However, there are sharp spikes at $f_{LO} = 3$ in the LO treatment, and at $f_{HI} = 7$ in the HI treatment; 15% and 16.7% of the subjects make these respective choices. These are also the modal choices in each treatment and are statistically different. By contrast, in the LO treatment, only 3.3% stop at an earnings of 7 euros and in the HI treatment, only 1.7% stop at an earnings of 3 euros.

The results are even sharper when we consider stopping values in some range that is close to the predicted value. For instance, 30% of the subjects stop in the earnings range of 2–4 euros in the LO treatment and 38.3% stop in the earnings range of 6–8 euros in the HI treatment. Average effort levels are higher under the HI treatment as compared to the LO treatment. Using a proxy for loss aversion, based on binary lottery choices, subjects who exhibit higher loss aversion are more likely to stop when their earnings are closer to f . The authors take their results as support for Köszegi–Rabin preferences and for the importance of expectations in the formation of reference points.

In the experiments of Abeler et al. (2011), subjects were not told that they were randomly assigned to one of two cases, $f = 3$ or $f = 7$. Hence, they might have inferred the value of their likely effort from the fixed payment, f , giving rise to treatment effect. Ericson and Fuster (2011) correct for this feature and perform new experiments to test the Köszegi–Rabin framework. Their first experiment is described in Figure 2.12. Experimental subjects are endowed with a mug. They then get an opportunity (Op) to exchange the mug for a pen with probability p . With probability $1 - p$, there is no opportunity to exchange (Nop) and they end the experiment with a mug. If there is an opportunity to exchange, then they can exchange with a pen or elect to keep the mug. The decision maker has to commit ex-ante (prior to getting the opportunity to exchange) if he would like to exchange the mug for a pen.

Figure 2.12 Decision tree for experiment 1 in Ericson and Fuster (2011).

Source: Keith M. Marzill Ericson and Andreas Fuster, "Expectations as endowments: evidence on reference-dependent preferences from exchange and valuation experiments," *The Quarterly Journal of Economics* (2011) 126(4): 1879–907, by permission of Oxford University Press.

Let u_P be the utility from owning a pen and u_M be the utility from owning a mug; we assume $u_P > u_M$. Under expected utility, committing ex-ante to exchange the mug for the pen gives the expected utility $pu_P + (1 - p)u_M$ and committing not to exchange gives u_M . Thus, exchange is better than no-exchange if $u_P > u_M$, which is independent of p .

Under expected utility and status-quo reference points, we can show that p does not have an effect on the decision to exchange. Here, the reference point is u_M because the decision maker is endowed with a mug. If the decision maker commits to exchange, his ex-ante utility is $p(u_P - u_M) + (1 - p)(u_M - u_M)$, and if he does not, it is $u_M - u_M = 0$. Thus, exchange is preferred if $u_P > u_M$, which is independent of p .

Under Köszegi–Rabin utility, we show below that p plays a role in the exchange decision. Hence, one can use experiments to compare the relative predictions of these theories. For pedagogical simplicity, we choose the CPE concept.

I. Suppose that the decision maker plans, ex-ante, to exchange the mug for the pen.

Let the realized utility of the decision maker be u_i , $i = P, M$ at any of the terminal nodes in Figure 2.12 (at the upper node in Figure 2.12, this is u_P , and at the lower node it is u_M). Then the Köszegi–Rabin utility, at that node, taking into account the stochastic reference point, r (u_P with probability p and u_M with probability $1 - p$), is

$$U(u_i | r) = u_i + [p\mu(u_i - u_P) + (1 - p)\mu(u_i - u_M)], \quad (2.99)$$

where μ is given in its linear form in (2.61). For ease of exposition, we shall assume $\eta(\lambda - 1) > 1$ (this can be easily implemented in experiments).

The ex-ante Köszegi–Rabin utility at the initial node in Figure 2.12, given the decision to “exchange,” is $U^{Ex} = pU(u_P | r) + (1 - p)U(u_M | r)$, where U is defined in (2.99). Thus, using μ , given in (2.61), and $u_P > u_M$, we get

$$U^{Ex} = p[u_P + (1 - p)\eta(u_P - u_M)] + (1 - p)[u_M - p\lambda\eta(u_P - u_M)],$$

or,

$$U^{Ex} = u_M + p(u_P - u_M)(1 - (1 - p)\eta(\lambda - 1)). \quad (2.100)$$

II. Suppose the ex-ante plan is not to exchange the mug.

In this case, the decision maker is always left with a mug in the end. The CPE equilibrium concept requires that the reference point in this case is u_M in all states. Thus, gain-loss utility is zero. The ex-ante Köszegi–Rabin utility in the case of “no-exchange” is simply $U^{Nex} = u_M$. Thus, the ex-ante plan to exchange the mug dominates if $U^{Ex} > U^{Nex}$, or

$$u_M + p(u_P - u_M)(1 - (1 - p)\eta(\lambda - 1)) > u_M.$$

or,

$$p > p^* = 1 - \frac{1}{\eta(\lambda - 1)}. \quad (2.101)$$

By assumption, $\eta(\lambda - 1) > 1$, hence, $0 < p^* < 1$. From (2.101), as the probability of exchanging the mug, p , increases, the decision maker is more likely to choose to exchange. Thus, in equilibrium, a higher expectation of exchange does lead to greater exchange. By contrast in the other models, p should not influence the exchange decision.

Köszegi and Rabin (2007) show that a decision maker is more risk averse when he anticipates a risk and has the possibility to insure against that risk, relative to the case where he does not anticipate the risk. A related result can be found in Köszegi and Rabin (2009) in a life-cycle consumption model. In this model, an increase in consumption today reduces the expectation of consumption tomorrow, hence, it reduces the reference point tomorrow. This is in contrast to models of habit formation where an increase in consumption today increases the reference point for consumption tomorrow by increasing the habitual consumption level.

In the Ericson and Fuster (2011) experiments, two treatments were considered: Treatment T^L where $p = 0.1$ and treatment T^H where $p = 0.9$. The findings are as follows. In treatment T^L , 22.% of the subjects chose to exchange the mug, while in treatment T^H , this figure is 55.6%; these differences are statistically significant.⁴⁸ Probit regressions that include treatment and gender indicators also confirm this result. In Treatment T^L , where $p = 0.1$, the decision maker who wishes to exchange his mug experiences a greater risk so the typical decision maker appears more risk averse by choosing not to exchange; this exemplifies the remark on the Köszegi and Rabin (2007) result alluded to in the last paragraph.

Heffetz and List (2014) modify several aspects of the experimental design in Ericson and Fuster (2011). They find that the expectations effects predicted by the Köszegi–Rabin framework are quite weak.

2.9 Limitations of PT

In this section, we consider evidence that contradicts PT in certain contexts. This evidence also typically contradicts all other mainstream decision theories in economics, such as EU and RDU.

⁴⁸ See also Smith (2008) for experimental evidence that supports the prediction of an endowment effect based on the Köszegi–Rabin framework.

2.9.1 The evidence and critique from configural weights models

We first consider the work of Michael Birnbaum and his associates who have conducted experiments that contradict the predictions of OPT (due to Kahneman and Tversky, 1979). Many of these experiments exploit the heuristics used in the editing phase of OPT (see Section 2.11.1), which are not a part of PT (due to Tversky and Kahneman, 1992). The following terminology should be helpful in understanding the experimental results.

1. (Branches) For any lottery, such as $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$, the i th *branch* is the ordered pair (x_i, p_i) . In a two branch lottery $L = (x_1, p_1; x_2, p_2)$, $x_1 < x_2$, (x_2, p_2) is sometimes known as the *upper branch* and (x_1, p_1) is known as the *lower branch*.
2. (Coalescing) Under EU, RDU, and PT if the same outcome occurs more than once in a lottery, we can simply add up the corresponding probabilities and write a lottery in *coalesced* form. For instance, the lottery $(50, 0.2; 50, 0.3; 75, 0.5)$, also known as a *split lottery*, can be written in the coalesced form $(50, 0.5; 75, 0.5)$. Under EU, RDU, PT, the decision maker should be indifferent among the split and the coalesced forms. Depending on which branch of a lottery is split up we get *upper coalescing* (branch with the highest outcome is split) and *lower coalescing* (branch with the lowest outcome is split).
3. (Consequence monotonicity) If one outcome in a gamble is improved, then this should be preferred by the decision maker. Thus, if more is preferred to less, then the lottery $(200, 0.5; 0, 0.5)$ should be preferred to $(100, 0.5; 0, 0.5)$.
4. (Branch independence) Suppose that there are two lotteries L_1, L_2 such that (1) $L_1 \succeq L_2$, (2) there is a common branch in the two lotteries, say, (x_i, p_i) for some i , and (3) the outcomes in each lottery are all distinct. Branch independence implies that if, in both lotteries, we replace branch i with another branch (y_i, p_i) , $x_i \neq y_i$ it is still the case that $L_1 \succeq L_2$. Consider the following additional property: (4) All corresponding probabilities are identical, i.e., for any i if (x_i, p_i) is the i th branch of L_1 and (y_i, q_i) is the i th branch of L_2 , then $p_i = q_i$. When all four properties hold, we have the case of *restricted branch independence* (RBI).

Experiments indicate that coalescing lotteries can alter choices among lotteries.⁴⁹ Consider, for instance, the choice between the following two pairs of lotteries.

$$A = (50, 0.05; 50, 0.10; 100, 0.85) \text{ versus } B = (7, 0.05; 100, 0.10; 100, 0.85) \\ A' = (50, 0.15; 100, 0.85) \text{ versus } B' = (7, 0.05; 100, 0.95)$$

In this pair of choices, if coalescing holds, then lotteries A, A' are identical and lotteries B, B' are also identical. Under EU, RDU, or PT, $A \succeq B$ implies $A' \succeq B'$. In contrast, for 200 subjects, Birnbaum (2004a) found that for 63% of the subjects, $B \succeq A$ and for 80% of the subjects, $A' \succeq B'$, which violates EU, RDU, and PT for a majority of the subjects.

Now consider a choice between the following two lotteries, C, D, where C first order stochastically dominates D,

$$C = (12, 0.05; 14, 0.05; 96, 0.90) \text{ versus } D = (12, 0.10; 90, 0.05; 96, 0.85).$$

⁴⁹ See, for instance, Birnbaum (1999, 2004a, 2007), Humphrey (1995, 1998, 2000), Starmer and Sugden (1993).

Birnbaum and Navarrete (1998) found that 70% of the undergraduate students in their sample chose D over C.⁵⁰ Birnbaum (2004b) found that these results are not due to subject error in reporting their true preferences. Further, he showed that splitting the branches of a tree in a particular manner can reduce violations of stochastic dominance. Consider, for instance, C' , D' that, in coalesced form, are identical to C , D respectively (so C' also first order stochastically dominates D'),

$$C' = (12, 0.05; 14, 0.05; 96, 0.85; 96, 0.05) \text{ versus } D' = (12, 0.05; 12, 0.05; 90, 0.05; 96, 0.85).$$

In C' , relative to C , the top branch has been split, while in D' , relative to D , the bottom branch is split. The splitting is done in such a way that the corresponding probabilities of all branches, when outcomes are ordered monotonically, are identical. This is known as the *canonical split form*. Birnbaum (2004b) found that 71% of the subjects violated stochastic dominance in a choice between C , D but only 5.6% did so when the choice was between C' , D' .

Birnbaum (2008) reports the following two pairs of lotteries from Birnbaum (2001).⁵¹

$$E = (0, 0.50; 68, 0.07; 92, 0.43) \text{ versus } F = (0, 0.52; 92, 0.48).$$

$$E' = (0, 0.50; 68, 0.07; 97, 0.43) \text{ versus } F' = (0, 0.52; 92, 0.05; 97, 0.43).$$

RDU and PT imply that $F \succeq E$ if and only if $E' \succeq F'$ (the reader should check this). In contrast, out of a sample of 1438 respondents, for 66%, $E \succeq F$, while for 62%, $E' \succeq F'$, which contradicts RDU/PT.⁵²

Birnbaum and Chavez (1997) find violations of restricted branch independence (RBI) but the direction of these violations is opposite to that predicted by PT.

2.9.2 Violations of gain-loss separability

Consider a lottery, as in (2.21), that is expressed in incremental form,

$$A = (y_{-m}, p_{-m}; y_{-m+1}, p_{-m+1}; \dots; y_{-1}, p_{-1}; 0, p_0; y_1, p_1; y_2, p_2; \dots; y_n, p_n),$$

where the reference outcome relative to the reference point is zero. We shall make use of the observation that in prospect theory, $v(0) = 0$, so we can assign any probability to an outcome of zero. Let the sum of probabilities in the domain of losses and gains be denoted, respectively, by $p_- = \sum_{i=-1}^{-m} p_{-i}$ and $p_+ = \sum_{j=0}^n p_j$. Then, denote by A^- and A^+ , respectively, the negative and positive components of A , having adjusted for the probability of a zero outcome in each case such that the respective probabilities in each component add upto 1.

$$A^- = (y_{-m}, p_{-m}; y_{-m+1}, p_{-m+1}; \dots; y_{-1}, p_{-1}; 0, p_+) , A^+ = (0, p_-; y_1, p_1; \dots; y_n, p_n).$$

The probabilities in each of the lotteries in incremental form, A^- and A^+ , add up to one. Using Definition 2.34, we can write the value function for lottery A as

⁵⁰ Birnbaum et al. (1999) found similar results on a new dataset.

⁵¹ These lotteries were designed to test the property of *upper tail independence* in Wu (1994).

⁵² See also Birnbaum (2005) for newer experiments that also arrive at similar findings.

$$V(A) = V(A^-) + V(A^+), \quad (2.102)$$

where $V(A^-)$ and $V(A^+)$ give the value function under PT corresponding to the two lotteries A^- and A^+ . Consider another lottery in incremental form, B , whose positive and negative components are respectively B^- and B^+ . The decision maker is given a choice between the two pairs of prospects (i) A^+ and B^+ , and (ii) A^- and B^- . Suppose that the following preference pattern is observed,

$$A^+ \succeq B^+, A^- \succeq B^-. \quad (2.103)$$

(2.103) implies that $V(A^+) \geq V(B^+)$ and $V(A^-) \geq V(B^-)$. Adding these two inequalities and using (2.102) we get

$$V(A) \geq V(B) \Leftrightarrow A \succeq B. \quad (2.104)$$

The pattern of preferences in (2.103), (2.104) constitute the property of *gain-loss separability* and it is satisfied by EU/RDU/OPT/PT. Wu and Markle (2008) give experimental evidence to reject gain-loss separability. They took the following lotteries

$$\begin{aligned} A^+ &= (0, 0.5; 4200, 0.5), \quad B^+ = (0, 0.25; 3000, 0.75) \\ A^- &= (0, 0.5; -3000, 0.5), \quad B^- = (0, 0.75; -4500, 0.25) \end{aligned}$$

In a within-subjects experimental design, they found that for a clear majority of subjects $B^+ \succeq A^+$, $B^- \succeq A^-$, yet for a slight majority of subjects, it was found that $A \succeq B$.

2.9.3 Interaction between probability weights and stake sizes

The *stake size effect* refers to the observed change in relative risk aversion as the stake size in the domain of gains goes up; the idea goes back at least to Markowitz (1952). Empirical evidence suggests that the stake size effect arises from probability weighting rather than from the utility function. This calls into question the assumed separability between probabilities and outcomes that is assumed in EU, RDU, and PT

The stake size effect has been verified in many studies but the stakes in these studies have typically not been very high or the high stakes have been hypothetical.⁵³ However, in the context of decision theory, doubts have been expressed about the use of hypothetical stakes relative to incentive compatible elicitation mechanisms.⁵⁴

Not surprisingly, some of the high stakes experiments have come from subjects in developing countries; these studies report a significant stake effect in the domain of gains (Binswanger, 1981; Kachelmeier and Shehata, 1992). Post et al. (2008) consider data with very high stakes from the TV show *Deal or no Deal* and they report changes in risk aversion depending on the initial expectations and changes in the resolution of uncertainty. They offer support for PT over EU in explaining the observed facts.

⁵³ See, for instance, Hogarth and Einhorn (1990), Bosch-Domenech and Silvestre (1999), and Weber and Chapman (2005).

⁵⁴ See, for instance, Camerer and Hogarth (1999), Beattie and Loomes (1997), and Holt and Laury (2002, 2005).

What is the source of the stake size effect? Most empirical studies have attempted to identify the source as the utility function. However, some empirical studies have identified the role of probability weighting.⁵⁵ An important advance was made by Fehr-Duda et al. (2010) who dispensed with hypothetical rewards and considered lotteries in the domain of gains and losses. We now consider their work.

Experiments were conducted in Beijing in 2005 with 56 two-outcome lotteries—28 in the domain of gains and 28 in the domain of losses. One of the lotteries each in the domain of gains and losses was then randomly selected and played for real. In order to allow for lotteries in the loss domain, subjects were given initial endowments that covered the maximum possible loss. Outcomes and probabilities varied widely in the experiment and high stake lotteries were constructed from the low stake lotteries by scaling up the amounts by integer values.

It was assumed that the subjects used RDU (which nests EU as a special case). The functional forms used were as follows. The utility is of the power form as in (2.20), and the probability weighting function is the two-parameter Goldstein–Einhorn function given in (2.7). A finite mixture model was used to detect the presence of decision makers with heterogeneous preferences.⁵⁶

Substantial heterogeneity in choices was found. About 27% of the subjects were expected utility types (labeled EUT types in Figure 2.13); they exhibited linear probability weighting functions and linear utility functions, so they are essentially expected value maximizers. The remaining 73% were non-expected utility types (labeled Non EUT types in Figure 2.13) and their probability weighting functions departed significantly from linearity. The experimental results for the two types of decision makers, separated by the gain and loss domains, and by stakes (high and low), are shown in Figure 2.13. On the vertical axis we have the relative risk premium (see 2.1). The main results arising from Figure 2.13 are as follows.

1. Fourfold classification of risk: The fourfold classification of risk that is explained above in Section 2.4.2 can be seen to hold. For each type of decision maker, in the domain of gains, for high and low stakes gains that are of low probability, we have $RRP < 0$ (see (2.1) for the definition of RRP), hence, the decision maker is risk seeking. However, for higher probabilities in the domain of gains, for both EU and non-EU types, $RRP > 0$, so the decision maker is risk averse. The reverse picture emerges in the loss domain. Here, for both high and low stakes, $RRP > 0$ for small probabilities (risk aversion) and $RRP < 0$ for high probabilities (risk seeking).
2. The stake size effect: For any probability, p , in Figure 2.13, the stake size effect can be seen to hold for both types of decision makers (EU and non-EU) in the domain of gains. In the domain of gains, RRP is higher at each level of probability (except $p = 0.95$) when stakes are high as compared to when the stakes are low. However, no clear pattern on the stake size effect emerges in the domain of losses.

What causes the stake size effect to be prominent for gains but not for losses? The curvature of the utility function captured by the parameter γ does not vary with the stake size for both types of decision makers. Statistically, one cannot reject the hypothesis that the curvature of the utility function is stake-invariant. Since the only other component of the objective function is probability weights, it seems likely that this causes the stake size effect. This intuition is confirmed statistically.

⁵⁵ See, for instance, Kachelmeier and Shehata (1992), Tversky and Kahneman (1992), Camerer (1992), and Etchart-Vincent (2004).

⁵⁶ The model is not designed to pick out prospect theory preferences because there are no mixed gambles, so loss aversion cannot be detected.

Figure 2.13 Median relative risk premium (RRP) for different types of decision makers as the probability, p , is varied.

Source: *Journal of Risk and Uncertainty*, 40(2): 147–80 (2010) “Rationality on the rise: why relative risk aversion increases with stake size,” Helga Fehr-Duda, Adrian Bruhin, Thomas Epper, and Renate Schubert, Figure 2, © Springer Science + Business Media, LLC 2010, with kind permission from Springer Science and Business Media.

The Goldstein–Einhorn function is a two-parameter family of probability weighting functions, hence, the inference about the contribution of probability weighting to the stake size effect must be based on the joint contribution of the two parameters, δ and η (see equation (2.7)). This is achieved by constructing 95% confidence bands based on the percentile bootstrap method, and using 2000 replications.

The probability weighting function for the EU types is approximately linear, so in Figure 2.14 we report only the results in the gain and loss domains for the non EU types. The probability weighting functions for high and low stakes in the domain of losses are quite similar, but there is a more marked difference in the domain of gains. In terms of the estimated parameters in the domain of gains, δ , which captures the elevation of the Goldstein–Einhorn function, decreases from 1.304 to 0.913 as stakes increase. This corresponds to a lower degree of optimism. At the same time, η goes up with stakes, which mitigates slightly the inverse S-shape of the weighting function.

In the lower panel of Figure 2.14, if the confidence band includes the zero line, then we cannot reject the null hypothesis of stake-independent probability weights; this is the case in the

Figure 2.14 Stake dependent probability weights in the domain of losses and gains (upper panel) and 95% confidence bands based on the percentile bootstrap method (lower panel).

Source: *Journal of Risk and Uncertainty*, 40(2): 147–80 (2010) “Rationality on the rise: why relative risk aversion increases with stake size,” Helga Fehr-Duda, Adrian Bruhin, Thomas Epper, and Renate Schubert, Figure 3, © Springer Science + Business Media, LLC 2010, with kind permission from Springer Science and Business Media.

domain of losses. There is also no noticeable difference between probability weights by stake in the domain of losses. However, in the domain of gains we can reject the hypothesis that the probability weighting function is stake independent (lower panel of Figure 2.14).

Not much is known about the determinants of probability weights but there have been several suggestions in the literature. These include differences in probability weights in the domain of gains and losses,⁵⁷ dependence on the timing of the resolution of uncertainty,⁵⁸ role of emotions,⁵⁹ and the *affect heuristic*.⁶⁰ Fehr-Duda et al., (2011) consider the effect of *incidental*

⁵⁷ See, for instance, Abdellaoui (2000) and Bruhin et al. (2010).

⁵⁸ See, for instance, Abdellaoui, Diecidue, and Öncüler (2011), and Noussair and Wu (2006).

⁵⁹ See, for instance, Walther (2003) who showed that anticipation of elation and disappointment lead to departures from linear probability weighting. The literature on regret aversion and disappointment aversion also identifies the effect of anticipated emotions on the shape of the probability weighting function; see, for instance, Bell (1982), Loomes and Sugden (1986), and Gul (1991). For other empirical evidence, see Fehr-Duda et al. (2011).

⁶⁰ See, for instance, Rottenstreich and Hsee (2001).

moods on probability weighting by estimating a probability weighting function of the Goldstein–Einhorn form. Their subjects are asked if their day has been better or worse than normal on a scale of 0 (worse) to 5 (promising) and their probability weights for lotteries are elicited. Women who were in a better mood tended to weight probabilities more optimistically. No effect was found for men, most of whom behaved in a manner consistent with expected utility maximization.

2.9.4 Heterogeneity in preferences

Given a choice between two lotteries, non-stochastic versions of EU and most behavioral decision theories predict a preference for either of the two lotteries (unless one is indifferent between the two). In contrast, in most experiments, we observe heterogeneity in choices in the sense that there is a fraction of subjects who prefer each lottery. Experimental economists have tried to accommodate this stylized fact by allowing for subjects in experiments to make noisy decisions. The interested reader can consult Hey (2014) for a detailed and readable account of the various issues that we only briefly touch on here.

Suppose that subjects in experiments are asked to make a choice between two lotteries, L_1 and L_2 . If the utility function V represents the decision maker's preferences in some decision theory, then we should observe L_1 to be chosen over L_2 if $V(L_1) > V(L_2)$. In this case, one typically conducts a test of differences in proportions to determine if the predictions of the relevant theory hold (Kahneman and Tversky, 1979). However, for whatever reasons, subjects in experiments may not state their preferences accurately, so they may exhibit a preference of L_1 over L_2 if $V(L_1) > V(L_2) + \varepsilon$, where ε is some random variable. This error term may be assumed to be common across all subjects in experiments (Camerer, 1989), or might vary by subjects in experiments (Carbone and Hey, 1994), or might even vary by the questions asked in experiments.

By assuming a specific error structure, one can engage in more sophisticated testing such as maximum likelihood rather than a simple test of proportions. For instance, Hey and Orme (1994) assumed that ε is normally distributed, while Carbone and Hey (1994) assume that ε has an extreme value distribution. Hey's (2014, p. 821) reading of the evidence based on experiments, which allow for noisy choices is this: "SEU is not bad, and where it is, then it is Rank Dependent that is better." But in other studies, there is strong support for prospect theory (Kothiyal et al., 2014; Abdellaoui, 2000; Erev et al., 2010).

One complication in models that are based on a uniform error structure across individuals is that the propensity to make decision errors varies with observed characteristics (von Gaudecker et al., 2011). Andersen et al. (2012) show that ignoring such heterogeneity may result in spurious correlation between background variables and risk attitudes. In particular, they show that cognitive ability is related to noisy decision making and that this can cause both positive and negative relationships between risk attitudes and cognitive ability, depending on the construction of the elicitation task.

An even more satisfactory method of testing is to allow for a mixture of types in the experimental population who follow different behavioral decision theories. In addition, subjects may choose with noise. Identifying heterogeneity in types, based on a *mixture model approach* has been an active area of research in recent years. In Fehr-Duda et al. (2010) that we considered above (Section 2.9.3), the evidence shows a mixture of types in the population. About 23% are expected value maximizers, while the behavior of the remaining 73% is consistent with non-linear probability weighting.

Several recent papers ask the question: Is there a mixture of individuals in the population who follow different decision theories?⁶¹ Harrison and Rutström (2009) calculated the probability that choices made by decision makers in their experiments are consistent with EU or with PT. They found that each of these two decision theories is equally likely to account for the observed choices. However, the authors recognize that these proportions are likely to vary with the task, context, and demographics of the subjects in experiments.⁶²

Bruhin et al. (2010) use a finite mixture model and run three sets of experiments—two in Zurich and one in China. Across the three experiments, they find that about 20% follow expected value maximization, or EU maximization with risk neutrality. The remaining 80% exhibit non-linear probability weighting; 30% exhibit pronounced non-linear probability weighting and 50% somewhat less pronounced weighting. These proportions are roughly similar across the three experiments. Interestingly, these proportions (20% EU and 80% PT) are very similar to those found by Conte et al. (2011) who also use finite mixture models for British experimental subjects in experiments, although there are several differences in the procedures followed by the two studies.

Figure 2.15 shows the estimated probability weighting functions for the student and the representative population in the study by Fehr-Duda and Epper (2012) that we have described above. For the student population (left panel of Figure 2.15), 80% exhibit a pronounced departure from linearity, of the inverse S-shaped form (Type I), while the remaining appear to be expected value maximizers (Type I). For the representative sample (right panel of Figure 2.15), 67% exhibit the inverse S-shaped form and have a more elevated probability weighting function (Type I), so they

Figure 2.15 Two types of decision makers for the student and the representative population.

⁶¹ See Hey and Orme (1994) for an earlier paper that revealed substantial heterogeneity between individuals.

⁶² For evidence from diverse geographical regions, see Harrison et al. (2010).

are more optimistic. The remaining 33% also exhibit a pronounced departure from linearity but they underweight probabilities significantly over a large range of higher probabilities (Type II). There are no expected value types in the representative sample. These results make a strong case for moving away from models of decision theory with linear probability weighting.

Mixture models would seem to have a better chance of explaining the dispersion in experimental results relative to any of the theories on their own. Heterogeneity in risk preferences can also arise in other dimensions. For gender based heterogeneity in risk attitudes, see Eckel and Grossman (2008), and Croson and Gneezy (2009); women are often more risk averse than men.⁶³ Dohmen et al. (2012) consider the intergenerational transmission of risk attitudes. Dohmen et al. (2011) uncover substantial heterogeneity of risk attitudes that depend on gender, age, parental background, and even height. Dohmen et al. (2010) find that lower cognitive ability is correlated with higher risk aversion as well as greater time impatience.

2.10 A selection of other behavioral theories

In this section, we consider some of the other important theories of behavioral decision making.

2.10.1 Regret theory

The ideas of *regret*, and its counterpart, *rejoice*, are not directly incorporated into EU/RDU/OPT/PT. In a recent book, Kahneman (2012, p. 288) lists the absence of the emotions of regret and disappointment as one of the blind spots of prospect theory. *Regret theory* tries to plug this gap.⁶⁴

Suppose that there are n states of the world, $s_1, s_2, \dots, s_n$, that can arise, respectively, with the objective probabilities $p_1, p_2, \dots, p_n$. Suppose that a decision maker can take two possible actions, A_1 and A_2 , each of which induces an outcome for each possible state. Let action A_1 induce outcomes $x_1, x_2, \dots, x_n$ and action A_2 induce the outcomes $y_1, y_2, \dots, y_n$. Suppose that outcomes are real numbers, say, levels of wealth.

Each state s_i is associated with a regret-rejoice function $R(x_i, y_i)$, where x_i, y_i are the respective outcomes under actions A_1 and A_2 . When $R > 0$, the decision maker rejoices, and when $R < 0$, the decision maker regrets. If action A_1 is taken, the function $R(x_i, y_i)$ has the following properties:⁶⁵

- P1. $R(x_i, y_i)$ is positive if $x_i > y_i$, negative if $y_i > x_i$ and zero if $x_i = y_i$.
- P2. $R(x_i, y_i)$ is increasing in the first argument and decreasing in the second.
- P3. R is skew symmetric (or antisymmetric), i.e., $R(x_i, y_i) = -R(y_i, x_i)$.
- P4. (Regret aversion) If $x > y > z > 0$ (where “ $>$ ” means greater than), then

$$R(x, y) + R(y, z) < R(x, z). \quad (2.105)$$

⁶³ For a review of several studies of gender differences in risk seeking, which support the finding that men are more risk taking than women, see Charness and Gneezy (2012).

⁶⁴ Important early ideas that formed the basis of subsequent developments in this area are Bell (1982), Loomes and Sugden (1982), and Fishburn (1982a).

⁶⁵ Not all of these properties appeared in the early versions of regret theory. For instance, P2 and P4 were introduced by Loomes and Sugden (1987).

From P1, in state s_i , the decision maker rejoices from taking action A_1 when it gives a relatively higher outcome ($x_i > y_i$). If $x_i > y_i$, rejoicing increases as the gap between x_i and y_i widens (property P2). P3 imposes strict symmetry into the model. The early formulations of regret theory allowed only for pairwise comparisons among tuples of the form x_i, y_i . Hence, transitivity could be easily shown to be violated. Loomes and Sugden (1987) then introduced property P4 that enabled comparisons between outcome triples.

In regret theory, action A_1 is preferred to action A_2 if, and only if,

$$\sum_{i=1}^n p_i R(x_i, y_i) > 0. \quad (2.106)$$

Regret theory is equivalent to EU in the special case where $R(x_i, y_i) = u(x_i) - u(y_i)$.

Regret aversion leads to fanning-out of the indifference curves in the probability triangle; see Sugden (1986). Hence, it is able to explain the Allais paradox. The early versions of regret theory can also easily account for intransitivity. Some early evidence indicated that the pattern of observed intransitivity was consistent with the predictions of regret theory (Loomes et al., 1989, 1991). However, subsequent evidence on observed patterns of intransitivity has been inconsistent with the predictions of regret theory (Starmer and Sugden, 1998). Furthermore, preferences under regret theory do not require that the decision maker should be indifferent between stochastically equivalent prospects (one of the exercises gives an example of such prospects). And so, regret theory is also able to account for violations of monotonicity. Some of these issues are further developed in exercises.

Bleichrodt et al. (2010) use the trade-off method to devise two separate tests for regret theory. Their two methods give similar results. In each case, they find support for an implication of regret aversion—namely that the regret function is convex. For a recent evaluation of regret theory, its ability to explain several facts that are puzzling for other decision theories, and a review of the relevant empirical evidence, see Bleichrodt and Wakker (2014).

2.10.2 The theory of disappointment aversion

Gul (1991) proposed a model of *disappointment aversion* in which decision makers distinguish between outcomes in a lottery that cause ex-post *elation* and *disappointment*. The reference point relative to which outcomes cause elation and disappointment is the *certainty equivalent* of the lottery. More formally, consider the lottery $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$ such that $x_1 < x_2 < \dots < x_n$. Denote the certainty equivalent of this lottery by C_L . Suppose that

$$x_1 < \dots < x_{k-1} \leq C_L < x_k < \dots < x_n.$$

If the ex-post outcome is $x \leq x_{k-1}$ the decision maker feels disappointed and if it is $x > x_{k-1}$, then the decision maker feels elated. Define $q = \sum_{i=k}^n p_i$ as the sum of elation probabilities and $1 - q$ as the sum of disappointment probabilities. A *disappointment-averse* decision maker then evaluates the lottery L as follows (Gul, 1991, Theorem 1):

$$U(L) = \sum_{j=1}^{k-1} \pi_j^D u(x_j) + \sum_{i=k}^n \pi_i^E u(x_i), \quad (2.107)$$

where u is a utility function, π_j^D is the decision weight accorded to the j th disappointing outcome, and π_i^E to the i th elating outcome. For $\theta > -1$, we define:

$$\pi_i^E = \left(\frac{q}{1 + (1-q)\theta} \right) \frac{p_i}{q} = \frac{p_i}{1 + (1-q)\theta}, k \leq i \leq n. \quad (2.108)$$

$$\pi_j^D = \left(1 - \frac{q}{1 + (1-q)\theta} \right) \frac{p_j}{1-q} = (1+\theta) \frac{p_j}{1 + (1-q)\theta}, 1 \leq j \leq k-1. \quad (2.109)$$

The parameter θ measures the sensitivity of the decision maker towards disappointment. To see this, suppose that an elating outcome, $i \geq k$, and a disappointing outcome, $j \leq k-1$, have identical probabilities $p_i = p_j = p$, then $\pi_j^D = (1+\theta) \pi_i^E$. When $\theta > 0$, the decision weight assigned to a disappointing outcome is magnified relative to the case if it were actually an elating outcome. In the special case of $\theta = 0$, we get the formulation under EU, i.e., $\pi_i^E = p_i$ and $\pi_j^D = p_j$. The greater is θ , the more risk averse the decision maker appears to be to an outside observer. The construction of the model has similarities with prospect theory because the certainty equivalent of the lottery plays the role of an endogenous reference point.⁶⁶

Let us compare the model of disappointment aversion with RDU for the case of binary lotteries, $L_1 = (x_1, 1-p; x_2, p)$, where $x_1 < x_2$. In this case, the certainty equivalent of L_1 lies between x_1 and x_2 . Thus, x_1 is the disappointing outcome and x_2 is the elating outcome. Using (2.107), (2.108), (2.109), and defining $\tilde{w}(p) = \frac{p}{1+(1-p)\theta}$ and $\tilde{w}(1-p) = \frac{1-p}{1+(1-p)\theta}$ we get⁶⁷

$$U(L_1) = (1+\theta) \tilde{w}(1-p)u(x_1) + \tilde{w}(p)u(x_2). \quad (2.110)$$

Define a new probability function $w(p) = \frac{p}{1+(1-p)\theta}$ that is convex and subproportional (see Definition 2.24) for $\theta > 0$. Then (2.110) can be written as

$$U(L_1) = [1 - w(p)]u(x_1) + w(p)u(x_2). \quad (2.111)$$

(2.111) is observationally equivalent to the utility function under RDU. But there are other differences between the two theories. Consider a three-outcome lottery $L_1 = (x_1, p_1; x_2, p_2; x_3, p_3)$, $x_1 < x_2 < x_3$ and $p_1 + p_2 + p_3 = 1$. Fehr-Duda and Epper (2012) show that in a probability triangle with p_1 on the horizontal axis and p_3 on the vertical axis, the indifference curves under disappointment aversion are linear and they fan-out in the bottom half and fan-in in the top half. This contrasts with the indifference curves under RDU which are non-linear. The reason is that under disappointment aversion, the betweenness axiom is satisfied but it does not hold under RDU. Furthermore, consider a concave utility function. Then under RDU, the decision maker can be risk averse or risk seeking, depending on the shape of the probability weighting function. However, under disappointment aversion and $\theta > 0$, the decision maker can only be globally risk averse with a concave utility function; see Fehr-Duda and Epper (2012).

Abdellaoui and Bleichrodt (2007) find that Gul's model of disappointment aversion is too parsimonious and data suggests that disappointment aversion is not constant but variable.⁶⁸ Gill and Prowse (2012) find evidence for the general class of models of disappointment aversion, which they classify to include, Gul's disappointment aversion model, regret aversion, and the Köszegi–Rabin endogenous reference point model. They conduct a novel experiment in which

⁶⁶ See Routledge and Zin (2010) for a two-parameter generalization of the model of disappointment aversion.

⁶⁷ Note that the reference point, the certainty equivalent of the lottery, C_L , is endogenous, and given by $u(C_L) = U(L|C_L)$, so in the general case, there is a fixed point to solve for (though not in the case with just two outcomes).

⁶⁸ Camerer and Ho (1994) and Hey and Orme (1994) also report findings that are negative for models of disappointment aversion.

two players sequentially choose effort levels in a tournament setting. Given their assumptions, the second mover's choice of effort is independent of the first mover's effort choice. Some of the results appear to be sensitive to the specification of the cost of effort function. Empirically, they find that the second mover's choice is influenced by the first mover's choice, which is consistent with models of disappointment aversion.

2.10.3 Saliency and context in decision theory

We now consider an alternative model of decision making under risk that highlights the *saliency* outcomes (Bordalo et al., 2012). Let $S = \{s_1, s_2, \dots, s_n\}$ be the set of possible states. State $s_i \in S$ occurs with probability $p_i \geq 0$, and $\sum_{i=1}^n p_i = 1$. Consider two lotteries or choices $\{L_1, L_2\}$, and let x_s^j be the payoff in state $s \in S$ when lottery L_j , $j = 1, 2$ is chosen. Let $x_s = (x_s^1, x_s^2)$ be the payoffs in the two choices when the state is s ; $x_s^{\min}$ and $x_s^{\max}$ give the minimum and maximum payoffs in state s . Sometimes we shall denote x_s^{-i} as the payoff of lottery L_j in state s .

In most alternatives to EU, whether a particular outcome is overweighted (more salient) or underweighted (less salient) depends on the probability associated with the outcomes. For instance, in the Prelec (1998) probability weighting function, low probabilities are overweighted and high probabilities are underweighted. However, Bordalo et al. (2012) propose that the notion of saliency is a feature of the relative monetary payoffs of the two lotteries in each state.

Definition 2.50 *The saliency of state s for lottery L_i , $i = 1, 2$, is given by a continuous and bounded saliency function, $\sigma(x_s^i, x_s^{-i})$, that has the following properties.*

- (a) *Ordering: Let $s, \tilde{s} \in S$. If $[x_s^{\min}, x_s^{\max}] \subset [x_{\tilde{s}}^{\min}, x_{\tilde{s}}^{\max}]$, then $\sigma(x_s^i, x_s^{-i}) < \sigma(x_{\tilde{s}}^i, x_{\tilde{s}}^{-i})$.*
- (b) *Diminishing sensitivity: Suppose that in some state s , the outcomes in both lotteries are strictly positive, i.e., $x_s^i > 0$, $i = 1, 2$. Then, for any $\epsilon > 0$,*

$$\sigma(x_s^i + \epsilon, x_s^{-i} + \epsilon) < \sigma(x_s^i, x_s^{-i}).$$

- (c) *Reflection: Let $s, \tilde{s} \in S$ and $x_s^j > 0$, $x_{\tilde{s}}^j > 0$, then*

$$\sigma(x_s^i, x_s^{-i}) < \sigma(x_{\tilde{s}}^i, x_{\tilde{s}}^{-i}) \Leftrightarrow \sigma(-x_s^i, -x_s^{-i}) < \sigma(-x_{\tilde{s}}^i, -x_{\tilde{s}}^{-i}).$$

Ordering implies that a state is more salient if the distance between the two payoffs increases. Diminishing sensitivity implies that a state is less salient if, preserving the distance between the two outcomes, the outcomes are further away from zero. So zero plays the role of a reference point in this analysis. Reflection implies that saliency is preserved under sign changes of outcomes. The last two properties also capture the notion of *context* in the model.

A decision maker in neoclassical theory, such as EU, treats all states as equally salient (in the sense defined above). However, decision makers may assign higher probability weights to more salient states relative to less salient ones. Unlike decision makers in neoclassical theory, following Gennaioli and Shleifer (2010), we may term such decision makers as *local thinkers*.

Before we see how local thinkers make decisions, consider an example of a saliency function that satisfies all the conditions in Definition 2.50.

$$\sigma(x_s^i, x_s^{-i}) = \frac{|x_s^i - x_s^{-i}|}{|x_s^i| + |x_s^{-i}| + \theta}; \theta > 0. \quad (2.112)$$

In (2.112), ordering is captured by the term in the numerator, and diminishing sensitivity by the denominator. Ordering and diminishing sensitivity are the two most important properties used in this model. Yet another property, symmetry, is intuitive when there are only two lotteries. Symmetry implies that $\sigma(x_s^i, x_s^{-i}) = \sigma(x_s^{-i}, x_s^i)$ and is satisfied by (2.112).

Example 2.23 (*Saliency of states in the Allais paradox*): Consider the Kahneman and Tversky (1979) version of the Allais paradox in its common consequence form that we have considered above. The decision maker chooses between the two lotteries

$$L_1(z) = (0, 0.01; z, 0.66; 2500, 0.33) \text{ and } L_2(z) = (z, 1), z > 0.$$

When $z = 2400$, most decision makers choose the safe choice, $L_2(2400)$, and when $z = 0$ decision makers make the risk seeking choice, $L_1(0)$. This violates EU. Let $z = 2400$, denote the three states by s_1, s_2, s_3 , and rewrite $L_2(2400) = (2400, 0.01; 2400, 0.66; 2400, 0.33)$. Then, the three state-dependent outcome tuples in the two lotteries are $x_1 = (0, 2400)$, $x_2 = (2400, 2400)$, $x_3 = (2500, 2400)$ with associated probabilities $p_1 = 0.01$, $p_2 = 0.66$, $p_3 = 0.33$. We now consider the relative saliency of these states. Using diminishing sensitivity,

$$\sigma(0 + 100, 2400 + 100) < \sigma(0, 2400). \quad (2.113)$$

Using the ordering property,

$$\sigma(2400, 2500) < \sigma(100, 2500). \quad (2.114)$$

From (2.113), (2.114),

$$\sigma(2400, 2500) < \sigma(0, 2400). \quad (2.115)$$

Also, by the ordering property,

$$\sigma(2400, 2400) < \sigma(2400, 2500). \quad (2.116)$$

From (2.115), (2.116), the relative saliency of the three states is given by

$$\sigma(2400, 2400) < \sigma(2400, 2500) < \sigma(0, 2400). \quad (2.117)$$

If we wish to invoke symmetry, then we can also write the middle term as $\sigma(2500, 2400)$. We leave it to the reader to describe the saliency of the various states when $z = 0$.

Definition 2.51 Let $s, \tilde{s} \in S$. Then state s is relatively more salient for lottery L_i if $\sigma(x_s^i, x_s^{-i}) > \sigma(x_{\tilde{s}}^i, x_{\tilde{s}}^{-i})$. Using this method we can rank the n states in the order of saliency for lottery L_i . Let this ranking be $k_s^i \in \{1, 2, \dots, n\}$ where a lower number denotes higher saliency. Then, given the saliency rankings of states, for lottery L_i , a “local thinker” transforms the relative probabilities of states s and $\tilde{s}$, $\frac{p_s}{p_{\tilde{s}}}$, as follows

$$\frac{p_s^i}{p_{\tilde{s}}^i} = \delta^{k_s^i - k_{\tilde{s}}^i} \left(\frac{p_s}{p_{\tilde{s}}} \right), \delta \in (0, 1], \quad (2.118)$$

where the ratio of transformed probabilities is denoted by $\frac{p_s^i}{p_{\tilde{s}}^i}$. We normalize $\sum_{s \in S} p_s^i = 1$. The decision weight associated with the state s for lottery L_i is given by

$$p_s^i = p_s \omega_s^i, \text{ where } \omega_s^i = \frac{\delta^{k_s^i}}{\sum_{r \in S} \delta^{k_r^i} p_r}. \quad (2.119)$$

By definition,

$$\begin{aligned} \sum_{s \in S} p_s^i &= \sum_{s \in S} \omega_s^i p_s = \sum_{s \in S} p_s \left(\frac{\delta^{k_s^i}}{\sum_{r \in S} \delta^{k_r^i} p_r} \right) \\ &= \frac{1}{\sum_{r \in S} \delta^{k_r^i} p_r} \sum_{s \in S} p_s \delta^{k_s^i} \\ &= 1. \end{aligned}$$

Thus, the average distortion in probabilities must be zero (because $\sum_{s \in S} p_s = 1$). From (2.118), if state s is relatively more salient than state $\tilde{s}$, then $k_s^i < k_{\tilde{s}}^i$, so $\delta^{k_s^i - k_{\tilde{s}}^i} > 1$, thus, the transformed probabilities of state s are also relatively higher. Conversely, if s is relatively less salient, then the transformed probability of that state is relatively lower. The size of δ is a measure of how much the probabilities are transformed. If $\delta = 1$, then $\delta^{k_s^i - k_{\tilde{s}}^i} = 1$, so there is no distortion of probabilities and we have the case of EU; by contrast when $\delta < 1$, the decision maker is a local thinker. From (2.119), if $\delta^{k_s^i}$ is higher than the average $\sum_{r \in S} \delta^{k_r^i} p_r$, i.e., $\omega_s^i > 1$, then state s receives a higher decision weight; in other words it is relatively more salient. Thus, unlike some other behavioral theories, e.g., RDU, OPT, PT, the distortion in probabilities does not depend on the size of the probabilities, but rather on the salience of the outcomes in different states. Thus, low probability states are only overweighted if they are salient, otherwise not.

Definition 2.52 The objective function of a “local thinker” for the lottery L^i , denoted by $V^{LT}(L^i)$ is given by

$$V^{LT}(L^i) = \sum_{s \in S} p_s^i u(x_s),$$

where $u(x_s)$ is the utility of outcome x_s .

Let us revisit Example 2.23. Empirical evidence shows that most decision makers prefer $L_2(2400)$ to $L_1(2400)$. The explanation based on the framework of a local thinker is along the following lines. From (2.117), the most salient state for lottery $L_1(2400)$ is the one in which the outcome is 0, despite the fact that the outcome 0 occurs with a very small probability of 0.01. This leads to a substantial overweighting of this outcome (as is the case under RDU/OPT/PT, but for an entirely different reason). Thus, the decision maker prefers the lottery $L_2(2400)$ to $L_1(2400)$.

The model can explain the Allais paradox, preference reversal, and certain context dependent choices. Bordalo et al. (2013a) apply this model to explain four puzzles in finance. For instance, they can explain why the prices of assets with skewed returns are so high; the reason is that skewed returns are relatively more salient. For an alternative account, based on inverse S-shaped probability weighting functions, under RDU/PT, see Section 3.9. They can also explain the equity premium puzzle because downside risk is more salient than upside risk, an implication that does the job of loss aversion under PT. Bordalo et al. (2013b) apply the theory to consumer choice. They consider various attributes of consumer goods such as quality, price, and context. They then determine the consumer’s willingness to pay for the good, depending on which attributes are more salient.

There is strong empirical support for the separate components of prospect theory that is also able to explain most of the phenomena that this theory of salience can explain. Hence, what is needed are empirical tests that stringently pit the predictions of the two theories against each other in domains where these predictions differ.

2.10.4 Case-based decision theory

One criticism of the Bayesian approach is that it is agnostic about the source of beliefs. One possible response to this criticism is the *case base decision theory* approach developed in Gilboa and Schmeidler (1995, 1996, 1997, 2001).⁶⁹ A central construct in this theory is a *similarity function*. When evaluating a new choice, individuals use a similarity function to compare it with all other cases in their database. The degree of similarity with other cases as well as the historical outcomes associated with choices made in the other cases then guide individuals in forming beliefs about their new choice.

The essence of the idea can be explained as follows. Suppose that an individual has some action set $A = \{a_1, a_2, \dots, a_n\}$. There is also some universal set of *cases*, or possible situations, $C = \{c_1, c_2, \dots, c_m\}$. Suppose that, at some instant in time, an individual has experience with the subset of cases $\bar{C} = \{c_1, c_2, \dots, c_n\}$, $n \leq m$. Denote the utility arising from taking action a_i (in the past) in case c_j by u_{ij} . Then, for all i, j , the memory of the individual is given by $\Omega = \{A, \bar{C}, C, \{u_{ij}\}\}$. Suppose now that some new case arises, say, $c_k \in C$, $c_k \notin \bar{C}$. What action should the decision maker take?

Define an exogenously given similarity function $s(c_j, c_k)$, $c_j \in \bar{C}$. This captures the similarity between the new case and any case $c_j \in \bar{C}$. Suppose that the decision maker wishes to evaluate the utility from taking action a_i under the new case, c_k . Let M_i be the subset of cases in which action a_i was taken in the past. Then the utility from taking action a_i in case c_k , given M_i , is denoted by $U(a_i | c_k, M_i)$; this is sometimes called a *similarity weighted utility*:

$$U_i = U(a_i | c_k, M_i) = \sum_j s(c_j, c_k) u_{ij}; \quad c_j \in M_i. \quad (2.120)$$

In (2.120), all cases in which action a_i was not taken in the past are irrelevant for the calculation and assigned zero utility, which is taken to be the *default aspiration level* of the decision maker. The chosen action a^* then satisfies

$$a^* \in \arg \max_{a_i \in A} U_i. \quad (2.121)$$

One implication of this framework is that if an action was never taken in the past, then it might never be taken in the future. However, because the aspiration utility level is zero, if all actions taken in the past yield negative utility, then the decision maker randomly chooses an action from among the set of actions not tried in the past. In this case, an action that was never chosen in the past can get chosen.

Gilboa and Schmeidler (1997) ask: What does the behavior of a case-based decision maker converge to in the long run? To answer this question, they postulate dynamics for the aspiration level as well as a specific form of the similarity function. In particular, this similarity function rules out the possibility that the outcome of an act reveals any information that is relevant for the

⁶⁹ For axiomatizations, see Billot et al. (2005) and Gilboa et al. (2006).

evaluation of another act.⁷⁰ Based on these assumptions they find that the long-run behavior of the decision maker is optimal in the sense that it converges to one that would be chosen by an expected utility maximizer.

Guerdjikova (2008) shows that the optimality result fails if the specific similarity function used by Gilboa and Schmeidler (1997) is altered. She goes on to show how a modification of the similarity function and the dynamics of the aspiration levels can ensure the achievement of optimality. Extensive empirical evidence is required to sharpen and test these models. Using agent-based computational methods, Pape and Kurtz (2013) find evidence in support of case-based decision theory. Bleichrodt et al. (2013) also report evidence that is supportive of the theory.

Two further issues that need to be addressed are as follows. First, often individuals construct *hypothetical cases* and case studies in their minds before making current choices, yet such cases are not a part of the existing theory. These hypothetical actions might be completely unrelated to past actions or payoffs, yet, be crucial in making current choices. Indeed, the ability to construct hypothetical cases is often cited as an ability that is unique to humans. Second, convergence of the model to an expected utility framework needs to deal with the issue of the empirical rejection of the expected utility model.

2.10.5 Configural weights models

We now briefly outline some *configural weight models* that have been proposed to deal with the violations of PT outlined in this section, followed by an assessment.⁷¹ Like other non-EU alternatives, these models also weight probabilities in a non-linear manner. In these models, one first writes down the decision tree corresponding to the problem.

Definition 2.53 (*Lotteries and ranks*): Consider some lottery, $L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$ where $x_1 \geq x_2 \geq \dots \geq x_n$.⁷² Outcome x_j is then said to have rank j , $j = 1, 2, \dots, n$.

THE RANK AFFECTED MULTIPLICATIVE WEIGHTS MODEL (RAM)

In the *rank affected multiplicative weights model* (RAM), the utility from lottery, L , is:⁷³

$$RAM(L) = \frac{\sum_{i=1}^n a(i, n, s) t(p_i) u(x_i)}{\sum_{j=1}^n a(j, n, s) t(p_j)}. \quad (2.122)$$

Indices i, j denote the *rank* of the outcome (see Definition 2.53). s is the *augmented sign* of the branch's consequence (positive, zero, or negative). The weighting function under RAM, $t(p)$, is an increasing function of p that takes the form,

$$t(p) = p^\nu; 0 < \nu < 1. \quad (2.123)$$

⁷⁰ One can immediately think of many examples to convince oneself that this is quite a strong assumption. For instance, a car accident while being drunk may convince an individual to avoid drinking while operating other forms of machinery.

⁷¹ The interested reader can consult Birnbaum (2008) for an exhaustive set of references and a detailed survey of these models.

⁷² Note that configural weights models write the successive outcomes in a lottery (reading from left to right) in decreasing order. This convention is used only in this section in the book.

⁷³ The reader can consult Birnbaum (1997) for the details.

The utility function $u(x)$ typically takes the power form,

$$u(x) = x^\beta; 0 < \beta < 1. \quad (2.124)$$

$a(i, n, s)$ is the *rank and sign augmented branch weight* corresponding to the outcome that has rank i . The sign s of an outcome can be positive, negative, or zero. For two branch gambles, e.g., the lottery $L = (100, 0.5; 0, 0.5)$, the branch corresponding to the lower outcome (\$0) is associated with $a = 2$ and the higher outcome is associated with $a = 1$. For m branch gambles, such that $m \geq 3$, the weights (the a s) are simply the ranks of the outcomes for that branch. For example, for the set of outcomes, $x_m \leq x_{m-1} \leq \dots \leq x_1$ the weights are, respectively, $m, m-1, m-2, \dots, 1$. Thus, lower outcomes are given higher weights, which is one of the main features of the model. The presence of the sign, s , of the outcome in $a(i, n, s)$ allows one to alter the branch weight, depending on the sign. Finally, using (2.123), we get

$$\lim_{p \rightarrow 0} \frac{t(p)}{p^\nu} = 1. \quad (2.125)$$

TRANSFER OF ATTENTION IN EXCHANGE MODELS (TAX)

Transfer of attention in exchange models (TAX) assume that the decision maker has a fixed and limited amount of attention. Hence, it is assumed, as in RAM models, that the decision maker transfers weight from higher ranked to lower ranked outcomes. Consider a *three-branch* lottery, L , given by $L = (x_1, p_1; x_2, p_2; x_3, p_3)$, $x_1 \geq x_2 \geq x_3$. Then, the utility of lottery L to the decision maker under TAX is given by

$$TAX(L) = \frac{w_1 u(x_1) + w_2 u(x_2) + w_3 u(x_3)}{w_1 + w_2 + w_3}, \quad (2.126)$$

where,

$$w_1 = t(p_1) - \frac{2}{4} \delta t(p_1); w_2 = t(p_2) - \frac{1}{4} \delta t(p_2) + \frac{1}{4} \delta t(p_1); w_3 = t(p_3) + \frac{1}{4} \delta t(p_1) + \frac{1}{4} \delta t(p_2); \quad (2.127)$$

$t(p)$ is given in (2.123) and $\delta > 0$ is some constant. In this version of the TAX model, also known as the *special TAX model*, due to Birnbaum and Stegner (1979), one transfers a fixed amount of probability weight from a higher outcome, proportionately, to lower outcomes. Thus, $w_1 + w_2 + w_3 = t(p_1) + t(p_2) + t(p_3)$. From w_1 given in (2.127), it follows that the weight on the highest outcome, x_1 , is reduced by $\frac{2}{4} \delta t(p_1)$, and each of the lower two outcomes gains one half of this weight. Similarly, the middle ranked outcome, x_2 , sheds weight $\frac{1}{4} \delta t(p_2)$, which is gained by the worse outcome, x_3 .

THE GAINS DECOMPOSITION UTILITY MODEL (GDU)

In the GDU model, multi-branch lotteries are reduced to simple, two-branch, lotteries.⁷⁴ For instance, consider the binary lottery $L_2 = (x_1, p; x_2, 1-p)$ such that $x_1 \geq x_2$. Then, under the *gains decomposition utility model* (GDU), the utility of this binary lottery is:

⁷⁴ For the GDU model, see Luce (2000), and Marley and Luce (2001, 2005).

$$GDU(L_2) = w(p)u(x_1) + (1 - w(p))u(x_2). \quad (2.128)$$

Notice that the decision weights are formed exactly as under RDU. Three-branch lotteries such as $L_3 = (x_1, p_1; x_2, p_2; x_3, 1 - p_1 - p_2)$, $x_1 \geq x_2 \geq x_3$, are then evaluated as follows. First, define the lottery

$$L_4 = \left(x_1, \frac{p_1}{p_1 + p_2}; x_2, 1 - \frac{p_1}{p_1 + p_2} \right),$$

which offers a binary choice between the two best outcomes with the probabilities normalized to add up to one. Next, consider the lottery

$$L_5 = (L_4, p_1 + p_2; x_3, 1 - p_1 - p_2),$$

which offers a binary choice between the worst outcome x_3 in lottery L_3 and the lottery L_4 . The worth of the lottery L_3 to the decision maker under the GDU model is

$$GDU(L_3) = w(p_1 + p_2)GDU(L_4) + [1 - w(p_1 + p_2)]u(x_3).$$

The weighting functions used in this theory are the standard weighting functions. Thus, $\lim_{p \rightarrow 0} \frac{w(p)}{p^\gamma} = \infty$ (see Definition 2.41).

AN EVALUATION OF THE CONFIGURAL WEIGHTS MODELS

Section 2.9.1 described several anomalies of EU/RDU/OPT/PT. These included coalescing, stochastic dominance, pattern of RBI, and upper tail independence. The configural weights models are able to explain these anomalies (Birnbbaum, 2008). So what are economists to make of these models, which seem to be the only ones that can explain the relevant evidence?

1. The main difference in predictions between PT and the configural weights models arises in the case of *event splitting* (see Section 2.9.1); see Birnbbaum (2008). This occurs when there are two identical outcomes in a lottery. This does not apply when all outcomes in a lottery are distinct, as for instance is the case with most of our applications (see Chapter 3).
2. For lotteries of the form $(x, p; y, 1 - p)$, where $x < 0 < y$, Birnbbaum (2008) reports that PT and TAX give close results. In many cases in economics, one is interested in binary decisions, often associated with binary outcomes, such as to pay or not pay taxes, to insure or not insure, to quit or not to quit one's job. So, for TAX to offer different predictions, we need lotteries with at least three outcomes.
3. More generally, it is difficult to distinguish between PT and TAX within the probability triangle. Hence, where PT is successful (e.g., the experiments reported by Kahneman and Tversky (1979), Tversky and Kahneman (1992) and, more generally, events that can be represented in the probability triangle), TAX is also successful. But for the "new" paradoxes, TAX succeeds where PT fails.
4. In many applications that involve use of hypothesis H2 (i.e., behavior for near-zero probabilities), configural weights models fail (see, e.g., (2.125)) as do EU, RDU, and PT, while *composite prospect theory* (CPT) succeeds in these cases (see Section 2.11). In these cases, the configural weights models can benefit by incorporating hypothesis H2 and the insights generated by composite prospect theory (described in Section 2.11).

5. To many economists, the practice of transferring an arbitrary amount of weight from a higher outcome to a lower outcome (see, e.g., (2.127)) will appear unattractive and mechanical. Proponents of configural weights models will argue that the weight to be transferred is calculated to fit the existing data; see Birnbaum (2008). But this begs the question of uniqueness; is there a unique way to transfer weight from the upper to the lower branches that leads to a successful prediction? This is the sense in which these models may appear arbitrary to some. Although this is not a fatal flaw, it is also not clear what restrictions on preferences will lead to the RAM and TAX models or even if these restrictions are likely to be reasonable.

Overall, economists are likely to be persuaded more by the evidence presented by the proponents of the configural weights models and less by the configural weights models that have been proposed to explain the evidence. Explaining the evidence gathered in this literature remains a challenge for behavioral decision theory.

2.11 Human behavior for extreme probability events

Many behavioral economists believe that for situations of risk, uncertainty, and ambiguity, RDU, OPT, and PT are the most satisfactory alternatives to EU (Wakker, 2010). Recall hypotheses H1 and H2 from Section 2.2. RDU and PT only take account of hypothesis H1, however, no decision theory accounts for the more general hypothesis H2 in a satisfactory manner. al-Nowaihi and Dhami (2010a) propose a modification of PT, *composite prospect theory* (CPT), that is able to account for H2. They also show how RDU can be modified to produce *composite rank dependent utility theory* (CRDU) that can also explain H2, but it is less satisfactory as compared to CPT. For the benefit of the readers we reproduce H2 here:

H2: There are two kinds of decision makers:

(H2a) A fraction $\mu \in [0, 1]$ of decision makers (i) ignore events of extremely low probability and, (ii) treat extremely high probability events as certain.⁷⁵ For all other (non-extreme) probabilities they behave as in H1, i.e., they overweight small probabilities and underweight large ones.

(H2b) A fraction $1 - \mu$ of the decision makers behave as in H1 for all levels of probabilities.

We may also view H2 as a *bimodal perception of risk*. Namely, that some individuals ignore very low probabilities altogether. Others do not ignore very low probabilities, particularly in the domain of losses; see for instance, McClelland et al. (1993) in an insurance context. Similar arguments can be constructed from the work of Viscusi (1998). Kunreuther et al. (1978) argue that the bimodal response to low probability events is pervasive in field studies. In their OPT, Kahneman and Tversky (1979) were acutely aware of H2.

The bimodal perception of risks framework and OPT (see Section 2.11.1 below) do not specify the size of μ . It is likely that μ depends on the context and the type of problem and that it can be influenced by the media, family, friends, and public policy. The size of μ is also likely to be influenced by emotions, experience, time available to make a decision, bounded rationality, framing,

⁷⁵ In the context of the take-up of insurance for low probability natural hazards, the results from one set of experiments by Kunreuther et al. (1978) are consistent with $\mu = 0.8$.

incentive effects, and so on.⁷⁶ For the purposes of our exposition we shall simply take μ as given. The endogeneity of μ is likely to be a fruitful avenue for future work.

2.11.1 Original prospect theory (OPT)

The only decision theory that incorporates hypothesis H2 is Kahneman and Tversky's (1979) *original prospect theory* (OPT). OPT makes a distinction between an *editing* and an *evaluation/decision* phase. From our perspective, the most important aspect of OPT is that decision makers decide *which improbable events to treat as impossible and which probable events to treat as certain*. Kahneman and Tversky (1979) employ an objective function similar to (2.24) in Definition 2.34, with one main difference: they use point transformations of probabilities, $\pi_i = w(p_i)$. From Example 2.7, we know that decision makers who use such a transformation can choose stochastically dominated options (Fishburn, 1978). Based on $\pi_i = w(p_i)$, and taking account of H2, they drew their decision weights function (or probability weighting function), $\pi(p)$, as in Figure 2.16; for our purposes the exact shape is less important than the gaps at the endpoints.

Kahneman and Tversky (1979, pp. 282–3) summarize the evidence for H2, as follows.

The sharp drops or apparent discontinuities of $\pi(p)$ at the end-points are consistent with the notion that there is a limit to how small a decision weight can be attached to an event, if it is given any weight at all. A similar quantum of doubt could impose an upper limit on any decision weight that is less than unity . . . the simplification of prospects can lead the decision maker to discard events of extremely low probability and to treat events of extremely high probability as if they were certain. Because people are limited in their ability to comprehend and evaluate extreme probabilities, highly unlikely events are either ignored or overweighted, and the difference between high probability and certainty is either neglected or exaggerated. Consequently $\pi(p)$ is not well-behaved near the end-points.

Figure 2.16 A hypothetical probability weighting function.

Source: Kahneman and Tversky (1979, p. 282) with permission of The Econometric Society.

⁷⁶ See chapter 4 (Anomalies on the demand side) in Kunreuther and Pauly (2005).

In this quote, Kahneman and Tversky are very explicit about human behavior near $p = 0$. Such events, in their words, are either *ignored* by some fraction μ of individuals (H2a) or *overweighted* by the complementary fraction $1 - \mu$ (H2b). This is what creates the gaps at the end points in Figure 2.16. However, the informal and heuristic approach of OPT is not always practical in dealing with H2.

We briefly describe some of the other simplifications or heuristics undertaken in the editing phase, although these do not necessarily deal with extreme probabilities. *Coalescing* or *combination* is the property that if an outcome appears more than once in a lottery, its probabilities can be added. For instance, the lottery $(30, 0.2; 30, 0.3; 75, 0.5)$, also known as a *split lottery*, is equivalent to the lottery written in the coalesced form as $(30, 0.5; 75, 0.5)$. The *cancellation heuristic* is used to eliminate common components among the lotteries being compared. The *dominance heuristic* is used to recognize and eliminate lotteries that are stochastically dominated.

In OPT, following the *editing phase*, the decision maker is left with a set of lotteries, which are converted into incremental form (Definition 2.30). In the *evaluation phase*, the decision maker then proceeds to evaluate these lotteries as in Definition 2.34 above.

OPT was heavily criticized for the feature that decision makers could choose stochastically dominated options. In response to these difficulties, Tversky and Kahneman (1992) modified OPT to *cumulative prospect theory* (PT) by incorporating the insight of *cumulative transformation of probabilities* from RDU. Hence, they needed a probability weighting function, $w(p)$, that, unlike the one in Figure 2.16, was *defined* for the entire probability domain $[0, 1]$ (otherwise Definition 2.33 could not be applied). Modifying OPT to PT meant eliminating the psychologically rich *editing phase*, which may have been a difficult choice for its authors. However, since PT lacks the relevant editing phase, it cannot account for H2a.

2.11.2 The evidence on behavior under low probability events

In this section we present a brief overview of the evidence for hypothesis H2. The interested reader can consult al-Nowaihi and Dhami (2010a) for the details. In all the low probability anomalies in this section, the most natural explanation is that a fraction of the individuals behave as in H2a. Thus, they ignore the very low probability of the potentially high levels of harm that might be caused by their actions (actions with low levels of harm are not as interesting). We note that under EU, but particularly under RDU and PT, decision makers place too great a salience on low probability events because for most probability weighting functions, $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$ (see Proposition 2.12).

INSURANCE FOR LOW PROBABILITY EVENTS

Kunreuther et al. (1978) provides striking evidence that decision makers buy inadequate non-mandatory insurance against low probability natural hazards, e.g., earthquakes, floods, and hurricane damage in areas prone to these hazards.⁷⁷ EU predicts that a risk averse decision maker facing an actuarially fair premium will, in the absence of transactions costs, buy full insurance for all probabilities, however small. Kunreuther et al. (1978, chapter 7) presented subjects with varying potential losses with various probabilities, and fixed expected loss. Subjects faced actuarially

⁷⁷ In the foreword, Arrow (Kunreuther et al., 1978, p. vii) writes: "The following study is path breaking in opening up a new field of inquiry, the large scale field study of risk-taking behavior." The reader can also consult similar but more recent evidence in Kunreuther and Pauly (2004, 2005).

fair, unfair, or subsidized premiums. In each case, they found that as the probability of the loss decreases, there is a point below which the take-up of insurance robustly drops dramatically.⁷⁸

The lack of interest in buying insurance for low probability natural hazards arose despite active government attempts to (i) provide subsidy to overcome transaction costs, (ii) reduce premiums below their actuarially fair rates, (iii) provide reinsurance for firms, and (iv) provide the relevant information. Furthermore, insurees were aware of the losses due to natural hazards (many overestimated them). Moral hazard issues (e.g., expectation of federal aid in the event of disaster) were not found to be important.

Arrow's own reading of the evidence in Kunreuther et al. (1978) is that the problem is on the demand side rather than on the supply side. Arrow writes (Kunreuther et al., 1978, p. viii) "Clearly, a good part of the obstacle [to buying insurance] was the lack of interest on the part of purchasers." Kunreuther et al. (1978, p. 238) write: "Based on these results, we hypothesize that most homeowners in hazard-prone areas have not even considered how they would recover should they suffer flood or earthquake damage. Rather they treat such events as having a probability of occurrence sufficiently low to permit them to ignore the consequences." This behavior is in close conformity to H2a.

THE BECKER (1968) PARADOX

A celebrated result, the *Becker (1968) proposition*, states that the most efficient way to deter crime is to impose the "severest possible penalty, F , with the lowest possible probability of detection and conviction, p ." By reducing p , society can economize on the costs of enforcement, such as policing and trial costs. But by increasing F , which is relatively less costly, the deterrence effect of the punishment is maintained. In an appropriately specified model, one can prove the following proposition

Proposition 2.22 (*Dhami and al-Nowaihi, 2013*): *Under EU, risk-neutrality or risk-aversion, potentially infinitely severe punishments,⁷⁹ and a utility that is unbounded below, the Becker proposition implies that crime would be deterred completely, however small the probability of detection and conviction.*

Kolm (1973) memorably phrased this proposition as: *it is efficient to hang offenders with probability zero*. Empirical evidence strongly suggests that the behavior of a significant number of people does not conform to the Becker proposition. This is known as the *Becker paradox*. For instance, Levitt (2004) shows that the estimated contribution of capital punishment in deterring crime in the US, over the period 1973–1991, was zero.⁸⁰

Under RDU and PT, because decision makers heavily overweight the small probability of a punishment (see Proposition 2.12), they can be shown to be deterred by Becker type punishments even more as compared to EU and so the Becker paradox remains; see Dhami and al-Nowaihi (2013) for a formal proof. There are several competing explanations for the Becker paradox but none of them are ultimately satisfactory; see al-Nowaihi and Dhami (2010a) for the details.

A natural explanation for the Becker paradox is that a fraction μ of individuals ignore (or heavily underweight) the very low probability of getting caught (as in H2a), so they commit a crime despite high levels of punishment.

⁷⁸ These results were shown to be robust to changes in subject population, changes in experimental format, order of presentation, presenting the risks separately or simultaneously, bundling the risks, compounding over time, and introducing "no claims bonuses."

⁷⁹ For instance, ruinous fines, slavery, torture, extraction of body parts (all of which have been historically important), and modern capital punishment.

⁸⁰ See also Radelet and Ackers (1996) and Polinsky and Shavell (2007).

EVIDENCE FROM JUMPING RED TRAFFIC LIGHTS

Consider the act of running a red traffic light. There is at least a *small probability* of an accident. al-Nowaihi and Dhami (2010a) show that the nature of this problem is very similar to the Becker proposition, except that the consequences are *self-inflicted* and potentially have *infinite costs*, such as loss of one's life. Indeed, under EU, we should not expect anyone to run red traffic lights. Decision makers using RDU and PT should be even more reluctant to run red traffic lights because of the feature $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$ (see Proposition 2.12) in most probability weighting functions.

Bar-Ilan and Sacerdote (2001, 2004) estimate that there are 260,000 accidents per year in the US caused by red-light running with implied costs of car repair alone of the order of \$520 million per year. Clearly, this is an activity of economic significance and it is implausible to assume that running red traffic lights are simply "mistakes." Using Israeli data, Bar-Ilan (2000) calculated that the expected gain from jumping one red traffic light is, at most, one minute (the length of a typical light cycle). Given the known probabilities, they find that if a slight injury causes a loss greater or equal to 0.9 days, a risk-neutral person who follows EU will be deterred by that risk alone. However, the corresponding numbers for the additional risks of serious and fatal injuries are 13.9 days and 69.4 days respectively, which should ensure complete compliance with the law. However, evidence is to the contrary.

Clearly, EU combined with risk aversion struggles to explain this evidence. So too do RDU and PT. A plausible explanation for observed red traffic light running is that a fraction μ of individuals run red traffic lights because they ignore or seriously underweight the very low probability of an accident (as under H2a).

OTHER EXAMPLES OF HYPOTHESIS H2

Consider the usage of hand-held mobile phones in moving vehicles. A user of mobile phones faces potentially *infinite punishment* (e.g., loss of one's and/or the family's life) with *low probability*, in the event of an accident.⁸¹ Evidence from the UK indicates that up to 40% of individuals drive and talk on mobile phones (The Royal Society for the Prevention of Accidents, 2005). Pöystia et al. (2005) report that two thirds of Finnish drivers and 85% of American drivers use their phone while driving, which increases the risk of an accident by two to six fold. Hands-free equipment, although now obligatory in many countries, seems not to offer essential safety advantages.

People were initially reluctant to use non-mandatory seat belts in cars despite publicly available evidence that seat belts save lives. Prior to 1985, in the US, only 10–20% of motorists wore seat belts voluntarily (Williams and Lund, 1986). Car accidents may be perceived by individuals to be *very low probability events*, particularly if individuals are overconfident of their driving abilities.⁸² Although accidents are *potentially fatal*, people seem to ignore the low probability of facing such events.

Even as evidence accumulated on the dangers of breast cancer (*low probability, potentially fatal, event*⁸³) women only sparingly took up the offer of breast cancer examination. In the US, this changed only after the greatly publicized events of the mastectomies of Betty Ford and Happy

⁸¹ Extensive evidence suggests that the perceived probability of an accident might be even lower than the actual probability because drivers are *overconfident* of their driving abilities. Taylor and Brown (1988) suggest that upto 90% of car accidents might be caused by overconfidence.

⁸² People assign confidence intervals to their estimates that are too narrow and 90% of those surveyed report that they have above-average levels of intelligence and emotional ability (Weinstein, 1980).

⁸³ We now know that the *conditional* probability of breast cancer if there is such a problem in close relatives is not low. However, we refer here to data from a time when such a link was less well understood.

Rockefeller; see Kunreuther et al. (1978, p. xiii, 13–14). Hence, the fraction of individuals to whom stylized fact H2(a) applies, μ , is not static.

CONCLUSION FROM THESE DISPARATE CONTEXTS

Two main conclusions arise from these examples. First, human behavior for low probability events cannot be easily explained by most decision theories. EU and the associated auxiliary assumptions are unable to explain the stylized facts. RDU and PT make the problem even worse because $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$ (see Proposition 2.12). Second, a natural explanation for these phenomena is that many individuals (the fraction, μ) simply ignore or seriously underweight very low probability events, even when the consequence is a huge loss.

2.11.3 Composite Prospect Theory

The theoretical solution offered by al-Nowaihi and Dhami (2010a) to incorporate hypothesis H2 is a proposal for a new probability weighting function—the *composite Prelec probability weighting function* (CPF). The CPF is generated by *smooth pasting* three standard Prelec functions; see Figure 2.17 for the general shape of a CPF. In Figure 2.17, decision makers heavily underweight very low probabilities in the range $[0, p_1]$ in the sense that is made clear in Remark 2.8.

Remark 2.8 *The CPF zero-underweights infinitesimal probabilities, i.e., $\lim_{p \rightarrow 0} \frac{w(p)}{p} = 0$, and zero-overweights near-one probabilities, i.e., $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = 0$. This contrasts with the standard Prelec function where $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$ and $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = \infty$ (see Proposition 2.12).*

Decision makers who use the CPF ignore very low probability events by assigning low subjective probability weight, w , to them, hence, conforming with H2a. By contrast, decision makers who use the standard Prelec function heavily overweight very low probabilities (see Proposition 2.12), and so they conform to H2b. Events in the interval $[p_3, 1]$ are overweighted in the CPF, as suggested by Kahneman and Tversky (1979, pp. 282–3). In the middle segment, $p \in [\underline{p}, \bar{p}]$, the CPF is inverse S-shaped, identical to a standard Prelec function. al-Nowaihi and Dhami (2010a)

Figure 2.17 The composite Prelec weighting function (CPF).

show formally that CPF is *flexible* and has preference foundations. The standard Prelec function is a special case of the CPF.

A BRIEF, MORE FORMAL TREATMENT OF THE CPF

The CPF takes three segments from three different Prelec functions (see Definition 2.22) and joins them up in a continuous manner. The two points, $\underline{p}, \bar{p}$, in Figure 2.17 are the cutoff points between the three Prelec functions. Define,

$$\underline{p} = e^{-\left(\frac{\beta}{\beta_0}\right)^{\frac{1}{\alpha_0-1}}}, \bar{p} = e^{-\left(\frac{\beta}{\beta_1}\right)^{\frac{1}{\alpha_1-1}}}. \quad (2.129)$$

Definition 2.54 (*al-Nowaihi and Dhami, 2010a*): By the composite Prelec weighting function we mean the probability weighting function $w : [0, 1] \rightarrow [0, 1]$ given by

$$w(p) = \begin{cases} 0 & \text{if } p = 0 \\ e^{-\beta_0(-\ln p)^{\alpha_0}} & \text{if } 0 < p \leq \underline{p} \\ e^{-\beta(-\ln p)^{\alpha}} & \text{if } \underline{p} < p \leq \bar{p} \\ e^{-\beta_1(-\ln p)^{\alpha_1}} & \text{if } \bar{p} < p \leq 1 \end{cases} \quad (2.130)$$

where $\underline{p}$ and $\bar{p}$ are given by (2.129) and

$$0 < \alpha < 1, \beta > 0; \alpha_0 > 1, \beta_0 > 0; \alpha_1 > 1, \beta_1 > 0, \beta_0 < 1/\beta^{\frac{\alpha_0-1}{1-\alpha}}, \beta_1 > 1/\beta^{\frac{\alpha_1-1}{1-\alpha}}. \quad (2.131)$$

The restrictions $\alpha > 0, \beta > 0, \beta_0 > 0$, and $\beta_1 > 0$, in (2.131), are required by the axiomatic derivations of the Prelec function; see *al-Nowaihi and Dhami (2006)*. The restriction $\beta_0 < 1/\beta^{\frac{\alpha_0-1}{1-\alpha}}$ and $\beta_1 > 1/\beta^{\frac{\alpha_1-1}{1-\alpha}}$ ensure that the interval $(\underline{p}, \bar{p})$ is not empty. The interval limits are chosen so that the CPF in (2.130) is continuous across them.

Proposition 2.23 (*al-Nowaihi and Dhami, 2010a*): The composite Prelec function (Definition 2.55) is a probability weighting function in the sense of Definition 2.19.

Define p_1, p_2, p_3 (see Figure 2.17) as follows:

$$p_1 = e^{-\left(\frac{1}{\beta_0}\right)^{\frac{1}{\alpha_0-1}}}, p_2 = e^{-\left(\frac{1}{\beta}\right)^{\frac{1}{\alpha-1}}}, p_3 = e^{-\left(\frac{1}{\beta_1}\right)^{\frac{1}{\alpha_1-1}}}. \quad (2.132)$$

Proposition 2.24 (*al-Nowaihi and Dhami, 2010a*): (a) $p_1 < \underline{p} < p_2 < \bar{p} < p_3$. (b) $p \in (0, p_1) \Rightarrow w(p) < p$. (c) $p \in (p_1, p_2) \Rightarrow w(p) > p$. (d) $p \in (\bar{p}, p_3) \Rightarrow w(p) < p$. (e) $p \in (p_3, 1) \Rightarrow w(p) > p$.

By Proposition 2.24, a CPF overweights low probabilities in the range (p_1, p_2) and underweights high probabilities in the range (p_2, p_3) , thus, it is inverse S-shaped in the middle. But, in addition, and unlike all the standard probability weighting functions, it underweights near-zero probabilities in the range $(0, p_1)$, and overweights near-one probabilities in the range $(p_3, 1)$ as required in H2a.

The restrictions $\alpha_0 > 1, \alpha_1 > 1$ in (2.131) ensure that a CPF has the following properties, that help explain human behavior for extremely low probability events.

Proposition 2.25 For the CPF (Definition 2.54), $\forall \gamma > 0$, the CPF (i) zero-underweights infinitesimal probabilities, i.e., $\lim_{p \rightarrow 0} \frac{w(p)}{p^\gamma} = 0$, and (ii) zero-overweights near-one probabilities, i.e., $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = 0$.

The CPF has not yet been empirically estimated, so its ability to explain H2 is still an open question. The larger number of parameters in the CPF relative to any of the standard weighting functions can pose difficulties in estimation. Indeed, as Peter Wakker points out in personal communication, one needs to conduct proper statistical tests such as Akaike's criterion for weighing the pros and the cons of additional parameters. We welcome such tests. However, most economic situations of interest where the CPF has real bite are low probability events. Over this range, a CPF is simply a Prelec function with $\alpha > 1$. Hence, at a very minimum, one might wish to estimate if for low probabilities we observe a separation of decision makers into two groups: One with a Prelec parameter $\alpha > 1$ and another with $\alpha < 1$. Clearly, these low probabilities must be lower relative to those that are used in the standard experiments, say, one in 10,000 or one in 20,000. These could be the approximate chances of a house being burgled in some area, or the probability of suffering an accident while driving and talking on a mobile phone.

DEFINITIONS OF CPT AND CRDU

We now give definitions of *composite prospect theory* (CPT) and *composite rank dependent utility* (CRDU).

Definition 2.55 (Composite prospect theory (CPT), al-Nowaihi and Dhami, 2010a): Under CPT, a fraction $1 - \mu$ of the population uses cumulative prospect theory, PT, with any of its standard probability weighting functions, such as the standard Prelec function, so $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$. This fraction conforms to hypothesis H2b. The remaining fraction, μ , uses PT but replaces the standard probability weighting function with the composite Prelec probability weighting function, CPF, for which $\lim_{p \rightarrow 0} \frac{w(p)}{p} = 0$ (see Propositions 2.12 and 2.25). This fraction conforms to H2a.

From Definition 2.55, for the respective fractions μ and $1 - \mu$, the decision weights in Definition 2.33 are calculated by using, respectively, the CPF and the standard probability weighting function. Once these probability weights are calculated, the objective function in Definition 2.34 is used to compute the utility from any lottery in incremental form.

Definition 2.56 (Composite rank dependent utility (CRDU); al-Nowaihi and Dhami, 2010a) In CRDU, RDU replaces PT in Definition 2.55.

From Definition 2.56, we use the appropriate probability functions (CPF for the fraction μ and any standard function for the fraction $1 - \mu$) to calculate the decision weights in Definition 2.25, followed by the calculation of the value of the objective function in Definition 2.26.

Other than the probability weighting functions, CPT and CRDU share all other elements with PT and RDU, respectively. In this sense, both are conservative extensions of existing and established theories. However, the extension enables the explanation of hypothesis H2, which is more general than H1. Thus, we have the nested structure: CPT can explain everything that PT can, which in turn can explain everything that RDU can, which in turn can explain everything that

EU can, which in turn explains everything that expected value maximization (EV) can. However, the converse is false in each case.⁸⁴

CRDU could be thought of as a special case of CPT in the absence of a reference point.⁸⁵ However, this rules out the psychologically powerful and robust notions of loss aversion and reference dependence, which have strong explanatory power in a variety of contexts and are too important to be ignored.⁸⁶ This is likely to weaken the explanatory power of CRDU relative to CPT.

CPT has potential applications to a wide range of economically important problems such as insurance, and crime and punishment. Some of these applications are considered in the exercises.

2.12 Risk preferences and time preferences

In economics, it is typical to give a separate treatment of risk preferences and time preferences and assume that these two kinds of preferences are unrelated. Yet, the outcomes of most human decisions are uncertain and take time to materialize, which is suggestive of a potential link between the two. An emerging literature has tried to grapple with the complex interaction between these two entities. The contributions have been both theoretical and empirical.⁸⁷ Issues of time discounting are considered more fully in Part 3 where we also consider the effect of uncertainty on time preferences. In this section, we consider some of the theoretical and empirical contributions that explore the links between these two areas but with greater focus on risk preferences.

2.12.1 Can non-linear probability weighting explain temporal behavior under risk?

We begin by considering the contribution by Andreoni and Sprenger (2012b). In order to separate the role of risk and time preferences, they use a test method known as *convex time budgets*. This method and the basic research question here is adapted from their earlier work in Andreoni and Sprenger (2012a). At date 0, subjects are allocated 100 tokens. They can allocate integer amounts between an earlier date, t , or a later date, $t + k$. A generic allocation is denoted by $(n, 100 - n)$, where $0 \leq n \leq 100$. These tokens can then be exchanged for cash at dates t and $t + k$, respectively, at exchange rates of a_t and a_{t+k} per token. Two values of k are considered: $k = 28$ and $k = 56$.

In the experiments, $a_{t+k} = \$0.2$ per token and $a_t = \frac{a_{t+k}}{1+r}$, where r is the gross interest rate over k days.⁸⁸ The interest rate was varied from 0% to 2116.6% in discrete steps. Suppose that we refer to the income realized at any date as the consumption at that date. The future is uncertain in the sense that the payments at t and $t + k$, respectively, are honored with probabilities p_1 and p_2 that

⁸⁴ See al-Nowaihi and Dhami (2010a) for these claims. CPT can also incorporate the insight from *third generation prospect theory* of Schmidt et al. (2008). One may also refer to CPT as *fourth generation prospect theory* if one prefers this kind of terminology.

⁸⁵ This requires, of course, that we collapse lotteries in incremental form in CPT back to ordinary lotteries first (i.e., add the reference point to each outcome), and then apply CRDU.

⁸⁶ See, for instance, the applications discussed in Camerer (2000), Kahneman and Tversky (2000), and Barberis and Thaler (2003).

⁸⁷ For the theoretical contributions, see, for instance, Halevy (2008), Walther (2010), Baucells and HeuKamp (2012), Epper and Fehr-Duda (2014b). For the empirical contributions, see for instance, Andreoni and Sprenger (2012b) and Epper and Fehr-Duda (2014a).

⁸⁸ The standardized daily net interest is, therefore, $(1 + r)^{1/k} - 1$.

are independent of each other. If the payments at both dates go through, then the consumption stream is given by

$$(c_t, c_{t+k}) = (na_t, (100 - n)a_{t+k}). \quad (2.133)$$

Using $a_t = \frac{a_{t+k}}{1+r}$, the budget constraint of the consumer, expressed in date $t+k$ units, is given by⁸⁹

$$(1+r)c_t + c_{t+k} = 100a_{t+k}. \quad (2.134)$$

Given the uncertainty in the payments, the decision maker faces the following prospect

$$L(p_1, p_2) = ((c_t, c_{t+k}), p_1 p_2; (c_t, 0), p_1(1 - p_2); (0, c_{t+k}), (1 - p_1)p_2; (0, 0), (1 - p_1)(1 - p_2)). \quad (2.135)$$

In order to evaluate the utility of the consumer, we follow the *portfolio approach* in Chew and Epstein (1990). There are at least two other possibilities—the *separable case* and the *recursive case*; see Appendix A1 in Epper and Fehr-Duda (2014a). Andreoni and Sprenger (2012b) use the separable case. The separable and recursive cases do not correctly predict the behavior in the left panel of Figure 2.19, while the portfolio case correctly predicts it, as we show below. It is worth noting how the three cases reduce lotteries when both time and risk are present; see the self-explanatory Figure 2.18.

In this section, we shall consider only the portfolio case. Denote the *intertemporal discounted utility* from the consumption profile (c_t, c_{t+k}) by $D(t)v(c_t) + D(t+k)v(c_{t+k})$, where D is a discount function that is differentiable throughout, is decreasing, and has continuous partial derivatives up to order two. v is a utility function such that

$$v(0) = 0, v' > 0 \text{ and } v'' < 0. \quad (2.136)$$

Figure 2.18 Reduction of lotteries when both time and risk are present, in three different cases.

Source: Epper and Fehr-Duda (2014a) with permission from the American Economic Association.

⁸⁹ We could alternatively have expressed the budget constraint in date t units as $c_t + \frac{c_{t+k}}{(1+r)} = 100a_t$.

In a baseline condition, (1, 1), the prospect is $L(1, 1)$ and it is compared to a scaled down version (λ, λ) , with the corresponding prospect $L(\lambda, \lambda)$, where $0 < \lambda < 1$, in order to check for the common ratio effect. Two different risk conditions are considered, (1, q) and (q , 1). In each case, their respective scaled down conditions $(\lambda, \lambda q)$ and $(\lambda q, \lambda)$ are also considered to check for the common ratio effect under risk.

Proposition 2.26 *In any delay-discounting model (exponential discounting is a special case), where the decision maker follows expected utility, suppose that the optimal number of tokens purchased by the decision maker is n^* .*

- (i) *The optimal number of tokens, n^* , and the optimal consumption levels, c_t^* and c_{t+k}^* , do not change when p_1 and p_2 are scaled up or down by a common factor.*
- (ii) *The optimal number of tokens, n^* , and optimal consumption c_t^* , decrease as the interest rate, r , goes up.*

Proof: (i) In any delay-discounting model, the utility of the prospect in (2.135), given $v(0) = 0$, is given by

$$V_D = p_1 p_2 [D(t)v(c_t) + D(t+k)v(c_{t+k})] + p_1(1-p_2)D(t)v(c_t) + (1-p_1)p_2 D(t+k)v(c_{t+k}). \quad (2.137)$$

The decision maker optimally chooses c_t and c_{t+k} , subject to the constraint in (2.134). Substituting c_{t+k} from (2.134) in (2.137), we get the following unconstrained problem in which the decision maker chooses c_t ; the number of tokens can then be recovered from (2.133). The unconstrained problem is

$$c_t^* \in \arg \max_{0 \leq c_t \leq 100a_t} V_D = p_1 D(t)v(c_t) + p_2 D(t+k)v(100a_{t+k} - (1+r)c_t).$$

Using (2.133), the optimal number of tokens is $n^* = \frac{c_t^*}{a_t}$. V_D is a strictly concave function on a compact set, so the condition for a unique interior maximum value, c_t^* , is given by

$$\frac{v'(c_t)}{v'(c_{t+k})} = (1+r) \frac{D(t+k)}{D(t)} \frac{p_2}{p_1}. \quad (2.138)$$

(2.138) is the key condition that unlocks the main comparative statics in the model. A scaling of p_1 and p_2 by a common factor λ does not alter the ratio $\frac{p_2}{p_1}$. Thus, both sides of (2.138) are unaffected, so c_t^* (and n^*) is unchanged.

(ii) Given that v is strictly concave, any increase in the LHS must relatively increase $v'(c_t)$, or equivalently, reduce c_t . As r increases, the RHS of (2.138) increases so c_t^* falls and $n^* = \frac{c_t^*}{a_t}$ also falls. ■

Based on Proposition 2.26 we expect the following pairs of conditions to give identical results in terms of the optimal consumption levels: (i) (1, 1) and (λ, λ) . (ii) (1, q) and $(\lambda, \lambda q)$. (iii) (q , 1) and $(\lambda q, \lambda)$. A representative set of results is shown in Figure 2.19, which reports the average consumption level of decision makers at date t , $\bar{c}_t$, as a function of $(1+r)\frac{p_2}{p_1}$.⁹⁰

⁹⁰ Andreoni and Sprenger (2012b) give the full set of results, i.e., first for $k = 26$ they give a comparison of the three pairs of conditions listed above, for $\lambda = 0.5$ and $q = 0.8$. Then they repeat the same comparison for $k = 52$.

Figure 2.19 Average consumption, $\bar{c}_t$, in various conditions. In the left panel, the delay is $k = 28$ days, and we compare the two conditions $(1, 1)$ and $(0.5, 0.5)$. In the right panel, we consider a delay of $k = 56$ days, and we compare the conditions $(1, 0.8)$ versus $(0.5, 0.4)$ and $(0.8, 1)$ and $(0.4, 0.5)$.

Source: Epper and Fehr-Duda (2014a) with permission from the American Economic Association.

Figure 2.19 shows that Proposition 2.26 is violated. For instance, in the left panel of Figure 2.19, the average optimal level of consumption is predicted to be identical in the two conditions $(1, 1)$ and $(0.5, 0.5)$, yet average consumption is initially higher in the $(1, 1)$ condition and then drops below the level for the $(0.5, 0.5)$ condition, i.e., the curves cross over. This result has been replicated by Cheung (2014) and Miao and Zhong (2012). In the $(1, 1)$ condition, where there is complete certainty of payment, about 80% of the allocations are at one corner ($n^* = 100$ or $n^* = 0$). But in the risky condition, $(0.5, 0.5)$, subjects try to diversify and only 26.1% are at a corner solution.

Consider the right panel of Figure 2.19 where $q = 0.8$ and $\lambda = 0.5$. First consider the conditions $(1, q)$ versus $(\lambda, \lambda q)$. The average consumption in the $(0.5, 0.4)$ condition is always lower than the $(1, 0.8)$ condition. The converse is true in a comparison of the conditions $(q, 1)$ and $(\lambda q, \lambda)$ (i.e., the conditions $(0.8, 1)$ and $(0.4, 0.5)$).

Andreoni and Sprenger (2012b) argue that models of non-linear probability weighting, such as RDU, cannot explain these results either. Their preferred explanation is models where the common ratio property (see (2.138)) does not hold; models in this category include those by Kreps and Porteus (1978), Chew and Epstein (1989b), and Epstein and Zin (1989). However, reworking through the same set of results, Epper and Fehr-Duda (2014a) show that the results can be explained by RDU if the decision maker cares for portfolio risk rather than employ the separable case that is used by Andreoni and Sprenger (2012b); see Figure 2.18.

Let us now consider a decision maker who follows RDU and faces the lottery in (2.135). There are four possible outcomes, but each outcome is a pair of consumption values. How are these pairs to be ranked? Consider the binary relation $<$ such that $(c_t, 0) < (0, c_{t+k})$ means that c_{t+k} received at date $t + k$ is “ranked higher” than c_t received at date t . We assume that

By contrast, we report in Figure 2.19, a comparison between the first pair for $k = 26$ and a comparison for the remaining two pairs for $k = 52$.

$$\begin{cases} (0, c_{t+k}) \prec (c_t, 0) & \text{if } D(t+k)v(c_{t+k}) < D(t)v(c_t) \\ (c_t, 0) \prec (0, c_{t+k}) & \text{if } D(t)v(c_t) < D(t+k)v(c_{t+k}) \end{cases} \quad (2.139)$$

With this definition, it is always the case that $(0, 0) \prec (c_t, 0) \prec (c_t, c_{t+k})$ and $(0, 0) \prec (0, c_{t+k}) \prec (c_t, c_{t+k})$. Depending on which row of (2.139) applies, we get two possibilities, I and II.

$$\begin{cases} I: & (0, 0) \prec (0, c_{t+k}) \prec (c_t, 0) \prec (c_t, c_{t+k}) \\ II: & (0, 0) \prec (c_t, 0) \prec (0, c_{t+k}) \prec (c_t, c_{t+k}) \end{cases} \quad (2.140)$$

The lottery in (2.135) gives the associated probability of each of the outcomes in cases I and II in (2.140). Let w be a probability weighting function. The decision weights (see Definition 2.25) of the lowest and the highest outcomes in cases I and II are identically given by

$$\pi(0, 0) = 1 - w(p_1 + p_2 - p_1 p_2), \pi(c_t, c_{t+k}) = w(p_1 p_2). \quad (2.141)$$

The decision weights for the two intermediate outcomes in cases I and II are:

$$\begin{cases} I: & \pi_I(0, c_{t+k}) = w(p_1 + p_2 - p_1 p_2) - w(p_1), \pi_I(c_t, 0) = w(p_1) - w(p_1 p_2) \\ II: & \pi_{II}(c_t, 0) = w(p_1 + p_2 - p_1 p_2) - w(p_2), \pi_{II}(0, c_{t+k}) = w(p_2) - w(p_1 p_2) \end{cases} \quad (2.142)$$

Let the utility function of an outcome continue to be given by v , with the conditions in (2.136). Given the decision weights in (2.141) and (2.142), we can now define the objective function of the decision maker who follows RDU in the two cases in (2.139), V_R^i , $i = I, II$.

$$\begin{aligned} V_R^i = & \pi_i(0, c_{t+k})D(t+k)v(c_{t+k}) + \pi_i(c_t, 0)D(t)v(c_t) \\ & + \pi(c_t, c_{t+k})[D(t)v(c_t) + D(t+k)v(c_{t+k})], i = I, II. \end{aligned}$$

A decision maker who follows RDU, maximizes his objective function V_R^i , $i = I, II$, subject to the constraint in (2.134). The first order condition, the analogue of (2.138), is given by

$$\frac{v'(c_t)}{v'(c_{t+k})} = (1+r) \frac{D(t+k)}{D(t)} \varphi(p_1, p_2), \quad (2.143)$$

where,

$$\varphi(p_1, p_2) = \begin{cases} \frac{w(p_2)}{w(1)} & \text{if } p_1 = 1 \\ \frac{w(1)}{w(p_1)} & \text{if } p_2 = 1 \\ \frac{\varphi_I(p_1, p_2) = \frac{w(p_1 p_2) + w(p_1 + p_2 - p_1 p_2) - w(p_1)}{w(p_1)}}{\frac{w(p_2)}{w(p_1)}} & \text{if } p_1 \neq 1, p_2 \neq 1, (0, c_{t+k}) \prec (c_t, 0) \\ \frac{\varphi_{II}(p_1, p_2) = \frac{w(p_1 p_2) + w(p_1 + p_2 - p_1 p_2) - w(p_2)}{w(p_2)}}{\frac{w(p_1)}{w(p_2)}} & \text{if } p_1 \neq 1, p_2 \neq 1, (c_t, 0) \prec (0, c_{t+k}) \end{cases} \quad (2.144)$$

In order to compare the average level of consumption under delay-discounting models and RDU we compare (2.138) and (2.143). The relevant comparison is between the terms $\frac{p_2}{p_1}$ and $\varphi(p_1, p_2)$.

We now consider the first order condition (2.143) for the three cases: (i) $(1, 1)$ versus (λ, λ) , (ii) $(1, q)$ versus $(\lambda, \lambda q)$, and (iii) $(q, 1)$ versus $(\lambda q, \lambda)$. Some illustrative results for the case of the

Table 2.5 Various computations to explain the relevant empirical findings in different conditions.

Conditions (1,1) and (0.5,0.5)	Conditions (1,0.8) and (0.5,0.4)	Conditions (0.8,1) and (0.4,0.5)
$\frac{p_1}{p_2} = 1$	$\frac{p_1}{p_2} = 1.25$	$\frac{p_1}{p_2} = 0.8$
$\varphi(1, 1) = 1$	$\varphi(1, 0.8) = 0.624$	$\varphi(0.8, 1) = 1.604$
$\varphi_I(0.5, 0.5) = 1.053$	$\varphi_I(0.5, 0.4) = 0.912$	$\varphi_I(0.4, 0.5) = 1.166$
$\varphi_{II}(0.5, 0.5) = 0.950$	$\varphi_{II}(0.5, 0.4) = 0.858$	$\varphi_{II}(0.4, 0.5) = 1.097$

Source: Epner and Fehr-Duda (2014a).

Prelec function (Definition 2.22) with $\alpha = 0.5$ and $\beta = 1$, and for $\lambda = 0.5$ and $q = 0.8$ are summarized in Table 2.5.

We are now interested in the empirical findings encapsulated in Figure 2.19.

I. Baseline condition: Consider first the comparison between the conditions (1, 1) and (λ, λ) . The illustrative example in Table 2.5 (first column) is consistent with the crossover of the two curves in the left panel of Figure 2.19 ($\varphi_{II}(0.5, 0.5) < \varphi(1, 1) < \varphi_I(0.5, 0.5)$). Now consider the more general case. For most probability weighting functions, including the Prelec function, that are inverse S-shaped, there is an initial concave segment, followed by a convex segment. The point of inflection that separates these segments is typically well below the probability of 0.5, which is used in the experiments in Andreoni and Sprenger (2012b), hence, we are in the convex region of the weighting function. Assuming a convex probability weighting function, we get

$$w(ap_1 + (1-a)p_2) < aw(p_1) + (1-a)w(p_2), 0 < a < 1. \quad (2.145)$$

From (2.144)

$$\varphi_I(\lambda, \lambda) = \frac{w(\lambda^2) + w(2\lambda - \lambda^2) - w(\lambda)}{w(\lambda)}, \varphi_{II}(\lambda, \lambda) = \frac{w(\lambda)}{w(\lambda^2) + w(2\lambda - \lambda^2) - w(\lambda)}. \quad (2.146)$$

From (2.145), (2.146) we get

$$\varphi_I(\lambda, \lambda) > \varphi(1, 1) = 1 > \varphi_{II}(\lambda, \lambda). \quad (2.147)$$

When $(0, c_{t+k}) < (c_t, 0)$ we have $\varphi_I(\lambda, \lambda) > 1$, thus, the RHS of (2.143) is greater under the condition (λ, λ) relative to the condition (1, 1). Since v is concave, it follows that c_t is relatively lower under the condition (λ, λ) . On the other hand, in the condition $(c_t, 0) < (0, c_{t+k})$ we have that $1 > \varphi_{II}(\lambda, \lambda)$ so c_t is greater under the condition (λ, λ) relative to the condition (1, 1). This implies the crossing over of the two curves that we observe in the left panel of Figure 2.19.

II. Differential risk conditions: Consider first the comparison $(1, q)$ versus $(\lambda, \lambda q)$ (the other comparison is $(q, 1)$ versus $(\lambda q, \lambda)$). In this case, from (2.144)

$$\begin{cases} \varphi_I(\lambda, \lambda q) = \frac{w(\lambda^2 q) + w(\lambda + \lambda q - \lambda^2 q) - w(\lambda)}{w(\lambda)} \\ \varphi_{II}(\lambda, \lambda q) = \frac{w(\lambda q)}{w(\lambda^2 q) + w(\lambda + \lambda q - \lambda^2 q) - w(\lambda q)} \end{cases}. \quad (2.148)$$

In the experiments of Andreoni and Sprenger (2012b), $\lambda = 0.5$ and $q = 0.8$. Most probability weighting functions are quite flat over this range. Thus, let us use a linear approximation

$w(p) \approx \widehat{w}(p) = a + bp$. Suppose that we apply this approximation to $\varphi_I(\lambda, \lambda q)$ in (2.148), then we get $\frac{a+b\lambda q}{a+b\lambda} = \frac{\widehat{w}(\lambda q)}{\widehat{w}(\lambda)}$. The same approximation applies to $\varphi_{II}(\lambda, \lambda q)$, thus,

$$\varphi_I(\lambda, \lambda q) \approx \frac{\widehat{w}(\lambda q)}{\widehat{w}(\lambda)} \approx \varphi_{II}(\lambda, \lambda q). \quad (2.149)$$

Thus, $\frac{\varphi_I(\lambda, \lambda q)}{\varphi_{II}(\lambda, \lambda q)} \approx 1$. From the RHS of (2.143), optimal consumption c_t is, thus, almost unchanged as the rank of outcomes change between $(0, c_{t+k}) < (c_t, 0)$ and $(c_t, 0) < (0, c_{t+k})$. From the subproportionality condition in Definition 2.24, applied to the function $\widehat{w}$ for $p = 1$ (this is the special case of the certainty effect), we get that $\frac{\widehat{w}(\lambda q)}{\widehat{w}(\lambda)} > \widehat{w}(q)$, so

$$\frac{w(\lambda q)}{w(\lambda)} \approx \frac{\widehat{w}(\lambda q)}{\widehat{w}(\lambda)} > \widehat{w}(q) \approx w(q). \quad (2.150)$$

For the condition $(1, q)$ we have, from (2.144),

$$\varphi(1, q) = \frac{w(q)}{w(1)} = w(q). \quad (2.151)$$

From (2.149)–(2.151) we get that

$$\varphi_I(\lambda, \lambda q) \approx \varphi_{II}(\lambda, \lambda q) > w(q) = \varphi(1, q). \quad (2.152)$$

Using (2.152) we get that the RHS in (2.143) is relatively higher in the condition $(\lambda, \lambda q)$ relative to the condition $(1, q)$ throughout the domain (even as we move across the two possibilities $(0, c_{t+k}) < (c_t, 0)$ and $(c_t, 0) < (0, c_{t+k})$). This feature is also present in the illustrative example as shown in the second column in Table 2.5. Thus, we expect average date t consumption, $\bar{c}_t$, to be relatively higher in the condition $(1, q)$, exactly as we have in the right panel of Figure 2.19. We leave it to the reader to show analogously that a comparison of the conditions $(q, 1)$ and $(\lambda q, \lambda)$ is also consistent with the right panel of Figure 2.19.

Thus, if we use the portfolio method, the results of Andreoni and Sprenger (2012b) are consistent with a decision maker who follows RDU in evaluating uncertain dated streams of consumption goods.

2.12.2 Intertemporal risk aversion

Epper and Fehr-Duda (2014b) make preliminary progress in operationalizing *intertemporal risk aversion*, based on the work of Richard (1975) and Bommier (2007). Intertemporal risk aversion refers to the desire of decision makers to diversify consumption across time; empirical evidence can be found in Cheung (2014) and Miao and Zhong (2012). Suppose that $c_t \in \{\underline{c}_t, \bar{c}_t\}$ and $c_{t+k} \in \{\underline{c}_{t+k}, \bar{c}_{t+k}\}$, where $\underline{c}_t < \bar{c}_t$ and $\underline{c}_{t+k} < \bar{c}_{t+k}$. Define the prospects

$$L^- = ((\bar{c}_t, \underline{c}_{t+k}), 0.5; (\underline{c}_t, \bar{c}_{t+k}), 0.5), L^+ = ((\bar{c}_t, \bar{c}_{t+k}), 0.5; (\underline{c}_t, \underline{c}_{t+k}), 0.5). \quad (2.153)$$

The prospect L^+ is not as well diversified as prospect L^- . This leads to the following definition.

Definition 2.57 (*Intertemporal risk aversion*): A decision maker is intertemporally risk averse if $L^+ \prec L^-$, where $\prec$ is the “strictly preferred to” binary relation.

Define

$$V_D(x_t, y_{t+k}) = D(t)v(x_t) + D(t+k)v(y_{t+k}),$$

and assume, as in (2.139), that

$$(x_t, y_{t+k}) \prec (x'_t, y'_{t+k}) \Leftrightarrow V_D(x_t, y_{t+k}) < V_D(x'_t, y'_{t+k}). \quad (2.154)$$

(2.154) allows us to express the preference $L^+ \prec L^-$ for decision makers who follow RDU. It is not clear if $(\bar{c}_t, \underline{c}_{t+k}) \prec (\underline{c}_t, \bar{c}_{t+k})$ or $(\underline{c}_t, \bar{c}_{t+k}) \prec (\bar{c}_t, \underline{c}_{t+k})$. Thus, in specifying the utility function of a RDU decision maker, V_R (Definitions 2.25 and 2.26), we need to consider two possibilities.

$$V_R(L^-) = \begin{cases} (1 - w(0.5)) V_D(\bar{c}_t, \underline{c}_{t+k}) + w(0.5) V_D(\underline{c}_t, \bar{c}_{t+k}) & \text{if } (\bar{c}_t, \underline{c}_{t+k}) \prec (\underline{c}_t, \bar{c}_{t+k}). \\ (1 - w(0.5)) V_D(\underline{c}_t, \bar{c}_{t+k}) + w(0.5) V_D(\bar{c}_t, \underline{c}_{t+k}) & \text{if } (\underline{c}_t, \bar{c}_{t+k}) \prec (\bar{c}_t, \underline{c}_{t+k}). \end{cases} \quad (2.155)$$

The ranking of outcomes under the prospect L^+ is unambiguous, hence, using Definitions 2.25 and 2.26

$$V_R(L^+) = (1 - w(0.5)) V_D(\underline{c}_t, \underline{c}_{t+k}) + w(0.5) V_D(\bar{c}_t, \bar{c}_{t+k}). \quad (2.156)$$

Comparing (2.155) and (2.156) we get

$$V_R(L^-) - V_R(L^+) = \begin{cases} (1 - 2w(0.5)) (v(\bar{c}_t) - v(\underline{c}_t)) D(t) & \text{if } (\bar{c}_t, \underline{c}_{t+k}) \prec (\underline{c}_t, \bar{c}_{t+k}). \\ (1 - 2w(0.5)) (v(\bar{c}_{t+k}) - v(\underline{c}_{t+k})) D(t+k) & \text{if } (\underline{c}_t, \bar{c}_{t+k}) \prec (\bar{c}_t, \underline{c}_{t+k}). \end{cases}$$

In each case, the condition for intertemporal risk aversion, $V_R(L^-) > V_R(L^+)$, holds if

$$1 - 2w(0.5) > 0, \text{ or } w(0.5) < 0.5. \quad (2.157)$$

This condition is satisfied for most inverse S-shaped probability weight functions; see Epper and Fehr-Duda (2014b). For instance it is satisfied by the Prelec function for commonly used values of α, β . In a nutshell, a decision maker who follows RDU also exhibits intertemporal risk aversion if the condition in (2.157) holds.

2.12.3 An agenda for the future

In an insightful paper, Epper and Fehr-Duda (2014b) lay out the agenda for future research that wishes to explore the link between risk preferences and time preferences. They propose a general theoretical framework designed to address a set of stylized facts that any aspiring theory in this area may wish to take into account. The stylized facts can be organized as follows.

1. Empirically observed risk tolerance and patience are *delay dependent*: People appear more risk tolerant for events that are to happen in the more distant future.⁹¹ An implication is that

⁹¹ See, for instance, Abdellaoui, Diecidue, and Öncüler (2011) and Coble and Lusk (2010).

people may be more tolerant in facing risks relating to global warming or insuring against natural hazards if the consequences are in the more distant future. Hyperbolic discounting captures delay dependence of behavior but does not incorporate risk.

2. Behavior under risk and time is *process dependent*. There is a very large number of process dependent behaviors that have been observed. For instance, it matters whether we first reduce lotteries in a one-shot manner or sequentially (see for instance, Figure 2.18). In other contexts, it matters if uncertainty is resolved gradually, or in the terminal period. For instance, a greater risk premium may be required on a portfolio whose returns are evaluated frequently rather than observed at the end of the period (Benartzi and Thaler, 1995; Barberis et al., 2001). More generally, in a range of contexts, people take on more risks if they are informed of the outcomes at the end rather than frequently over time.⁹² We shall also consider process dependence of time behavior in Part 3 of the book; in particular, we shall consider *subadditive discounting* in some detail.
3. The *timing of the resolution of uncertainty* affects behavior of subjects when they face situations that have a risk and time component: For instance, for negative news, people may prefer uncertainty to resolve later rather than sooner (e.g., is one affected by a genetic disorder that runs in the family?). For positive news, people may prefer uncertainty to resolve sooner rather than later (e.g., has the book that I ordered arrived?).⁹³
4. Time discount differs in the presence of risk: For instance, risky future incomes are discounted less than safe future incomes (Ahlbrecht and Weber, 1997a; Weber and Chapman, 2005). This is in contrast to the exponential discounting utility model that applies the same discounting to safe and risky returns. A literature also examines the dynamic inconsistency of choices in the presence of risk.⁹⁴
5. Behavior differs depending on whether we first reduce a lottery in the time dimension or in the risk dimension: It appears that the value assigned to prospects is lower if they are first reduced for risk and then for time (as compared to the reverse case). See, for instance, the recursive case in Figure 2.18 and for the empirical evidence, see Öncüler and Onay (2009).

We now consider some of these issues.

2.12.4 Delay dependence and probability weighting

Suppose that we have a binary lottery

$$L = (x, 1 - p; y, p), 0 \leq x < y. \quad (2.158)$$

A RDU decision maker evaluates the lottery L by

$$V_R(L) = [1 - w(p)]v(x) + w(p)v(y). \quad (2.159)$$

In (2.159), w is the “true” weighting function of the decision maker (i.e., it is a part of the decision maker’s preferences). We assume that w is subproportional (Definition 2.24).

⁹² See for instance, Gneezy and Potters (1997), Thaler et al. (1997), Gneezy et al. (2003), and Bellemare et al. (2005).

⁹³ For the empirical evidence, see Ahlbrecht and Weber (1997b), Lovallo and Kahneman (2000), Eliaz and Schotter (2007), and von Gaudecker et al. (2011). For papers that propose a theoretical framework, see Kreps and Porteus (1978), Chew and Epstein (1989b), and Grant et al. (2000).

⁹⁴ See, for instance, Cubitt et al. (1998) and Busemeyer et al. (2000).

Suppose that time is discrete, and the lottery L is paid out at time $t > 0$. Then we make two assumptions.

1. Utility is discounted back to time 0 using the exponential function

$$D(t) = e^{-\theta t},$$

where $\theta > 0$ is the discount rate.

2. There is uncertainty about whether the payments will be made in the future. Suppose that one is promised a payment at time 0 of an amount $z > 0$ to be received at time t . Then the probability of receiving the payment at time t is s^t , $0 < s \leq 1$, where s is the per-period probability of the payment being honored. Hence, if the prospect L in (2.158) is to be realized at time t , it is viewed at time 0 as the prospect⁹⁵

$$\tilde{L} = (0, 1 - s^t; x, (1 - p)s^t; y, ps^t), 0 \leq x < y, 0 < s \leq 1.$$

Under Assumptions 1 and 2, a decision maker, who uses RDU, evaluates at time 0 the prospect $\tilde{L}$ to be received at time t , as follows (see Definitions 2.25 and 2.26),

$$V_R(\tilde{L}; 0) = D(t) [(w(s^t) - w(ps^t)) v(x) + w(ps^t) v(y)], \quad (2.160)$$

where w is the *atemporal probability weighting function*. (2.160) can be rewritten as

$$V_R(\tilde{L}; 0) = D(t) w(s^t) \left[(v(y) - v(x)) \frac{w(ps^t)}{w(s^t)} + v(x) \right]. \quad (2.161)$$

Suppose that an observer does not realize that Assumption 2 applies; for instance, an experimenter (observer) may have no desire to withhold future payments to subjects (decision makers), but subjects may assign a positive probability to this event. Thus, the observer thinks that the decision maker evaluates lottery $\tilde{L}$ with $s = 1$, so, recalling that $w(1) = 1$, he imagines that

$$V_R(\tilde{L}; 0) = \hat{D}(t) [(v(y) - v(x)) \hat{w}(p) + v(x)], \quad (2.162)$$

where $\hat{w}$ and $\hat{D}$ are, respectively, the probability weighting function and the discount function, which the observer believes are used by the decision maker. Suppose that the observer uses (2.162) to estimate the true weighting function and the discount function of the decision maker. Then, comparing (2.161) and (2.162), the relation between his estimates, $\hat{w}$ and $\hat{D}$, and the true functions w and D is

$$\hat{w}(p) = \frac{w(ps^t)}{w(s^t)}. \quad (2.163)$$

$$\hat{D}(t) = w(s^t) D(t). \quad (2.164)$$

Epper and Fehr-Duda (2014b) use this simple framework to address the five stylized facts in Section 2.12.3, above. Consider the first hypothesis on delay dependence.

⁹⁵ This assumption is motivated by the work of Halevy (2008) and Walther (2010); see Part 3 of the book for more details.

Proposition 2.27 *Let the true probability weighting function w be subproportional (Definition 2.24), and $s < 1$. Then the properties of the estimated function, $\hat{w}$ (see (2.163)) are as follows.*

- (i) $\hat{w}$ is a probability weighting function.
- (ii) $\hat{w}$ is subproportional.
- (iii) $\hat{w}$ is more elevated than w . The degree of elevation of $\hat{w}$ increases with time delay, t , and survival risk, $1 - s$, but this increase is at a decreasing rate.
- (iv) $\hat{w}$ is less elastic than w .
- (v) The increase in risk tolerance is greater when w is more subproportional.

Proof: (i) Using (2.163), $\hat{w}(0) = \frac{w(0)}{w(s^t)} = 0$, $\hat{w}(1) = \frac{w(s^t)}{w(s^t)} = 1$, and $\hat{w}'(p) = s^t \frac{w'(ps^t)}{w(s^t)} > 0$, hence, $\hat{w}$ is a probability weighting function.

(ii) Using the definition of subproportionality in Definition 2.24, and noting that w is subproportional, we have for $0 < \lambda < 1$ and $q < p \leq 1$,

$$\frac{\hat{w}(p)}{\hat{w}(q)} = \frac{w(ps^t)}{w(qs^t)} > \frac{w(\lambda ps^t)}{w(\lambda qs^t)} = \frac{\frac{w(\lambda ps^t)}{w(s^t)}}{\frac{w(\lambda qs^t)}{w(s^t)}} = \frac{\hat{w}(\lambda p)}{\hat{w}(\lambda q)},$$

which proves the result.

(iii) Using the definitions of $w(p)$, $\hat{w}(p)$, and subproportionality, we get

$$\frac{1}{w(p)} = \frac{w(1)}{w(p)} > \frac{w(s)}{w(ps)} > \frac{w(s^2)}{w(ps^2)} > \dots > \frac{w(s^t)}{w(ps^t)} = \frac{1}{\hat{w}(p)},$$

hence, $w(p) < \hat{w}(p)$. Thus, $\hat{w}$ is more elevated than w . Differentiating $\hat{w}$ with respect to t and s gives the remaining results.

(iv) The elasticity, ε_w , of the weighting function, w is defined as $\varepsilon_w(p) = \frac{w'(p)p}{w(p)}$. It can be shown that if w is subproportional, then $\varepsilon'_w(p) > 0$. Thus, by the definition of $\hat{w}$, we have

$$\varepsilon_{\hat{w}}(p) = \frac{\hat{w}'(p)p}{\hat{w}(p)} = \frac{w'(ps^t)ps^t}{w(ps^t)} = \varepsilon_w(ps^t) < \varepsilon_w(p),$$

where the last inequality follows from $ps^t < p$ and $\varepsilon'_w(p) > 0$.

(v) We leave the proof of this part to the reader. ■

One of the central results here is Proposition 2.27(iii). The fact that the estimated probability weighting function, $\hat{w}$, is relatively more elevated means that the observed risk tolerance of the decision maker is also relatively higher (see Example 2.10). Thus, risk tolerance appears, to the observer, to increase with the time delay. Furthermore, this risk tolerance appears even larger as t increases. The empirical evidence is consistent with these findings. In particular, the utility function is not influenced by time delay, so the relevant channel operates through probability weighting;⁹⁶ see Figure 2.22 for an illustration of the delay effect that we discuss below.

From (2.164), $\hat{D}(t) = w(s^t)D(t)$. D takes the exponential form. Suppose that w is the inverse S-shaped Prelec function with $\alpha\beta = 1$ (Definition 2.22), so $w(s^t) = e^{(-\ln s^t)^\alpha}$. Thus, $\hat{D}(t) = e^{-\hat{\theta}t}$

⁹⁶ See Epper and Fehr-Duda (2014b) for the references.

Figure 2.20 A plot of the estimated discount rate $\hat{\theta}$ (vertical axis) and the time delay t (horizontal axis). The weighting function is a Prelec function with $\alpha = 0.5$ and $\beta = 1$.

where $\hat{\theta} = \theta - \ln(s) > \theta$. Thus, the presence of uncertainty increases the observed discount rates and increases the degree of observed impatience. However, this does not account for the typical finding of decreasing discount rates as, say, in hyperbolic discounting (because θ is independent of t). However, this can be accommodated if the probability weighting function is subproportional, an idea that is closely related to Halevy (2008) that we consider in more detail in Part 3 of the book. We summarize the results in the next proposition that we leave the proof to the reader as an exercise.

Proposition 2.28 (Epper and Fehr-Duda, 2014b): Suppose that w is subproportional.

- (i) $\hat{D}$ is a discount function if $1 < s \leq 1$, i.e., it is decreasing in t (impatience), $\lim_{t \rightarrow \infty} \hat{D}(t) = 0$, and $\hat{D}(0) = 1$.
- (ii) When $s < 1$ we have $\hat{\theta} > \theta$.
- (iii) The observed discount rate $\hat{\theta}$ is declining in t .
- (iv) Greater risk of survival (lower s) results in more steeply declining discount rates.
- (v) An increase in the degree of subproportionality of the weighting function leads to more steeply declining discount rates.

For the Prelec probability weighting function with $\alpha = 0.5$ and $\beta = 1$, Figure 2.20 shows the effect of varying survival risk, s , on the observed discount rate, $\hat{\theta}$ (vertical axis), while time t is on the horizontal axis. Thus, the estimated discount rate is hyperbolic and the degree of hyperbolicity is increasing with an increase in risk (lower s).

2.12.5 Probability weighting and process dependence

Empirical evidence suggests that the probability weighting function is more elevated when future rewards are received with a longer delay, while the utility function appears stable under delay;

Figure 2.21 A choice between a compound lottery and its equivalent simple lottery.

see Abdellaoui, Diecidue et al. (2011). Fehr-Duda and Epper (2012) give the example of a choice between a compound lottery and its equivalent simple lottery shown in Figure 2.21. The simple lottery is $L_s = (x_1, 1 - p; x_2, p)$, where $x_1 < x_2$, $p = rq$ and $1 - p = q(1 - r) + (1 - q) = 1 - rq$.

The RDU of the simple lottery is

$$V_R(L_s) = [1 - w(rq)] u(x_1) + w(rq) u(x_2). \quad (2.165)$$

Suppose that the compound lottery is reduced recursively. Then with probability q , the RDU of the decision maker is $[1 - w(r)] u(x_1) + w(r) u(x_2)$, and with probability $1 - q$ it is $u(x_1)$. Hence, at the initial node, the decision maker faces the lottery

$$L_c = (u(x_1), 1 - q; [1 - w(r)] u(x_1) + w(r) u(x_2), q).$$

The RDU of the compound lottery (reduced recursively) is

$$V_R(L_c) = [1 - w(q)] u(x_1) + w(q) ([1 - w(r)] u(x_1) + w(r) u(x_2)), \quad (2.166)$$

which can be rewritten as

$$V_R(L_c) = [1 - w(r)w(q)] u(x_1) + w(r)w(q) u(x_2). \quad (2.167)$$

Suppose that the weighting function is subproportional. Thus, the certainty effect (Definition 2.24) implies $w(qr) > w(q)w(r)$. Then, comparing (2.165) and (2.167) we get that $V_R(L_s) > V_R(L_c)$, so the decision maker tolerates less risk in the compound case. Thus, although the simple and compound lotteries are equivalent in the classical sense, the timing of the resolution of uncertainty does matter for a decision maker who follows RDU, if the weighting function is subproportional. As the number of stages in the compound lottery increase, the decision maker exhibits less and less risk tolerance.

Figure 2.22 shows the estimated Prelec weighting functions. Panel (a) shows the atemporal probability weighting function when there is one stage, i.e., a simple lottery ($m = 1$), two stages ($m = 2$), and twelve stages ($m = 12$). Elevation falls as the number of stages increases, so risk

Figure 2.22 Estimated Prelec weighting functions.

tolerance falls, and for $m = 12$, the probability weighting function becomes convex; in Section 2.3, we classified such a decision maker as exhibiting pessimism.

In panel (b) of Figure 2.22 we assume that the uncertainty in compound lotteries is realized in 12 months time. Comparing the corresponding curves in the two panels, we can compare the effect of time delay. With time delay, each of the curves is more elevated than the corresponding curve in the atemporal case, hence, they exhibit greater risk tolerance.

As Fehr-Duda and Epper (2012, pp. 585–86) put it: "Extreme risk aversion can thus result from several different underlying mechanisms: loss aversion, disappointment aversion, and rank dependence with convex probability weighting or frequent compounding of originally inverse S-shaped probability weights."

CHAPTER 3

Applications of Behavioral Decision Theory

3.1 Introduction

Prospect theory (PT) has been successful in explaining a wide range of problems in almost all areas of economics. In this chapter we consider several applications of PT. Many applications rely on a subset of the components of PT (reference dependence, loss aversion, concavity of utility in gains and convexity in losses, and non-linear probability weighting). The vast majority of the applications invoke reference dependence and loss aversion, but omit non-linear weighting of probabilities. While this explains much human behavior, which is a testament to the importance of these features of human behavior, sometimes this is undesirable, for two reasons. First, the calibration of such models to the data might not be very successful, particularly if one arbitrarily picks and chooses among the components of PT. Second, while the evidence supports the fourfold classification of risk under PT, the omission of non-linear probability weighting can induce, at best, twofold risk aversion, which may reduce the scope of the models' predictions.¹ There is a strong case for giving more attention to non-linear probability weighting in applications of PT, than has traditionally been the case (Fehr-Duda and Epper, 2012).

The general psychological principles behind reference dependence and loss aversion have excellent foundations in experimental and field data.² An important test of these principles has come from an examination of the disparity between *willingness to accept*, WTA, and *willingness to pay*, WTP, for the same good. This disparity is sometimes known as the finding of *exchange asymmetries*. Since this finding arises from mere physical ownership of an object, it is also known as the *endowment effect*.

In Section 3.2 we begin by describing the early and pioneering evidence for exchange asymmetries (Kahneman et al., 1990). The endowment effect arises for physical goods but typically not for money, intrinsically worthless items, or items held for exchange only. This finding, which has been replicated in a large number of experiments, survives controls for transaction costs of exchange, subject misconceptions, learning, and strategic concerns.

¹ For a classic example, see Wakker (2003).

² For experimental evidence on loss aversion, see, for instance, Kahneman and Tversky (1979), Tversky and Kahneman (1992), Thaler et al. (1997), Gneezy and Potters (1997), and Kahneman and Tversky (2000). For the field evidence, see, for instance, Camerer et al. (1997), Genesove and Mayer (2001), Fehr and Goette (2007), Odean (1998), and Mas (2006).

Section 3.2.1 considers the leading explanation of exchange asymmetries, loss aversion (Thaler, 1980). Parting with an object, when one is endowed with it, is coded as a loss by an individual. Hence, loss aversion applies to the act of parting with an object. But loss aversion does not apply to money, hence, the act of parting with the money to buy an object is not subject to loss aversion. In conjunction, this gives rise to the finding of $WTP < WTA$. Indeed, in a PT framework, it can be shown that loss aversion equals the ratio WTA/WTP . Kahneman et al. (1990) report an average value of $WTA/WTP \cong 2$, which is close to the typical values of loss aversion found in many experiments. One study reports the median estimate of WTA/WTP across 45 studies to be 2.6, although there is individual-level heterogeneity in estimates of loss aversion (Horowitz and McConnell, 2002). We also discuss, briefly, the dependence of loss aversion on a range of demographic, goods-specific, context-specific and emotional factors.

Typically, experiments on exchange asymmetries are conducted in riskless environments. In Section 3.2.2, we consider exchange asymmetries in risky environments (Novemsky and Kahneman, 2005), and pose a fundamental question: *Is there any risk aversion beyond loss aversion?* Loss aversion is found to be present in both conditions used to elicit exchange disparities: the risky and the riskless conditions. If there is any risk aversion beyond loss aversion, then one would expect, for instance, that WTA should be relatively higher in the risky situation. But this turns out not to be the case. Hence, there is no risk aversion beyond loss aversion.

Section 3.2.3 considers the effect of experience on the endowment effect. Some evidence suggests a slight reduction in the endowment effect from markets in sports cards memorabilia (List, 2003, 2004). However, contrary to common perception, this effect was found to be similar for lab subjects and market participants, so the conclusion that markets may reduce behavioral biases is not correct. Furthermore, it is not surprising that one may find lower loss aversion among people who hold goods from trade because they are interested in making a profit from the goods and do not necessarily derive satisfaction from owning the goods; this has been known since Kahneman et al. (1990). A comprehensive study based on more than 2.5 million data points from professional sports players shows that even experienced players exhibit loss aversion (Pope and Schweitzer, 2011). This ties in nicely with evolutionary explanations, which suggest that loss aversion may be hardwired in humans; see Section 3.3, below.

Section 3.2.4 considers the possibility that subject misinterpretation and the instructions themselves may be responsible for the endowment effect (Plott and Zeiler, 2005, 2007). However, using the altered instructions, and accounting for subject misperceptions in the suggested manner, it has not been possible to replicate these findings for the case of lotteries (Isoni et al., 2011), although they can be replicated for mugs. This suggests that it is not subject misperception that is the cause of the endowment effect but the particular context of the experiments.

Section 3.2.5 considers some implications and other explanations of exchange asymmetries. Indifference curves may cross over, depending on initial endowments, and the Coase theorem may be violated (Kahneman et al., 1990). We also consider some marketing implications of the endowment effect (Novemsky and Kahneman, 2005). *Stochastic reference points* may be a potential explanation of exchange asymmetries (Köszegi and Rabin, 2006); this is dealt with in more detail in Section 2.8.3. A potential explanation of exchange asymmetries is the *query theory of value construction* (Johnson et al., 2007), which is similar in spirit to the availability heuristic (see Part 7). This is a promising line of work, which shows that the nature of queries that sellers and buyers of objects pose may influence the extent of exchange asymmetries. Yet another possible explanation that we consider is the role of uncertainty in explaining the endowment effect (Engleman and Hollard, 2008).

Non-human primates share a common evolutionary history with humans. If they were to exhibit the endowment effect or PT preferences, then this might be the result of an evolutionary process that precedes the separation of chimpanzees and humans from a common ancestor. We consider this fascinating question in Section 3.3 (Chen et al., 2006; Brosnan et al., 2007; Lakshminarayanan et al., 2008, 2011). It turns out that capuchin monkeys have consistent preferences and they exhibit many of the features of PT that include reference dependence, loss aversion, and different risk attitudes in the domain of gains and losses. Chimpanzees exhibit an endowment effect for food items, but not for non-food items where they exhibit the reverse of the endowment effect (a preference for interacting with the experimenter makes them trade too much). This difference arises possibly because food is more salient for evolutionary success as compared to non-food items.

Section 3.4 considers the tendency of humans to evaluate gains and losses only over short horizons, even when the relevant horizons are longer. For instance, even if the returns on a portfolio are to materialize in two years, individuals may repeatedly check the market returns. Insofar as negative returns may lead to loss aversion, risky assets appear more aversive. Such a phenomenon is known as *myopic loss aversion*. This explains the *equity premium puzzle*, i.e., why the return differential on risky and riskless assets cannot be explained by any reasonable attitudes to risk (Benartzi and Thaler, 1995). Myopic loss aversion is supported in experimental data on individual subjects (Gneezy and Potters, 1997), team experimental data (Sutter, 2007), and in artefactual field data (Haigh and List, 2005).

Section 3.5 considers the only application in Chapter 3 that uses all the components of PT in order to address the *tax evasion puzzles*. The classic analysis of tax evasion, based on EU (Allingham and Sandmo, 1971), gives rise to qualitative and quantitative puzzles. The quantitative puzzle is that given the return from tax evasion for an amateur tax evader of 91%–98%, why should anyone bother to pay taxes?³ The qualitative puzzle arises because, under the reasonable assumption of decreasing absolute risk aversion, EU predicts that evasion should fall as the tax rate goes up (Yitzhaki, 1974). However, the bulk of the evidence indicates that people attempt to evade more if the government tries to tax away more of their incomes.

We show that PT is able to address the quantitative and qualitative tax evasion puzzles (Dhami and al-Nowaihi, 2007, 2010b). Although the probability of an audit and the penalty rates for tax evaders are low, loss aversion from being caught, and overweighting of small probabilities of detection, ensure that only about a third of those who can evade, do evade. Using parameters of risk from generic situations of risk under PT, we can explain well the evidence from tax evasion. This provides independent confirmation of PT in a two-horse race with EU. By contrast, the predictions of EU are wrong up to a factor of up to 100.

We considered Rabin's paradox for EU in Section 1.5.4 in Chapter 1. Section 3.6 shows that this paradox can be resolved by using loss aversion (Rabin, 2000a). Several alternative explanations for Rabin's paradox turn out to rely on reference dependence, which is central to PT (Wakker, 2005, 2010).

Under EU, the carriers of utility are final wealth levels, so *goals* or *targets* should not alter behavior. However, the evidence suggests that goals and targets do influence behavior and outcomes. We begin, in Section 3.7, by considering the role that *goals* play as reference points and propose a simple theoretical model of goals under PT, using unpublished notes by al-Nowaihi and Dhami.

³ The probability, p , of audit for an amateur tax evader is 1–5 % and, if caught, the taxpayer has to pay back the evaded tax, plus a fine, θ , at the rate of 0.5 to 2 times the evaded tax. Thus, the return on one dollar of evaded tax is $(1 - p) - p\theta$.

This model is able to address some of the stylized facts in the literature (Heath et al., 1999) that show the following. First, goals partition the space of outcomes into gains and losses, thus, they serve as reference points. Second, individuals often work harder when they have a goal. Third, individuals work even harder as they get closer to a goal. Finally, we make some preliminary progress in the direction of determining *optimal goals*.

Section 3.8 provides an application of PT to labor economics, as encapsulated in the following question. Why is it hard to find a taxi on a rainy day in New York (Camerer et al., 1997)? The behavioral explanation is that taxi drivers have a target daily level of earnings (reference dependence), which is possibly a response to issues of *self-control*, particularly for drivers who are not highly experienced (see Part 3). If they quit before achieving their target, then they suffer loss aversion. On a rainy day, they are more likely to achieve their target early because the average waiting times between successive jobs is low. Hence, they are more likely to quit early. Thus, the labor supply curve is backward bending, although it is less pronounced for more experienced drivers. We review the relevant empirical evidence (e.g., Fehr and Goette, 2007; Farber, 2005, 2008). We also sketch out models of labor supply with a single target (earnings) and the more recent work in which there are multiple targets (earnings and hours worked) (Crawford and Meng, 2011).

One implication of the inverse S-shaped probability weighting functions is that the decision maker places higher decision weight on more extreme outcomes (Fehr-Duda and Epper, 2012). In Section 3.9, we briefly consider applications of this idea, mainly to issues in finance. For additional applications to finance, see the chapter on behavioral finance in Part 7 of the book.

In Section 3.10, we consider sequential interaction between contracting parties who enter into a contract at date 0, and then engage in some economic transaction at date 1. At date 0, there is a competitive pool of contracting parties from which a pair (say, a buyer and a seller) are matched. The critical idea is that the date 0 contract may serve to define the *entitlements* of the two parties and, hence, serve as a reference point for decisions at date 1 (Hart and Moore, 2008). If the date 1 behavior of parties does not conform to their expected entitlements, then parties may shade their performance, and reduce the joint surplus. We consider the effect of these factors on the choice of optimal contracts. The empirical evidence is consistent with the model (Fehr et al., 2011).

Section 3.11 considers the effect of loss aversion on optimal contracts in the presence of moral hazard, in the standard principal–agent problem (De Meza and Webb, 2007). It turns out that loss aversion reduces the power of incentive schemes. If incentives schemes are too high powered, then loss aversion makes the satisfaction of the agent’s individual rationality constraint too expensive for the principal. Thus, it is optimal for the principal to offer relatively flat segments in the optimal wage schedule. We then examine heuristically how loss aversion may explain other observed contractual phenomena (Herweg et al., 2010).

Section 3.12 considers the issue of renegotiation of contracts under reference dependence and loss aversion (Herweg and Schmidt, 2013). The two main findings are that under loss aversion, renegotiation is sluggish and does not take place in all states of the world, although it would have, in the absence of loss aversion. The analysis also offers insights into the choice between long-term contracts and the use of spot markets.

This chapter explores only a very small set of the applications that have successfully applied PT. Some of the other successful applications include: prediction of complex states of health (Abellan-Perpiñan et al., 2009), life-cycle consumption savings models (Bowman et al., 1999), racetrack betting (Jullien and Selanié, 2000), crime and punishment (Dharm and al-Nowaihi, 2010a, 2014), asset market phenomena (Kliger and Levy, 2009; Gurevich et al., 2009; Barberis et al., 2001), the disposition effect (Shefrin and Statman, 1985), and asymmetric price elasticities (Camerer, 2000).

3.2 The endowment effect and exchange asymmetries

The idea behind exchange asymmetries is that ownership confers a psychic benefit, or an *endowment effect*. Kahneman et al. (1991) motivate the endowment effect through the following example. “A wine-loving economist we know purchased some nice Bordeaux wines years ago at low prices. The wines have greatly appreciated in value, so that a bottle that cost only \$10 when purchased would now fetch \$200 at auction. This economist now drinks some of this wine occasionally, but would neither be willing to sell the wine at the auction price nor buy an additional bottle at that price.” Neoclassical economics predicts that, depending on his valuation $v \gtrless 200$, either the seller would like to sell at a price of \$200 or prefer to buy it.

Let us term the amount of money that *owners* of an object are willing to accept in exchange for the object as the *willingness to accept* (WTA). The *willingness to pay* (WTP) for the object is the amount of money that individuals are willing to pay to buy an extra unit of the object. Thaler (1980) noted the presence of *exchange asymmetries*, i.e., $WTP < WTA$; a phenomenon also known as the *endowment effect*. The effects of ownership need not be immediate, but could be gradual, increasing over time as the duration of ownership increases (Strahilevitz and Loewenstein, 1998). Ariely and Simonson (2003) also demonstrate a similar pattern for the case of bidding in auctions. The highest bidder at any stage (who has not won the auction yet) become partially attached to the object (a pseudo-endowment effect).

Thaler (1980) invoked *loss aversion* to explain the endowment effect. The act of giving up the object is coded as a *loss* by the owner, so *loss aversion* applies to sales of items. However, the endowment effect has been found to apply to goods but not to money or to goods purchased for resale (Kahneman et al., 1990).⁴ Hence, loss aversion does not apply to the buyer's act of giving up cash, thus, $WTP < WTA$.

The endowment effect need not be limited to goods. It can also arise in the case of *perceived entitlements*, say, to a previously prevailing price. So, for instance, houses stay on the market longer in a period of falling prices. Sellers might be reluctant to sell at a lower price because they perceive that they are entitled to a previously prevailing, higher, price. There is also some evidence that the volume of stocks traded is lower for those stocks whose price is falling relative to those whose price is increasing (Shefrin and Statman, 1985).

We now describe a generic experiment in Kahneman et al. (1990), designed to test for the *endowment effect*. In order to control for factors such as subject misperception and transaction costs in potentially interfering with, or even causing, the endowment effect, Kahneman et al. (1990) first ran three markets in tokens. Tokens are intrinsically worthless and (in the absence of factors such as misperceptions and transactions costs) are not expected to induce an endowment effect, so $WTP = WTA$. The tokens can be redeemed at a pre-announced exchange rate from the experimenter.

We reproduce the instructions for sellers and buyers in some detail because these have played an important part in the debate on the explanation of the endowment effect. In the market for tokens, sellers receive the following instructions.

In this market, the objects being traded are tokens. You are an owner, so you now own a token which has a value to you of \$x. It has this value to you because the experimenter will give you this much money for it. The value of the token is different for different individuals. A price for the tokens will be

⁴ Using data from the TV show *Deal or no Deal*, Blavatsky and Pogrebna (2009) raise the possibility that the endowment effect might be weakened when the stakes are very high.

determined later. For each of the prices listed below, please indicate whether you prefer to: (1) Sell your token at this price and receive the market price. (2) Keep your token and cash it in for the sum of money indicated above. For each price indicate your decision by marking an X in the appropriate column.

The instructions for the buyers were as follows.

In this market, the objects being traded are tokens. You are a buyer, so you have an opportunity to buy a token which has a value to you of \$x. It has this value to you because the experimenter will give you this much money for it. The value of the token is different for different individuals. A price for the tokens will be determined later. For each of the prices listed below, please indicate whether you prefer to: (1) Buy a token at this price and cash it in for the sum of money indicated above. (2) Not buy a token at this price. For each price indicate your decision by marking an X in the appropriate column.

This is followed by a list of prices, ranging from \$0.25 to \$8.75, increased in steps of \$0.50. Sellers are asked to state their WTA, while buyers are asked to state their WTP. Subjects were made to alternate in the roles of buyers and sellers in three successive markets. The tokens were assigned a different individual redemption value in each trial. Once the subjects give their responses, the experimenter immediately computes the implied demand and supply schedules for each market as well as the market clearing price.

Three buyers and sellers are then selected and paid off in accordance with the market clearing price. The procedure described above is incentive compatible. The main finding was $WTP = WTA$. Hence, based on the trading in the market for tokens, one can rule out the presence of factors that might vitiate the endowment effect. These factors include subject misperception (e.g., confusing instructions), bargaining postures (sellers asking for more to strengthen their bargaining positions), and transactions costs of trade.

Kahneman et al. (1990) then gave Cornell coffee mugs to subjects on alternative seats (these mugs could be purchased from the University bookshop for \$6.00 each). Subjects were given an opportunity to examine the mugs. Then, the experimental procedure for tokens was applied by replacing mugs with tokens; all subjects found the mugs to be desirable items because they placed a positive valuation on them. Subjects were told that it was in their best interests to answer questions truthfully and that of the four mug markets conducted, one market, *the binding market trial*, would be selected at random and played for real. The initial assignment of subjects in the roles of buyers or sellers was maintained throughout. Following the four markets for mugs, four more markets were conducted for boxed ballpoint pens, which sold for \$3.98 in the University bookstore (the price tags were left visible to the subjects). This procedure is also incentive compatible.

The repetition of each of the markets for four times was designed to allow learning to take place. However, no learning effects were found in the experimental results (we comment more on these results below).

The results in the mugs and pens markets were very different from the results arising with tokens. In the markets for objects, Kahneman et al. (1990) found that the median selling price was more than twice the median buying price. The actual volumes of trade were only respectively 20% and 41%, respectively, of the predicted volumes.

Could sellers simply be inflating their WTA in order to get a higher equilibrium price? Kahneman et al. (1990) control for this objection by running another experiment in which the price is chosen randomly. Subjects are explicitly told that their decision will have no effect on the

actual price chosen. From Becker et al. (1964), it is known that this elicitation mechanism ensures truthful reporting of valuations and willingness to pay for the good. Since strategic postures on the part of sellers and buyers have no bearing on the actual price in this case, it is always at least a weakly dominant strategy to tell the truth. The experimental results still showed a large endowment effect and were nearly identical to the ones obtained when actual market clearing prices were used.

Experiments 6 and 7 in Kahneman et al. (1990) added an extra group of experimental subjects. Sellers in the experiment were given a mug and asked if they would sell the mug at prices ranging from \$0 to \$9.25. The *buyers* were asked if they would buy the mug at these prices. The third subset of subjects, the *choosers*, were asked at each price, say \$ x , if they would prefer to have a cash amount of \$ x , or the mug (which is exactly the same choice as faced by a seller). The only difference between choosers and sellers is that the latter have physical possession of the good.

If the behavior of the choosers and the sellers is similar, then the endowment effect does not have any bite, because, in this case, it is not physical possession of the good, per se, that creates a higher WTA. In contrast, it was found that the behavior of choosers was similar to that of buyers, but not the sellers, which confirms the endowment effect. Median valuations of the mug for sellers, choosers, and buyers, were \$7.12, \$3.12, and \$2.87, respectively.

By way of comparison, the earlier study of Knetsch (1989) used two objects (mugs and candy bars). Each object was, in turn, randomly allocated to some subjects (sellers) who had an opportunity to trade it for the other object. When endowed with the mug, 89% of the sellers preferred to keep the mug. When endowed with the candy bar, 90% of the sellers preferred to keep the candy bar. Since subjects are allocated randomly to the two treatments (i.e., mug ownership and candy ownership), in the absence of an endowment effect it is difficult to explain these results. An even earlier study by Knetsch and Sinden (1984) found the WTA to WTP ratio for lottery tickets to be about 4.⁵

The evidence for the endowment effect outlined in this section relied mainly on items such as mugs and pens. However, the endowment effect has also been documented for a range of other objects such as college basketball tickets (Carmon and Ariely, 2000), gift certificates (Sen and Johnson, 1997), choice of pizza toppings (Levin et al., 2002), hunting permits (Cummings et al., 1986), wine (Van Dijk and Van Knippenberg, 1996), and car attributes (Johnson et al., 2006). Kahneman et al. (1990) argue that the endowment effect is also likely to hold when the entities engaged in a transaction are firms rather than individuals. They conjecture that once firms obtain property rights over some economic asset (by accident of history, luck, or public policy) they might be reluctant to sell the asset, while at the same time being reluctant to buy such an asset at the market price.

The endowment effect suggests that individuals are relatively more reluctant to give up objects they own, so they appear to have a bias towards the current allocation, i.e., a *status-quo bias*. Samuelson and Zeckhauser (1988) gave subjects a choice between investing in one of four possible investments: moderate risk, high risk, treasury bills, and municipal bonds. In the neutral treatment, the endowment of the subjects is just money. In the non-neutral treatments, the endowment is one of the possible investments themselves. A status-quo bias (a larger fraction of the final portfolio consisting of the investment one is endowed with) is found in the non-neutral treatment relative to the neutral treatment. Furthermore, the status-quo bias is found to be more pronounced when there is a larger number of alternatives.

⁵ Perhaps one of the earliest studies to report a WTA-WTP gap was by Coombs et al. (1967). However, the experiment involved a hypothetical setting of lottery tickets without real exchange.

3.2.1 Loss aversion and the endowment effect

To understand exchange asymmetries in terms of loss aversion, consider the following piecewise-linear Köszegi–Rabin type utility function,

$$v(x) = \begin{cases} m + (x - r) & \text{if } x \geq r \\ m + \lambda(x - r) & \text{if } x < r \end{cases}, \quad (3.1)$$

where x is the actual value of the consumption of the good, r is some “reference point” for this value, m is the amount of money received (this is negative if money is paid out), and λ is the coefficient of loss aversion.⁶

In most exchange experiments, sellers are endowed with one unit of an object, say, a mug, hence, assume that the reference point of the seller is $r = 1$. In (3.1), the separability in goods and money is motivated by experimental results (see above), which suggest that there is no endowment effect for money. Suppose that the seller is offered a price p for the mug. Using (3.1), and noting that $m = p$, if he does not sell the mug, then his utility is $v(x = 1) = 0$. If he sells the mug, his utility is $v(x = 0) = p - \lambda$. Hence, he sells the mug if and only if

$$p - \lambda \geq 0. \quad (3.2)$$

Notice that the coefficient of loss aversion, λ , plays a critical role in the decision to sell the mug. Higher loss aversion impedes sales, unless the price is high enough.

Definition 3.58 (WTA): The WTA is the minimum price, $p = p_s$, that the seller is willing to accept in order to sell the mug. From (3.2)

$$p_s = \lambda. \quad (3.3)$$

Consider now the buyer who is not endowed with the mug, so his reference point is $r = 0$. Using (3.1), and noting that at any price that he pays, p , we have $m = -p$, if the buyer does not buy the mug, then his utility is $v(x = 0) = 0$. If he buys the mug, then, his utility is $v(x = 1) = 1 - p$. Hence, the buyer buys the mug if and only if

$$1 - p \geq 0. \quad (3.4)$$

Definition 3.59 (WTP): The WTP is the maximum price, $p = p_b$, that the buyer is willing to pay for the mug. From (3.4),

$$p_b = 1. \quad (3.5)$$

From (3.3), (3.5), we get that:

$$\frac{WTA}{WTP} = \frac{p_s}{p_b} = \lambda. \quad (3.6)$$

Hence, the ratio of WTA to WTP is simply the coefficient of loss aversion. In Kahneman et al. (1990), $WTA = 7.12$ and $WTP = 2.87$, so we get that $\lambda \approx 2.5$. Across 45 studies surveyed in Horowitz and McConnell (2002), the median estimate of WTA/WTP is 2.6.

⁶ Recall the first two lines of instructions above: “You are an owner, so you now own a token which has a value to you of \$ x . It has this value to you because the experimenter will give you this much money for it.” This is the value of x in (3.1).

What sort of factors does the endowment effect depend on? Insofar as the endowment effect is caused by loss aversion alone, one can equivalently ask, what factors does loss aversion depend on? Can the endowment effect be switched on and off, or be reduced/amplified? While more work remains to be done in this area, the literature already suggests several factors.

The endowment effect is reduced (equivalently loss aversion is reduced), when (1) the owned good and the unowned good are close substitutes (Chapman, 1998; Van Dijk and Van Knippenberg, 1996), (2) the duration of ownership is shorter (Strahilevitz and Loewenstein, 1998), (3) questions are framed in a way that directs sellers to the uses that money from sales can be put to and buyers to the benefits arising from ownership of the object (Carmon and Ariely, 2000), (4) a lesser proportion of money is earmarked for necessities (Wicker et al., 1995), (5) negative emotions such as disgust are invoked, prior to the elicitation of WTA and WTP,⁷ (6) subjects are relatively older or more educated individuals, and have greater knowledge of the attributes of a product (Johnson et al., 2006); the youngest subject had a loss aversion of 1.4, while the oldest subject had a loss aversion of 2.4, (7) there is a reduction in the ambiguity about the value of the good, and a reduction in the cost of gathering information (Kolstad and Guzman, 1999); explicit price information can reduce the ambiguity about value and reduce the WTA/WTP disparity (Zhao and Kling, 2001).

There is evidence of variability of loss aversion for an individual across different traits of a good or for different goods. Factors that could influence loss aversion for an individual include the following: whether the good is a health or a non-health good with greater disparity for health related goods (Brown and Gregory, 1999; Sayman and Oncüler, 2005), whether the good is an environmental or a non-environmental good (Irwin, 1994), whether trade in the good is legitimate or not (Sayman and Oncüler, 2005), and whether the good has hedonic or utilitarian attributes (Dhar and Wertenbroch, 2000).

To get a feel for how loss aversion might vary with the attributes to a product, consider the empirical study by Johnson et al. (2006). They conducted a survey of 360 German car buyers who had recently purchased a mid-sized car. Four different attributes of the car were considered. The aim was to measure loss aversion (using appropriate lotteries) for each individual and for each car attribute. Across all individuals, and attributes, the average loss aversion was 1.85. On average, for any individual, loss aversion for the four attributes was not correlated. There was also significant heterogeneity in measured loss aversion across individuals. The average coefficients of loss aversion across the four attributes were 1.66 (fuel consumption), 1.89 (comfort), 1.89 (safety), and 1.94 (information). One possible explanation is that people differ in their perceptions of the various attributes and loss aversion is context dependent. This supports a great deal of research elsewhere on the context dependence of preferences.

It is important to note that the same subjects who exhibit loss aversion in this study had recently engaged in a major purchase. This is a noteworthy point in the light of other studies (considered below) which push the alternative view that if subjects are sufficiently well trained, experienced, and briefed about strategies and equilibrium notions, then they might completely shed loss aversion. Johnson et al. (2006) conclude with the following. “Thus, we suggest that the question should not be whether or not loss aversion is important, but rather how important loss aversion is, and for which attributes and consumers.”

⁷ See, for instance, Lerner et al. (2004). These authors find that when disgust is invoked, the endowment effect gets switched-off. Peters et al. (2003) also point out the effect of emotionally difficult trade-offs on the WTA-WTP disparity. Boyce et al. (1992) find that the WTA-WTP disparity increases when the exchange of goods involves a degree of moral responsibility.

Individual-level heterogeneity is found in another study by Gächter et al. (2010) who compare loss aversion for risky and riskless choice. The correlation in loss aversion between these two choices is 0.635, which is statistically significant at the conventional levels. Averaged across all individuals they get the classic figure of loss aversion of around 2. However, across individuals they found that for 78% of the individuals, the loss aversion parameter is between 1 and 4; for 10 percent of the individuals, it is above 4; and for 22% of individuals, it is around 1.

3.2.2 Is there any risk aversion beyond loss aversion?

Novemsky and Kahneman (2005) extend Thaler's (1980) idea of using loss aversion as an explanation of exchange disparities to risky choice. Their most important conclusion is that *there is no risk aversion beyond loss aversion* when subjects are presented with lotteries that have balanced risks (i.e., equal probability of all outcomes). The idea that the finding of risk aversion could, at least partly, be caused by loss aversion is well recognized.⁸

Definitions 3.58, 3.59, respectively, define WTA and WTP. We now give another useful definition that relies on the concept of "choosers" in Kahneman et al. (1990) that we have defined above.

Definition 3.60 (*Choice equivalent*): The choice equivalent, CE, is defined as the minimum amount of money that "choosers" would accept in preference to the object.

Novemsky and Kahneman (2005) motivate their ideas through a series of hypotheses. Recall that choosers do not actually have possession of the object, and they exhibit no endowment effects. Empirically, they behave like buyers and not sellers. For this reason, they are willing to accept a lower amount of money in preference to the object (CE) relative to the WTA of sellers, hence, we get hypothesis H1, below.

H1: $\frac{WTA}{CE} > 1$ (endowment effect).

A second finding is that for intrinsically useless assets such as money and tokens, one does not find the presence of an endowment effect. In this case $WTA = WTP$, but $WTA = CE$ for choosers, thus, we get H2.

H2: $\frac{CE}{WTP} = 1$ (no loss aversion in parting with money).

In Novemsky and Kahneman (2005), the first three conditions are identical to Kahneman et al. (1990), namely, *sellers*, *buyers*, and *choosers*. In order to take account of risk, two additional conditions are introduced. In the first of these conditions, the *risky seller condition*, sellers are endowed with a mug. In addition, they are asked if they would be willing to accept the following voluntary *balanced risk* lottery with two outcomes. (i) Retain the mug and gain an amount of money, m , with probability 0.5. (ii) Lose the mug and receive nothing with probability 0.5.

Definition 3.61 (*RWTA*): The risky willingness to accept (RWTA) is the minimum sum of money, m_s , that the sellers require to accept the balanced risk gamble in the "risky seller condition."

In the second additional condition, the *risky buying condition*, buyers face the following balanced risk gamble with two outcomes. (i) Receive the object and pay nothing with probability 0.5. (ii) Pay some amount of money, m , and not receive the object with probability 0.5.

⁸ See, for instance, Kahneman and Tversky (2000), Kahneman (2003), List (2004), Marquis and Homer (1996), and Rizzo and Zeckhauser (2003).

Definition 3.62 (RWTP): The risky willingness to pay (RWTP) is the maximum amount of money, m_b , that the buyer will pay to accept the balanced risk gamble in the “risky buying condition.”

We use the classical utility function under PT (and not (3.11)) to calculate the relevant expressions for RWTA and RWTP. We use a probability weighting function $w(p)$ that has the same form for losses and gains. The decision maker’s utility from an outcome is given by (3.1).

In the *risky seller condition*, consider the problem faced by a seller who owns a mug, so $r = 1$. If the seller accepts the balanced risk gamble, then there is one outcome each in the domain of gains and losses, and his utility, v_s , is given by

$$v_s = w(0.5)(1 - 1 + m) + w(0.5)\lambda(0 - 1). \quad (3.7)$$

If the seller does not accept the gamble, then he retains the mug but gets no money, so his utility is $v_s = 1 - 1 = 0$. Hence, the seller accepts the gamble if and only if

$$w(0.5)m - \lambda w(0.5) \geq 0 \Leftrightarrow m - \lambda \geq 0.$$

Using Definition 3.61, the RWTA is given by

$$m_s = \lambda. \quad (3.8)$$

Now consider the *risky buyer condition*. Since the buyer does not own the mug to begin with, so his reference point $r = 0$. If the buyer engages in the balanced risk gamble, there is one outcome each in the domain of gains and losses, and his utility, v_b , is given by

$$v_b = w(0.5)(1 - 0 - 0) + w(0.5)\lambda(0 - 0 - m). \quad (3.9)$$

If the buyer does not engage in the gamble, then his utility is $v_b = 0$. Hence, in the *risky buyer condition*, the buyer accepts the gamble if and only if

$$w(0.5) - w(0.5)\lambda m \geq 0 \Leftrightarrow 1 - \lambda m \geq 0. \quad (3.10)$$

Using Definition 3.62 and (3.10), we get that the RWTP is given by

$$m_b = \frac{1}{\lambda} < 1. \quad (3.11)$$

(3.8) and (3.11), in conjunction with Definitions 3.58 and 3.59, allow us to formulate the next two hypotheses.

H3: For balanced risks, $\frac{RWTA}{WTA} \equiv \frac{m_s}{p_s} = 1$ (no risk aversion beyond loss aversion).

Hypothesis H3 simply follows from (3.3), (3.8). Its consequences are profound for economics, namely, that for balanced risks there is no risk aversion beyond loss aversion. Loss aversion is present in the risky and the riskless conditions. If the individual feels any risk aversion beyond loss aversion, then it must be the case that $RWTA > WTA$ (i.e., the seller would require greater compensation for parting with the object in the risky condition). But $RWTA = WTA$. Hypothesis

H3 also gives support to the notion that the parameter of loss aversion is the same in risky and riskless situations.

From (3.5), $p_b = 1$ and from (3.11) $m_b = 1/\lambda$, hence, we get our final hypothesis, H4.

H4: For balanced risks $\frac{WTP}{RWTP} \equiv \frac{p_b}{m_b} > 1$.

Hypothesis H4 assumes that in riskless conditions, buyers do not have loss aversion for the money that they are spending. However, in the risky condition, buyers are gambling away their money. If buyers are loss averse with respect to money under risk, then their risky willingness to pay should be relatively smaller, giving rise to H4.

To recap, there are five conditions: sellers, choosers, buyers, risky sellers, and risky buyers. The objects used are chocolates, pens, and mugs. The elicitation mechanism ensured that there would be no strategic responses. The median response by the appropriate subset of subjects is used to compute WTP, WTA. A bootstrapping method is used to estimate confidence intervals for the various ratios used in H1–H4. The aggregate estimates of these ratios were as follows,

$$\frac{WTA}{CE} = 1.85; \frac{CE}{WTP} = 1.07; \frac{RWTA}{WTA} = 0.91; \frac{WTP}{RWTP} = 2.31, \quad (3.12)$$

which supports all of the hypotheses H1–H4. The experimental results can thus be summarized as follows:

1. Because $\frac{WTA}{CE} > 1$ and $\frac{CE}{WTP} \cong 1$, as in earlier studies, there is no loss aversion for money in riskless situations.⁹ The 95% confidence interval for $\frac{WTA}{CE}$ included the number 2 (a commonly found magnitude for the parameter of loss aversion, λ) in five out of seven experiments.
2. Since $\frac{WTP}{RWTP} > 1$, there is loss aversion for money given up in risky situations. The ratio $\frac{WTP}{RWTP}$, however, turned out to be quite variable across experiments so there is need for more work in this area.
3. Since $\frac{RWTA}{WTA} \cong 1$ (the 95% confidence interval included the number 1 for all experiments), *there is no risk aversion beyond loss aversion*. This is a profound result for economics; indeed, economists who are detecting risk aversion in their empirical studies, might actually be picking out loss aversion.¹⁰

Schunk and Winter (2009) provide more indirect support for these results. They look at problems which require the computation of optimal stopping times. Such models typically postulate risk-neutral decision makers. The observed stopping times fall short of the predictions under standard theory with risk-neutral decision makers. Schunk and Winter (2009) find that the optimal stopping times are based on search heuristics. Furthermore, these search heuristics are not correlated with risk attitudes but with attitudes towards loss aversion.

3.2.3 Market experience and loss aversion

In their experiments, Kahneman et al. (1990) (see above) conducted two sets of market trials, respectively, with mugs and pens. Each set of trials consisted of four successive markets. At the

⁹ Unlike most other studies, Bateman et al. (1997) report loss aversion of buyers for money in riskless situations; they find that $\frac{CE}{WTP} = 1.67$, which is statistically different from 1. They also find little loss aversion in selling. Novemsky and Kahneman (2005) conjecture that the source of the difference lies in different subject pools (US versus UK students) as well as the perception of the UK subjects that they did not have budget reserves (hence leading to loss aversion for money).

¹⁰ An important condition for this result is that income effects must be small. Hence, for large stakes, this result might or might not hold.

end of each market trial, full feedback was provided to all the participants in order to facilitate learning. They found that as the market trials progressed (from 1 to 4) there was no evidence of learning, and the disparity between WTP and WTA remained. In contrast, some earlier studies report that market experience in practice trials (typically hypothetical and non-binding trials) significantly reduces the WTP/WTA disparity.¹¹ Kahneman et al. (1990) argue that the source of the difference between the two sets of results arises from the fact that each of their market trials was potentially binding, which is not the case with earlier empirical studies.

One may wonder if the time span required for learning is longer than what Kahneman et al. (1990) allow for in their experiments? List (2003) seeks to address these issues using field data. In his first market, he used two sports memorabilia items, A and B.¹² A distinction is made between dealers and non-dealers in the sports memorabilia market. Dealers have greater experience of trades as compared to non-dealers. Both dealers and non-dealers could be buying and/or selling objects. The pooled sample contained both dealers and non-dealers. There were also separate samples of dealers and non-dealers.

Dealers/non-dealers were given possession of one of the two objects. They were then given the opportunity to trade the object for the other object. Both items are somewhat non-standard in the sports memorabilia market. However, a pre-test suggested that the preference between the two items is nearly equally split, so we should expect trade to take place about 50% of the time. In the exit interviews, 95% indicated that they would like to keep the object for their own collection, rather than intending to use it for resale.

In the pooled sample of dealers and non-dealers, there was too little trading (i.e. trades below 50%) as predicted by the endowment effect. For items A and B, the actual trades were 32.8% and 34.6%, respectively, which suggest that $WTA > WTP$. Despite the random allocation of objects, a Fisher exact test was used to control for the problem that more people than the average could have received their most preferred item (and so do not need to trade). The test rejected the null hypothesis of no-endowment effect.

Splitting the pooled sample into dealers and non-dealers reveals a different picture. Dealers trade objects A, B, respectively, 43.6 and 45.7% of the time. For non-dealers, these percentages lie between 20–25. The Fisher test allows rejection of the null hypothesis (no-endowment effect) for non-dealers. However, the null hypothesis is accepted for dealers, i.e., dealers do not exhibit an endowment effect. When non-dealers are differentiated between experienced (who trade six or more items in a month) and inexperienced ones, it is found that for the latter category, the endowment effect is stronger. The nature of the results is similar when they are replicated with a different set of objects. A logit regression confirms that the propensity to trade is positively affected by trading experience, i.e., experience seems to mitigate the endowment effect.

An important issue is whether *selection effects* have been properly controlled for. Do dealers trade more because they are more experienced (treatment effect) or is it because the type of people who have lower loss aversion (and, so, a lower endowment effect) become dealers and trade more (selection effect)? To test for this effect, List followed up, a year later, the 148 people who

¹¹ See, for instance, Knez et al (1985), Brookshire and Coursey (1987), and Coursey et al. (1987). Loomes et al. (2003) also find a disappearance of the systematic part of the WTA–WTP disparity with experience, although they cannot pinpoint the mechanism that leads to this disappearance. Shogren et al. (1994) find that exchange asymmetries disappear with repeated experimental interaction when there are close substitutes for market goods. But this result does not hold for non-market goods with imperfect substitutes. However, Morrison (1997) raises doubts about these results.

¹² Item A is a ticket stub in which Cal Ripken Jr. broke the world record for consecutive baseball games played. Good B was a dated certificate to commemorate the game in which Nolan Ryan achieved the distinction of winning 300 baseball games.

participated in the earlier sports memorabilia experiment in 1999. Of these, he was able to meet 72 (less than half the original sample). The idea was that the subjects have had an extra year's experience and so would perhaps have shed their endowment effect even further. With this restricted set of subjects, two new A and B objects were introduced. The result was that the subjects, on average, engaged in slightly more trades in the year 2000 compared to the year 1999 (6.84 versus 5.66). List (2003) concludes that this demonstrates a reduction of the endowment effect with experience.

List (2004) seeks to address one possible criticism of List (2003). This is to take account of the possibility that no endowment effect should be observed if sellers hold a good for resale (e.g., Kahneman et al., 1990). Whilst the exit interviews in List (2003) suggested that subjects intended to keep the objects for personal consumption, List (2004) reverts back to the more traditional items used to test the endowment effect, such as mugs and Swiss chocolate bars. The expectation is that these items will not be used for resale. The other feature of List (2004) that is different from List (2003) is that experience in selling/buying one sort of item is expected to be transferred to selling/buying other objects (mugs, chocolates). The findings in List (2004) are similar to those of List (2003).

In conjunction, the findings in List (2003, 2004) have generated substantial interest. The skeptical view is that these findings have served to reject PT. A more balanced view is that the real contribution of List (2003) is to demonstrate that there are differences in the trading propensities of dealers and non-dealers. List (2003) is not alone in highlighting the role of experience in potentially affecting loss aversion. For instance, Camerer et al. (1997) find differences in loss aversion for experienced and inexperienced New York cab drivers. Similar evidence from the housing market comes from Genesove and Mayer (2001). However, we would urge caution in interpreting the List (2003) findings as a rejection of PT. We elaborate below.

1. Considerable experience is required in the market experiments of List for the endowment effect to diminish.¹³ However, in a range of plausible and non-trivial real-world situations such as selling a car, a house or a consumer durable, and making decisions such as marriage and divorce, one typically does not have the benefit of learning from a large number of repetitions. In these cases, one is likely to exhibit loss aversion, like non-dealers in the List experiments.
2. There are other possible interpretations of the results in List (2003). In 1999, his sample had 148 individuals, while the latter sample in 2000 had 72. It is quite likely that the average trades of the two groups could differ by a relatively small amount (6.84 versus 5.66, as it turns out) for a variety of other reasons, e.g., a more pessimistic trading environment in 2000 as compared to 1999. Further, the 72 people out of 148 is not a random sample. It is possible that the 72 who agreed to participate in the experiment, a second time, are the more committed traders who regularly go to the annual sports trade shows. Hence, there is a selection issue involved. Others are even more skeptical about the attempts to control for selection issues in the context of List's work. For instance, Plott and Zeiler (2007, p. 1451) write: "One can formulate other candidate theories, based on various features of List's experiments, to explain his observation . . . Conducting experiments in the field makes it difficult, if not impossible to control for selection effects."

¹³ In List (2003), experienced dealers carry out 6 or more trades per month, while in List (2004) the requirement increases to 11 or more trades per month. Furthermore, such intense trading is carried out by these dealers over several years.

3. Several other studies that we review below suggest that in other important contexts, with higher stakes, and much larger datasets (in one case, more than 2.5 million data points), experienced subjects are also loss averse.
4. List (2003) also finds a reduction in the endowment effect for students who participate in a WTA/WTP experiment for four successive weeks. Students exhibit experience effects that are similar to these effects for dealers in the field. In the first week, 12% of the students trade their endowed good, but 26% do so in the fourth week, suggesting that experience may mitigate the endowment effect. In the light of these experiments, the title of List's paper "Does market experience eliminate market anomalies?" is misplaced. Going by the results of the paper, market experience appears to reduce loss aversion both in the lab and in the field. Yet the misleading inference that only market experience in the field is somehow effective is routinely drawn. Consider, for instance, the following quote from Haigh and List (2005, p. 525): "In light of some recent studies (e.g., List, 2002, 2003, 2004) that report market anomalies in the realm of riskless decision-making are attenuated among real economic players who have intense market experience, the current lot of experimental studies with MLA [myopic loss aversion] may be viewed with caution."¹⁴

A recent field study by Pope and Schweitzer (2011) finds that even experienced players on the PGA golf tour exhibit loss aversion. The stakes in this study, in contrast to the work by List (2003, 2004) are very large. In golf, on the PGA circuit, players play 4 rounds of 18 holes, for a total of 72 holes, over 4 days. The objective is to minimize the number of shots required to complete the 72 holes. In order to complete a hole, the golfer begins with a drive (or a *tee*) and then a series of shots that takes the golfer to the "green." At the green, the golfer engages in a series of sequential shots, until eventually the ball rolls into the targeted hole. Technically, the shots on the green are known as *putts* and the aim is to *sink the putt into the hole*.

Each hole in a golf course is associated with a number, called the *par*. The par is the minimum number of shots that a skilled golfer would take in order to sink the putt, starting with the drive. The par score can differ among the holes because of the distance from the tee to the hole, or the level of difficulty involved. On the PGA golf tour, the par scores for holes are typically 3, 4, or 5. The scores are recorded on score cards that measure the number of shots taken to sink the putt relative to the par score. Thus, if one sinks a putt using one stroke less than the par score, then one is said to have shot a *birdie*, and two strokes below par is an *eagle*. In these cases, the golfer is said to be *under par*. On the flip side, sinking the putt one stroke above par is called a *bogey* and two strokes above par is called a *double bogey*. In this case, the golfer is said to be *over par*. The third possibility is that the golfer might be *on par* (matching the par score).

Since all scores are measured relative to the par score, the authors make the plausible assumption that the par score for a hole acts as the reference point for that hole. It follows that if the golfer is *under par* (say, on a birdie or an eagle), he/she faces a different situation as compared to being *on* or *over par*. When on par, there is the possibility of missing the par score (reference point) so shots ought to be hit with relatively greater precision and accuracy, otherwise the golfer might be in the domain of losses and suffer loss aversion. Thus, we expect more successful par putts as compared to birdie putts.

Pope and Schweitzer (2011) explore this idea by using a sample in excess of 2.5 million data points with laser measurements of initial and final ball placements. They control for a large number of potentially relevant factors. These include the following. (i) The greater difficulty of birdie

¹⁴ MLA in this quote refers to *myopic loss aversion*; see Section 3.4.

Figure 3.1 Fraction of successful par and birdie putts by distance to the hole.

Source: Pope and Schweitzer (2011) with permission from the American Economic Association.

putt positions of the ball relative to the par putt positions. (ii) Information revealed by a birdie putt that helps the par putt. (iii) Player and tournament specific factors. The findings are as follows.

First, controlling for other factors, and consistent with a loss aversion account, golfers are less successful with their birdie putts, relative to comparable par putts, by 2–3 percentage points; see Figure 3.1. Second, the contrast between the birdie and par putts is even more noticeable on the first hole, where the par score is even more salient relative to subsequent holes.¹⁵ Third, if the top 20 golf players on the PGA tour in 2008 were to shed the trait of loss aversion, then they would each stand to gain \$1.2 million. Fourth, players are more risk averse in the gains domain than in the loss domain. In conjunction, these results make a persuasive case that loss aversion persists even with experience when large stakes are involved.¹⁶

Using field data from school teachers in Chicago, Fryer et al. (2012) demonstrate that teachers, including experienced teachers, exhibit loss aversion. They distinguish between two treatments. In one treatment, teachers were promised an “end of year bonus” conditional on student grades. In a second treatment, teachers were given financial incentives in the form of money, up-front. However, they were told that the money would be clawed back from them at the end of the year if the students did not achieve the desired educational levels. In EU, RDU, the results should

¹⁵ In subsequent holes, other factors such as competitor’s scores also become important.

¹⁶ Readers, particularly golf enthusiasts, may wonder about the role of confounding factors in these results. Here we quote from the authors (p. 130): “Beyond controlling for distance, consider and rule out several competing explanations for this finding. First, prior to hitting a par putt, players may have learned something about the green (by having already attempted a birdie putt). Second, birdie putts may start from a more precarious position on the green than par putts due to a longer approach shot. Third, player or Tournament-specific differences may bias our results. Using detailed data, we are able to rule out competing explanations with control methods and matching estimators. For example, we can match par and birdie putts attempted within one inch of each other on the exact same hole in the same Tournament. We are also able to rule out other psychological explanations. For example, we consider whether or not players become more nervous or overconfident when they shoot birdie putts relative to par putts.”

be identical under the two treatments. However, if teachers follow PT, then in the second treatment, teachers who are already endowed with the money would be loss averse with respect to giving back the money at the end of the year. So, as expected from a loss aversion based explanation, the effect of the financial incentives on student grades was significantly larger in the second treatment.

Kliger and Levy (2009) put EU, RDU, and PT to the test, using real financial assets market data. Their findings provide strong support for the individual components of PT, which include reference dependence, diminishing marginal sensitivity, loss aversion, and non-linear weighting of probabilities in the domain of gains and losses. Gurevich et al. (2009) also find support for PT using US stock market data, although they find loss aversion that is asset specific and, on average, lower than that found in student populations.

The work of Abdellaoui et al. (2013) nicely complements these findings using as their subjects, finance professionals (private bankers and money managers handling \$300 million on average). Unlike Gurevich et al. (2009) who use more aggregate data, Abdellaoui et al. (2013) are able to get data at the level of the individual finance professional, and observe if these “individual choices” are in accordance with PT. Almost all elements of PT find strong support (with the exception of loss aversion), and there is significant preference heterogeneity among the professionals. Furthermore, these professionals violate EU. These are significant findings because finance professionals are experienced and well trained in diversifying risk, and provided with extensive feedback on their performance.

3.2.4 *Subject misinterpretation as explanation of exchange asymmetries*

Plott and Zeiler (2007) (henceforth, PZ) conjecture that disparities between WTP and WTA are caused by the “procedure” that is used to elicit WTA and WTP. In the traditional experiments for exchange asymmetries, it was typical for the experimenter to announce the following; “I am giving you this object. It is a gift. You own it.” The *language* used in these instructions potentially creates problems.¹⁷ In order to rectify this potential problem, PZ tell subjects that a coin is tossed to determine their endowment, which could be one of two objects. In the typical exchange asymmetry experiment, subjects make their choices publicly. To ensure that there are no spillover effects of such announcements, PZ asked subjects to report their choices privately, in writing.

In a control group under the standard procedure, they detected the presence of exchange asymmetries. However, having made the procedural changes, listed above, they find that the endowment effect is weakened or eliminated (depending on the treatment). PZ take their results as a challenge to the traditional explanations of exchange asymmetries. The explanations offered by PZ of their results are behavioral in nature, such as framing effects, reciprocity, and gift-exchange arguments. Some of these results have been replicated by Knetsch and Wong (2008).

In an earlier paper, Plott and Zeiler (2005) (henceforth, PZ1), examine the effect of subject misperceptions in generating exchange asymmetries. Subjects are extensively *tutored* in economic logic, prior to the conduct of actual experiments.¹⁸ In a baseline experiment, absent these controls

¹⁷ They also raise other potential confounds. One potential problem is asymmetric information about the quality of the object used. However, the objects are typically quite simple such as mugs and pens, so asymmetric information might not be a serious issue. Another potential confound is that sellers may have other-regarding preferences, so they could reciprocate a gift from the experimenter by placing a high value on it.

¹⁸ As part of the tutorial, they are taught how and why economic mechanisms designed to elicit truthful preferences, such as the Becker DeGroot and Marshak (1964) mechanism, work. They are also taught about the cost

for subject misrepresentation, the phenomenon of exchange asymmetry is confirmed. However, in the presence of the controls, the means of the ordered (WTA , WTP) pairs for three different experiments were (5.69, 5.60), (5.71, 7.88), (5.06, 7.29). The mean WTP exceeded the mean WTA for two out of three experiments. The authors conclude that the observed gaps are the result of subject “misconceptions about the nature of experimental tasks.”

Like PZ, the major contribution of PZ1 is to bring out the importance of framing effects in the area of exchange asymmetries. Subjects in experiments alternate in the roles of sellers and buyers, which might alter attitudes that produce, say, the ownership effect that is important for exchange asymmetries. Furthermore, as PZ1 recognize, their procedures might have created a feeling on the part of subjects that the experimenter wishes to remove notions of ownership of the object. If this is the case (which cannot be rejected by the data from the experiment), then there could be a gap between the subject’s stated and true preferences.

Isoni et al. (2011) question the results of PZ1 along the following lines. PZ1 first run lottery experiments for training purposes and then run their experiments using mugs. PZ1 find that controlling for subject misperceptions, no exchange asymmetries are found for the case of mugs. But they do not report the experimental results for the case of lotteries because these were subjected to two forms of contamination. The first problem was that the selling task preceded the buying task and the second problem was that the experimenter publicly corrected mistakes and gave public answers to questions. The result was that PZ1’s influential results were based only on coffee mug experiments with 36 subjects reporting WTP and 38 reporting WTA .

The aim of the experiments by Isoni et al. (2011) is to report the results for the WTA/WTP for not only coffee mugs but also experiments based on lotteries that were not subjected to any contaminating influences. To determine the WTA , subjects were asked to report their WTA for the lottery $(x, p; y, 1 - p)$ and to determine the WTP , subjects reported their WTP for the lottery $(x + c, p; y + c, 1 - p)$, where $c > 0$. Under EU and constant absolute risk aversion, we have $WTP - WTA = c$, while the alternative hypothesis is $WTP - WTA < c$; this allowed for a within-subjects test of exchange disparities. The experimental format replicated PZ1, so it was intended to control for subject misrepresentations. The main finding is that no WTA/WTP disparities were found for mugs (as in PZ1), but significant exchange disparities were found in the case of lotteries.

The exchange disparity is not mitigated as subjects gain more experience in successive rounds. If the elicitation procedure holds the key to explaining exchange asymmetries, then it should apply to both lotteries and mugs. But since exchange asymmetries are found for lotteries but not mugs, Isoni et al. (2010) conclude that the elicitation procedure is possibly a red herring in explanations of exchange asymmetries. It is an open question as to why exchange asymmetries are found for lotteries but not mugs. The authors offer some conjectures using the mental accounting literature, such as the *house money effect* caused by show-up fees.¹⁹ Based on their results, the authors also conjecture that the difference between the results from lotteries and mugs are not due to the certainty/uncertainty dimension but due to the nature of money and consumption goods.

and benefits of pursuing alternative strategies. Subjects could ask questions, which the experimenter would then clarify. Numerical examples with concrete illustrations were also provided. Each experimental session consisted of a detailed training session, 2 practice rounds (unpaid), followed by 14 paid rounds using lotteries and finally 1 paid round with mugs that tested for exchange asymmetries.

¹⁹ The house money effect refers to the tendency to take greater risks in the presence of prior gains (Thaler and Johnson, 1990). For a form of the house money effect, based on a loss aversion explanation, and using stock market data, see Zhang and Semmler (2009).

Fehr et al. (2015) suggest that if subject misconception is the cause of WTA/WTP anomalies, then we ought to separate subjects into those who understand the elicitation mechanism used in the experiments, and those who do not. When they make this separation, and use the experimental protocol in PZ1 and the insights of Isoni et al., they find that the WTA/WTP anomaly arises for both lotteries and mugs; the findings for mugs are also replicated for USB sticks. Hence the title of their paper: The Willingness to Pay-Willingness to Accept Gap: A Failed Replication of Plott and Zeiler.

3.2.5 Other implications/explanations of the endowment effect

PROPERTY RIGHTS AND EXCHANGE ASYMMETRIES

A basic lesson from microeconomics is that indifference curves can be specified in the absence of any information on endowments and the budget constraint. However, one implication of WTP and WTA disparities is that an individual's indifference curves might cross if their endowment changes.

Figure 3.2 shows indifference curves in the space of mugs (a commonly used object in experiments for which the endowment effect is found), and money (for which no endowment effect arises). For any individual in the respective roles of buyer (no mugs, no money) and seller (one mug, no money), the respective endowment points are $e_b = (0, 0)$ and $e_s = (0, 1)$. Starting from the endowment point, the evidence on exchange asymmetries shows that a seller places a greater marginal value on another unit of mug (in terms of money) as compared to a buyer. Thus, the indifference curves for a seller are relatively flatter, as shown in Figure 3.2; $I_b I_b$ is an indifference curve for a buyer and $I_s I_s$ for a seller. The implication is that the indifference curves of the seller and the buyer, who only differ in their endowment, can cross.

The Coase theorem states that in the absence of any frictions/transaction costs, the initial allocation of property rights is irrelevant to the efficiency of the eventual outcome. However, if the endowment effect is accepted, then the act of assigning ownership (i.e., property rights) alters one's valuation (for sellers) or willingness to pay for the good (for buyers). This, in turn, alters the efficient outcome before and after the allocation of property rights. Hence, the Coase theorem, as it is traditionally stated, does not hold, or has to be modified to take account of ownership effects.

Figure 3.2 Crossing of indifference curves when there is an endowment effect.

The increase in the value of an object that arises purely from the act of ownership is also recognized in common law. For instance, the common perception that “possession is nine-tenths of the law” exemplifies this. Kahneman et al. (1991) credit the US Supreme Court justice, Oliver Wendell Holmes with the following quote. “It is in the nature of a man’s mind. A thing which you enjoyed and used as your own for a long time, whether property or opinion, takes root in your being and cannot be torn away without your resenting the act and trying to defend yourself, however you came by it. The law can ask no better justification than the deepest instincts of man.”

SOME MARKETING IMPLICATIONS OF EXCHANGE ASYMMETRIES

Novemsky and Kahneman (2005) give several implications of the endowment effect for marketing that are based on two premises.

1. When the benefits of the good whose ownership is about to be given up are similar to the benefits of the good to be acquired, then loss aversion with respect to the owned good is not likely to present. In this view, loss aversion operates along the benefits dimension of the good rather than along the attributes dimension.
2. Goods that are intended to be used only for exchange are not evaluated as losses. This assertion has two dimensions. First, firms or merchants that acquire a good with the sole intention of reselling it for money, do not experience loss aversion from the act of selling. This also potentially explains why List (2003, 2004) finds a lower degree of loss aversion for dealers relative to non-dealers. Second, some consumers/households may have a budget for miscellaneous items in order to cover for unforeseen expenditures. The goods acquired by spending money from this account might not be close substitutes for other goods. However, there is no loss aversion with respect to the money spent from this miscellaneous account. Other consumers may not have a miscellaneous account for unanticipated purchases, which typically are not substitutes for other goods. These consumers may suffer loss aversion for the money spent on making such unanticipated purchases.

Novemsky and Kahneman use these premises to offer the following applications. *Trial-offers*, which give consumers the opportunity to use a good for a limited period without making a payment, induce consumers to include the good as part of their endowment. Having used the good, the consumer experiences loss aversion by giving up the good at the end of the trial period. Such consumers may be willing to buy the good at the end of the trial period, but in the absence of the trial period, they might never have decided to buy. Yet another effect of the trial period is that the expenditure on the good could be transformed from being an unanticipated item, to which loss aversion applies, to being a part of the consumer’s main budget for intended purchases. Thus, the money spent on such goods once the trial period expires may not be subjected to loss aversion.

Yet another marketing device is to trade in old cars for new ones. Consumers of older cars might be loss averse to selling their old cars (endowment effect), creating a trade friction. However, by trading-in their old car for another car, whose benefits are very similar, loss aversion is mitigated (premise 1 above). Consumers are then more likely to buy newer cars.

Another implication of the differing behavior of sellers and buyers in studies of the endowment effect is the following. Buyers consider the *opportunity cost* of buying objects such as mugs. Not buying the mug is a *reduction in gain*. If the endowment effect is accepted, then sellers on the other hand are worried about *out-of-pocket costs*; parting with the mug is an *actual loss*. Hence, the disparity between WTP and WTA can alternatively be viewed as a disparity between (1) opportunity costs versus out-of-pocket costs or, equivalently, as (2) reduction in gain versus actual loss.

Kahneman et al. (1986) test these ideas using telephone interviews conducted on Canadian subjects. Successive questions, which were designed to draw out the contrast between “opportunity costs versus out-of-pocket costs” or “reduction in gain versus actual loss” were posed to the subjects. These questions were as follows.

Q.1a: (134 respondents) A shortage has developed for a popular model of automobile, and customers must now wait two months for delivery. A dealer has been selling these cars at list price. Now the dealer prices this model at \$200 above list price.

71% found the dealer’s action to be unfair and 29% found the action to be acceptable.

Q.1b: (123 respondents) A shortage has developed for a popular model of automobile, and customers must now wait two months for delivery. A dealer has been selling these cars at a discount of \$200 below list price. Now the dealer sells this model only at list price.

42% find the dealer’s action to be unfair and 58% find it acceptable.

In Q.1b, the elimination of the discount is viewed as a “reduction in gain.” This, we know, from the endowment effect, is less troubling for the individual relative to the imposition of the surcharge in Q.1a, which is viewed as an “actual loss.” Hence, a larger percentage of subjects think of the dealer’s action in Q.1a to be unfair. Along these lines, Thaler (1980) explains why firms that charge customers differently depending on whether they pay by cash or credit, frame the cash price as a discount (rather than saying that the credit price contains a surcharge).

Similar considerations might explain why it is easier to cut real wages during inflationary periods as the next two questions illustrate.

Q.2a: (129 subjects) A company is making a small profit. It is located in a community experiencing a recession with substantial unemployment but no inflation. The company decides to decrease wages and salaries 7% this year.

63% consider the company’s actions to be unfair, while the remaining 27% find the actions acceptable.

Q.2b: (129 subjects) A company is making a small profit. It is located in a community experiencing a recession with substantial unemployment and inflation of 12%. The company decides to increase salaries only 5% this year.

22% find the company’s actions to be unfair, while 78% find those actions acceptable.

The only difference in questions Q.2a and Q.2b is that in the latter, inflation takes place at 12%. In both questions, the final outcome for the workers is a 7% cut in real wages. In Q.2a, the outcome is framed as a nominal wage decrease (which subjects in experiments interpret as an actual loss). In Q.2b, on the other hand, it is framed as a reduction in (wage) gains on account of inflation, which subjects find relatively more acceptable.²⁰

STOCHASTIC REFERENCE POINTS

The exchange disparities between WTA and WTP can be explained if reference points are stochastic, say, in the Köszegi and Rabin (2006) framework; we do this in Section 2.8.3.

²⁰ While loss aversion can explain the outcome of these sets of questions, there are other competing behavioral explanations such as “money illusion” which is particularly relevant for Q.2a, Q.2b, and theories of reciprocity that take account of the role of intentions; see Parts 2 and 4 of the book.

A QUERY THEORY OF VALUE CONSTRUCTION

Another explanation of the endowment effect, called the *query theory*, has been proposed by Johnson et al. (2007). The theory is based on four main premises, all grounded in well known psychological principles.²¹

(1) *Queries*: When subjects in experiments are asked how much they would accept, or pay, for an object, say, a mug, they decompose the question into a series of *queries* such as the following. What are the advantages of my status quo (mug for the seller, and money for the buyer)? What are the advantages of pursuing the alternatives (in this case, arising from trade)? Advantages and disadvantages are encapsulated by means of positive and negative *aspects* of a situation. For a seller, the positive or value increasing aspects could include the following aspects. “Nice memento from the experiment; can be used as a Christmas present; you can never have too many mugs.” The negative, or value decreasing aspects could be things like the following. “This mug is ugly, I don’t need a coffee mug, or this mug looks dirty.” For a potential buyer, on the other hand, there are also positive aspects such as: “I am a low-income student, a few extra dollars will be very valuable”; and negative aspects: “I could hardly buy anything with this amount of money.” Queries could be automatic responses to questions that are unobservable to an outsider. Unlike queries, positive and negative aspects of a decision can be observed.

(2) *Sequential execution of queries*: Queries are executed *sequentially*. The order in which the queries are executed depend on the conditions in the experiment.

(3) *Competing memories*: Suppose that one is trying to recall some items from a list. Then the directed recall of some items in the list reduces the available memory for the unrecalled items in the list. In particular, when there are two main queries, then the recall of answers to one query suppresses recall of the answers to the second query; this is termed as *output interference*. In the particular context of this example, output interference implies that the retrieval of one source of information such as the advantages of the mug, reduces the retrieval of information about what could be done with that money.

(4) *Dependence on the endowment state*: This premise implies that the order in which the queries are executed depends on one’s endowment of the mug. So, if one is an owner of the mug, then the first executed query is the advantages of the mug. Alternatively, if the endowment is no-mug, say, the subject is a buyer, then the first executed query is alternative uses of the money.

The first three of these premises have reasonably good psychological bases, while the fourth, which is specific to the exchange asymmetry problem, needs to be tested. An important motivation of Johnson et al. (2007) is to test this premise.

In order to perform these tests, the authors perform an exchange asymmetry experiment using mugs. However, in addition, they use the method of *aspect listing*. While queries used and the order in which they are executed is not observable, the *aspects* (positive or negative) used by subjects in experiments are observable and can be used to form inferences about the queries used. *Aspect listing* accomplishes this by asking subjects to list the aspects they consider when making their WTA and WTP decisions. Subjects are also asked to note down the order of these aspects as well as the salience of various aspects. Trading in mugs was real, actual money was exchanged, and tests were carried out to check for subject miscomprehension. Subjects were randomly assigned as either *sellers*, *choosers*, or *buyers* and an incentive compatible elicitation mechanism was used.

²¹ We omit the references. The interested reader can directly look up the references in Johnson et al. (2007).

The results are as follows.

1. On average, the WTA for the mugs is \$5.71, while the WTP is \$3.42; the difference is statistically significant.
2. Sellers of the mugs produced more *value increasing aspects of mugs* that highlighted advantages of holding on to the mug. By contrast, buyers and choosers produced more *value increasing aspects of the alternative uses of money*. Furthermore, the order of queries was also in the expected sequential order. Sellers of mugs first produced value increasing aspects of the mugs before thinking about the value decreasing aspects of the mugs. In contrast, buyers first produced aspects relating to the alternative uses of the money.
3. Value increasing aspects increase the price and value decreasing aspects reduce the price of mugs.
4. Even stronger support for the theory is provided by an experiment in which the natural order of queries was reversed. Sellers were asked to first produce value decreasing aspects of the mugs, followed by the value increasing ones. Buyers were asked to produce value increasing, followed by value decreasing aspects of the mugs. This reversal of the natural order of queries eliminated exchange asymmetries entirely.

UNCERTAINTY AND EXCHANGE ASYMMETRIES

Engleman and Hollard (2008) distinguish between two alternative sources of uncertainty. *Choice uncertainty* refers to uncertainty about the object at the time of making the choice. For instance, the value of an object might be uncertain, or the individual might have incomplete preferences over objects in a set. On the other hand, *trade uncertainty* refers to uncertainty arising from the trading procedure and aspects of the trading partners. For instance, does the trading partner have “other-regarding preferences”? Is it morally correct to trade this object?

The authors conjecture that the endowment effect is caused by trade uncertainty. If true, then the presence of trade uncertainty causes people to trade less. In the words of the authors: “The market would thus be a poor teacher because traders will avoid those trades that would teach them the crucial lessons.” In order to examine these ideas, two treatments are considered. In the first treatment, subjects are free to trade, as in the traditional experiments that test for exchange asymmetries. However, in the second treatment, subjects were forced to trade; if they did not trade, they lost their endowments. This allowed subjects to experiment in uncertain situations, where natural caution would have prevented them from trading. In subsequent rounds of the second treatment, subjects in experiments do not exhibit the endowment effect. The authors provide one possible resolution of the endowment effect by artificially inducing more trade.

Roca et al. (2006) find that the status-quo bias arising on account of the endowment effect persists when an individual is endowed with an ambiguous lottery that can be exchanged with a lottery that has no ambiguity.²²

3.3 Prospect theory preferences in primates

Humans and other primate species share a common evolutionary history. Humans (genus *Homo*) and chimpanzees and bonobos (genus *Pan*) split from a common ancestor, the genus *Hominini*,

²² The ambiguous lottery is simply a ticket that allows one to bet on the unknown urn in Ellsberg’s experiments (see Chapter 1.4). The unambiguous lottery is a ticket to bet on the color of the ball from the known urn in Ellsberg’s experiments.

Figure 3.3 Tests of capuchin monkey preferences.

Source: Lakshminarayanan et al. (2008).

about 5 to 6 million years ago. The two immediately previous temporal evolutionary splits from common ancestors gave rise to, respectively, the gorillas, orangutans, and the gibbons. Humans differ experientially from the other primates in having specific market experience, however, evolution is very slow and conservative. Hence, common evolutionary features are likely to be exhibited in shared behavior between humans and other primates in several domains; for a survey, see Santos and Platt (2014).

We focus on studies that have been done on two species of monkeys, capuchin and macaque.²³ Macaques are extremely spatially dispersed Old World monkeys that are found mainly in Africa and Asia. The most common species of macaques in neurophysiological studies is the rhesus macaque. In contrast, the most common species of monkeys used in experiments on economic preferences and risk is capuchin monkeys. The habitat of these monkeys is in South and Central America; these are also sometimes known as New World monkeys. There are several reasons why capuchin monkeys are particularly suitable for these studies. The ratio of their brain to body size is high, they live in social groups, are socially sensitive, can learn from others, share food, engage in using tools, and quickly learn to trade tokens for food with experimenters (Fragaszy et al., 2004). Humans, chimpanzees, bonobos, and gorillas are part of the genus *Hominidae*, but monkeys belong to a different genus. Macaques separated from the evolutionary line that led to humans about 25 million years ago, while capuchins separated about 35 million years ago.

Chen et al. (2006) is one of the first studies to test elements of prospect theory on capuchin monkeys. They used monkeys who were trained to exchange tokens for food rewards. Under certainty, the monkey offers a token to the experimenter, who simultaneously holds a food item in one hand; see Figure 3.3. On receiving the token, the experimenter gives the food item to the monkey. Under risk, the experimenter offers a probabilistic reward, as explained below. The monkeys were placed in an enclosure and given a budget of tokens. Two experimenters wearing different colored clothing then positioned themselves on different sides of the enclosure. The monkey could trade tokens for food with both experimenters using openings in the enclosure.

²³ We ignore studies on pigeons and rats because they are more distant in evolutionary terms.

Two initial tests of consistency of capuchin preferences were conducted. In the first test, the monkeys' original allocation of budget on two food items (jello pieces and apple slices) was established after repeated trials. Then the monkeys were given a new budget but the price of one of the food items, in terms of tokens, was dropped. The monkeys substituted consumption towards the relatively cheaper item by spending a greater fraction of their budget on it. In fact, the choices of monkeys reliably satisfied the generalized axiom of revealed preference. As the authors note, many naive models and even some forms of random behavior can satisfy GARP.

In the second consistency test, experimenter 1 always offered and traded one apple slice in return for one token. However, experimenter 2 made a risky offering; he initially held out two apple slices to the monkey, but was equally likely to offer either two slices or one slice after receiving the token from the monkey. Thus, on average, experimenter 2 offered 1.5 slices, which is higher than the number offered by experimenter 1. Clearly, the offering of experimenter 2, first order stochastically dominates the offering of experimenter 1. Over 60 trials, spread over five sessions, 87% of the trading choices were directed towards experimenter 2. Thus, the vast majority of capuchins satisfied stochastic dominance.

In order to test for reference dependence, the offerings made by the two experimenters were as follows. In each case, the initial offer made by any experimenter, say, offering x slices of apples in return for a token, may be considered as the reference point. However, once a token is received from the monkey, the experimenter offers a trade in the following lottery in apple slices $(y, 0.5; z, 0.5)$. For experimenter 1, $x = y = 1, z = 2$ for an average offering of 1.5, while for experimenter 2, $x = y = 2, z = 1$, for an average offering of 1.5. The reference point is low for experimenter 1 and half the time his offering leads to a gain relative to the reference point. In contrast, the reference point for experimenter 2 is high and half the time his offering leads to a loss. Pooled across all monkey subjects, in the last five sessions, 71% of the monkeys traded with experimenter 1; the results are statistically different from an equal split in trading between the two experimenters. One cannot explain this result in a theory that ignores reference dependence of preferences. For instance, under EU this implies that $0.5u(1) + 0.5u(2) > 0.5u(2) + 0.5u(1)$, which is absurd.

Finally, in order to test for loss aversion, experimenter 1 always initially offered two pieces of apple but after receiving a token, always traded one piece in return. Experimenter 2 always initially offered one piece and always traded one piece in return for a token. The final choice is identical for both experimenters, however, under reference dependence, the offering of experimenter 1 invokes loss aversion. As expected, in nearly 80% of the trades, monkeys preferred to trade with experimenter 2, suggesting an explanation based on loss aversion.

Lakshminarayanan et al. (2011) test for different risk attitudes in the domain of gains and losses with capuchin monkeys. In one experiment, both experimenters framed their offerings as a gain. Experimenter 1, the safe experimenter, initially offered one piece of food, but on receiving the token always traded two pieces. Experimenter 2, the risky experimenter, initially offered one piece of food, but then was equally likely to trade either one or three pieces in exchange for a token. Most trades occurred with the safe experimenter. However, when the offerings were framed as losses, most trades occurred with the risky experimenter. These results are consistent with prospect theory preferences but are not immediately consistent with theories that do not have a reference point.

Brosnan et al. (2007) wonder if the endowment effect arises from the shared evolutionary history of humans and chimpanzees, on account of a common ancestor? To test this conjecture, they perform standard endowment effect experiments, using food and non-food items on 33 chimpanzees. They ran six trials with items that are familiar to chimpanzees. The food items were a

Figure 3.4 Choices made by chimpanzees in different conditions. Hatched bars represent the percentage of the population that preferred the object in a choice condition, and solid bars represent the percentage of the population that chose to maintain possession. Vertical bars show standard errors of means.

frozen fruit juice stick and a PVC pipe filled with peanut butter (henceforth, juice and PB). The non-food items were a rubber-bone dog chew toy and knotted-rope dog toy (henceforth, bone and rope).

Three trials were run for each of the food and non-food items. The trials were similar to those run for human subjects with the difference that the exchange of an item by a chimpanzee takes place with a human at the other end (and not with another chimpanzee). Prior to the experiment, chimpanzees are trained to exchange items with an experimenter. If they wish to exchange an item for another, they must do so within two minutes, otherwise no exchange takes place. The results are shown in Figure 3.4.

In the food trial, it was found that 58% of the chimpanzees preferred PB to juice. When endowed with the PB, however, 79% of the chimpanzees preferred to keep it rather than exchange it for juice. In another trial, when chimpanzees were endowed with juice, 58% of the chimpanzees preferred not to trade their juice for the PB.

For non-food items, the outcome was opposite to that predicted by the endowment effect: 74% of the chimpanzees preferred the bone over the rope. Despite this, when chimpanzees are given ownership of the bone, they prefer to keep it only 16% of the time. When endowed with the rope, they preferred to keep it only 10% of the time (rather than the predicted 26%). There are two possibilities for this difference in result between the food and non-food items. First, chimpanzees simply do not have a strong enough preference for non-food items. Second, they like interacting with the experimenter.

To test for the possibility that chimpanzees simply like interaction with the experimenter, further tests were carried out. For food items, no chimpanzee (with one exception) exchanged one food item with an identical item offered by the experimenter. However, for non-food items, the opposite result was found: 82% traded a bone for a bone, while 79% traded a rope for a rope.

In conjunction, these results suggest that chimpanzees exhibit the endowment effect for evolutionary salient items such as food, but there is no endowment effect for non-food items. The evolutionary explanation is that food has a greater bearing on the fitness (i.e., reproductive success) of the animal relative to non-food items. Since humans share a common evolutionary history with chimpanzees, the authors conjecture that it is also likely that humans too possess the endowment

effect. Lakshminarayanan et al. (2008) showed that the results on endowment effect survive when one controls for transactions costs and timing issues.

3.4 Myopic loss aversion

Yet another determinant of loss aversion is the horizon over which a risky situation is to be evaluated. *Myopic loss aversion* (MLA) relies on two concepts. The first is loss aversion. The second is *mental accounting*, due to which individuals may evaluate the *return* on lotteries over very short horizons, even when the *actual return* accrues over a longer horizon.

Example 3.24 (Gneezy and Potters, 1997): Consider the following PT utility function that exhibits loss aversion.

$$v(x) = \begin{cases} x & \text{if } x \geq 0 \\ 2.5x & \text{if } x < 0 \end{cases}. \quad (3.13)$$

Suppose that the individual is offered two identical prospects on two separate days. The prospect is (200, 0.5; −100, 0.5). Assuming linear weighting of probabilities, the utility of the prospect under PT is

$$0.5(200) - 0.5(250) = -25 < 0. \quad (3.14)$$

Now consider two individuals who use two different mental accounting procedures. Individual *S* uses a short horizon and evaluates the prospect on each day separately. From (3.14), his utility on each day is negative, so he refuses the prospect on each day. The other individual, *L*, who uses a long horizon, combines the two prospects on the two days to give the composite prospect (400, 0.25; 100, 0.5; −200, 0.25). Using the utility function in (3.13), the utility of the combined prospect for individual *L* is

$$0.25(400) + 0.5(100) - 0.25(500) = 25 > 0.$$

MLA applies to individual *S*, who does not choose to invest in the gamble. Individual *L*, who does not use MLA, in contrast, prefers to invest in the gamble.

Gneezy and Potters (1997) provide direct evidence for MLA. They gave individuals an endowment of $e = 200$ cents; a part $x \in [0, 200]$ of the endowment could be invested. The individual was then offered a lottery $(-x, 2/3; 2.5x, 1/3)$ and asked to make an investment decision over nine rounds. The same level of endowment, e , is given at the beginning of each round. In any round, subjects could only bet using their endowment for that round.²⁴

In one treatment, treatment *S* (short horizons), subjects were asked to make an investment decision, x , in every period, having observed the outcome of the lottery in the previous period. Thus, a total of nine investment decisions had to be made. In the second treatment, treatment *L* (long horizons), investment decisions are made in three rounds 1, 4, 7 and, in each case, the investment decision also applies for the following two periods. Individuals can observe their earnings in rounds 1–3 when they choose their investment in round 4, and observe earnings in rounds 4–6 when they choose their investment in round 7.

²⁴ Three more rounds were run after the 9th round. In each of these rounds, the money won in the first nine rounds divided by 3 became the new endowment level.

The average level of investment in treatment *S* is found to be significantly lower as compared to treatment *L*. On average, subjects bet about half their endowment in treatment *S* and about two-thirds of their endowment in treatment *L*. The basic result on MLA has proven to be robust to several changes in the experimental design, such as changing the number of rounds, and the number of lotteries.²⁵

Haigh and List (2005) examine MLA for professional traders in finance, relative to a control group of undergraduate students. There were 32 students and 27 traders. They elicited, over several rounds, the amount of money each of the groups was willing to bet in two treatments. In one treatment (Treatment I) subjects were given “infrequent” feedback on the returns to their investment, while in the other (Treatment F) “frequent” feedback was given. The prediction of MLA that there should be less betting on the risky investment in Treatment F relative to Treatment I was confirmed for both subject groups. However, professional traders exhibited statistically significantly greater MLA as compared to students; see, Figure 3.5. Traders bet an average of 75 units in Treatment I but only 45 units in Treatment F. The corresponding numbers for students are 62.50 and 50.89. These results are in contrast to the ones by List (2003, 2004), reviewed above, that seek to demonstrate elimination or reduction in loss aversion with real-world experience.

Sutter (2007) uses the framework of Gneezy and Potters (1997) to determine if membership of a team weakens or strengthens MLA. Subjects were asked to make their decisions individually, or as part of a team of three individuals. The endowment was $e = 100$ euro-cents. The two conditions were short (*S*) and long (*L*) planning horizons. The results are shown in Figure 3.6. Two main findings emerge from Sutter’s (2007) experiments. First, individuals invest more when they are part of a team. Second, individuals and teams invest more when the horizon is longer.

Figure 3.5 Average bets of students and professionals.

The frequency of the evaluation of a lottery and the horizon over which the return from the lottery accrues, play a similar role in determining the effect of MLA on the amount invested. So what is the relative contribution of each of these factors. The experimental results of Fellner and Sutter (2009) indicate that each of these factors contributes equally. They find that making subjects opt for either longer horizons or a lower frequency of evaluation leads to an increase in investment.

Benartzi and Thaler (1995, p. 73) make the following observation: “Since 1926 the annual real return on stocks has been about 7 percent, while the real return on treasury bills has been less than 1 percent.” The difference in returns between the two assets is not explained by differences in the standard deviations; the annual standard deviation of stock returns over the period 1926–1997 is about 20%. This is known as the *equity-premium puzzle*.

The main distinction between stocks and bonds in terms of their returns is the greater variability of returns on stocks. Risk averse individuals will naturally demand a greater return on stocks relative to bonds. However, Mehra and Prescott (1985) find that for EU to explain the equity premium puzzle, an unreasonably high coefficient of relative risk aversion of about 30 is required.²⁶ The actual coefficient of risk aversion is close to 1 (see, Bombardini and Trebbi, 2012), and in some estimates, up to about 5.

Benartzi and Thaler (1995) seek to explain the equity premium puzzle by PT and narrow bracketing (stock returns are considered in isolation from all other returns and sources of wealth). They first ask, what planning horizon must investors be choosing so that they are indifferent between stocks that give a 7% return and bonds which give a 1% return? Their empirical results give a best estimate of one year. This is plausible, given that individuals prepare tax returns, and receive company annual newsletters over the same horizon. They term a one year planning horizon as *myopic investor behavior*. Furthermore, most stock returns fluctuate a lot over a one year horizon, hence, the investor potentially experiences repeated gains and losses. The resulting loss aversion

²⁶ Mankiw and Zeldes (1991) illustrate the absurdity of such a high level of risk aversion. A decision maker with a relative risk aversion coefficient of 30 evaluates the certainty equivalent of the lottery (100,000, 0.5; 50,000, 0.5) to be 51209.

accentuates the downward movements in returns, and ensures that the return on stocks must be sufficiently high if they are to be held in a portfolio that contains bonds. Under these assumptions, it turns out that a 7% return on stocks is indeed required to explain the observed compositions of portfolios between stocks and bonds.

Example 3.25 Suppose that initial wealth I is 1 and the decision maker uses PT with linear probability weighting. The reference income, r , is the status quo, so it also equals 1. There are two assets, each with a maturity period of 1 year. A safe asset offers a return of 0.01. The value function is piecewise linear so it takes the form

$$v(x) = \begin{cases} x & \text{if } x \geq 0 \\ -\lambda(-x) & \text{if } x < 0 \end{cases}.$$

The coefficient of loss aversion $\lambda = 2.25$. The value function from holding the safe asset is

$$V_S = (1 + 0.01)I - r = (1 + 0.01) - 1 = 0.01. \quad (3.15)$$

Assume that the return on the risky asset, θ , can take either of two values, a low level of return, $\theta_L = -0.06$ (with probability 0.8), or a high level of return θ_H (with probability 0.2). Hence, there is one outcome each in the domain of gains and losses. The value function in this case is given by:

$$V_R = 0.8(-2.25(0.06)) + 0.2\theta_H.$$

What level of return, θ_H , is required for the decision maker to be indifferent between the two assets? Setting V_S equal to V_R , we get that $\theta_H = 0.59$. Hence, the average return on the risky asset is

$$0.2(0.59) - 0.8(0.06) = 0.07 = 7\%,$$

which is seven times higher than the return on the riskless asset. Thus, relatively high average returns are required on the risky asset in the presence of loss aversion. This is the main insight of Benartzi and Thaler.

The insights in the Benartzi–Thaler model were formalized more fully in Barberis et al. (2001). While there are no direct empirical tests of these insights, Barberis (2013) cites the empirical work of Dimmock and Kouwenberg (2010) that found a relation between loss aversion and stock market participation.

3.5 Why do people pay taxes?

So far, we have seen applications where researchers selectively choose the components of PT that they feel are most essential for explaining their research questions. We now consider one of the few applications that uses all the components of PT. Issues of tax evasion are extremely important and losses to society from tax evasion are huge.²⁷ The existing literature on tax evasion, since

²⁷ For the US, for example, Slemrod and Yitzhaki (2002) give a conservative estimate of the *tax gap* (difference between taxes paid and taxes owed) of the order of \$300 billion per year.

Allingham and Sandmo (1972) and Yitzhaki (1974), had largely assumed that taxpayers use EU. Dhimi and al-Nowaihi (2007, 2010b) used, instead, all components of PT to model the tax evasion decision; a simplified version of the model is given below.²⁸

An EU model of tax evasion leads to several puzzles.

1. Quantitative puzzle: Suppose that tax is not withheld at source, and taxpayers have a choice to report or evade their income. Consider a taxpayer who follows EU and evades \$1. With probability $1 - p$, he is not caught, so he can keep \$1. With probability p , he is caught, so he surrenders \$1 to the tax authorities, and, in addition, pays a fine at the rate $\theta > 0$ on \$1. Thus, under EU, the taxpayer will evade taxes if the expected return per dollar on evading the tax,

$$1 - p - p\theta > 0. \quad (3.16)$$

In actual practice, for the amateur tax evader, the audit probability, p , ranges from 0.01 to 0.03, while the penalty rate, θ , on the amount evaded, ranges from 0.5 to 2.0. Using these values of p and θ , the expected return on tax evasion lies between 91 and 98.5%; it would be hard to find assets with such high rates of return. So, why do people pay taxes? This contradicts the empirical evidence in two ways. First, only about 40% of taxpayers who have a chance of evading, do evade. Further, experimental evidence suggests that at least 20% of taxpayers fully declare all their income, even when $p = 0$. Second, to make these results consistent with EU, taxpayers are required to be risk averse to an absurd degree.²⁹

2. Qualitative puzzles: In addition to the quantitative puzzle, there are also qualitative puzzles arising from the application of EU to tax evasion. First, Yitzhaki (1974) showed that using EU, and under the reasonable assumption of decreasing absolute risk aversion (DARA), an increase in the tax rate leads to a decrease in tax evasion. However, most empirical evidence rejects this result; people try to hide more income if the government tries to extract greater tax revenues. Second, obligatory advance tax payments should not influence the taxpayer's evasion decision under EU. This is because under EU, the carriers of utility are final levels of wealth (see Remark 1.1); final levels are identical under advance tax payment or post tax payment. In contrast, obligatory advance payments alter tax evasion; see, for example, Yaniv (1999) for the evidence and an explanation based on PT.

Dhimi and al-Nowaihi (2007) run a two-horse race that pits EU against PT. They show that these qualitative and quantitative paradoxes can be explained by PT.

THE BASIC SET UP

The government moves first and levies a tax at the constant marginal rate $t \in [0, 1]$ on the declared income of the taxpayer, D . Each taxpayer who has exogenous taxable income $W > 0$ can then choose to declare an amount $D \in [0, W]$; we focus only on those individuals for whom tax is not withheld at source. An exogenous fraction $p \in [0, 1]$ of the taxpayers are randomly audited,

²⁸ We shall keep references to a minimum. The interested reader can look up Dhimi and al-Nowaihi (2007, 2010b) for the references, the justification behind the assumptions, robustness tests, etc.

²⁹ In one example, Skinner and Slemrod (1985) calculate that in order to square the observed tax evasion rates a coefficient of relative risk aversion (CRRA) of 70 is required, while realistic magnitudes of CRRA lie between 1 and 5.

subsequent to the filing of tax returns, and the audit reveals the true taxable income; Dhimi and al-Nowaihi (2007) consider the more general case where this probability is *endogenous* and it depends negatively on the amount of income declared. If caught, the dishonest taxpayer must pay the outstanding tax liabilities $t(W - D)$ and a penalty on the amount evaded, $\theta t(W - D)$, where $\theta > 0$ is the penalty rate. If evasion is discovered, the taxpayer also suffers some stigma $s(W - D)$, where $s \in [0, 1]$ is the stigma rate on evaded income.³⁰ There is a distribution of stigma rates over the taxpayers with density $\phi(s)$. Thus, our treatment of the stigma rate parallels the tax rate; both lie in the interval $[0, 1]$.

Denoting by Y_A and Y_{NA} , respectively, the income of the taxpayer when he is audited and when he is not, for any $D \in [0, W]$ we have

$$\begin{cases} Y_{NA} = W - tD, \\ Y_A = W - tD - t(1 + \theta)(W - D) - s(W - D). \end{cases} \quad (3.17)$$

Under EU, individuals derive utility from their final wealth levels. In order to facilitate comparison with the utility function under PT (see (2.20)) the utility of any outcome for an EU decision maker is defined as $v(Y_i) = Y_i^\beta$; $\beta \in (0, 1)$.³¹ Thus, the EU of a taxpayer is given by

$$EU = (1 - p)Y_{NA}^\beta + pY_A^\beta. \quad (3.18)$$

Under PT, take the *legal after-tax income*, $R = (1 - t)W$, as the reference point of the taxpayer; this is in the spirit of the status-quo justification of reference points. A simple calculation shows that (provided R is independent of p) this is the *unique* reference income, that has the following desirable property. For any D , if the taxpayer is caught, he is in the domain of losses, and if he is not caught, he is in the domain of gains. Thus, it is an eminently sensible reference point.

The taxpayer's income relative to the reference point, in the two states, is $X_i = Y_i - R$, $i = A, NA$. Using (3.17), we get

$$\begin{cases} X_{NA} = t(W - D) \geq 0 \\ X_A = -(\theta t + s)(W - D) \leq 0 \end{cases}. \quad (3.19)$$

The taxpayer is in the *domain of gains* in the No Audit state, and the magnitude of the gains is the amount of the tax evaded. In the Audit state, the taxpayer is in the *domain of losses*; the magnitude of the loss equals the penalty on the evaded tax plus stigma costs. The taxpayer faces the following lottery in incremental form (or *prospect*), denoted by L .

$$L = \{-(\theta t + s)(W - D), p; t(W - D), 1 - p\}.$$

³⁰ The UK government initiative of naming and shaming tax offenders, spearheaded by the HMRC, is at least partly motivated by tapping into such stigma costs of the taxpayer.

³¹ From (3.17) it is possible that $Y_A < 0$. The simplest way to incorporate $Y_A < 0$ into EU is to define $v(Y_A) = 0$ whenever $Y_A < 0$ as we have done. Other possibilities are $v(Y_A) = -v(-Y_A)$ and $v(Y_A) = -\infty$. None of our results depend on which specification we use for $v(Y_A)$ when $Y_A < 0$.

The *value function* under PT is given by (2.24), which in this case is

$$V(L) = \pi(1-p) v(X_{NA}) + \pi(p) v(X_A),$$

where v is the utility function under PT. Substituting (3.19) in the value function, using the power form of utility in (2.20), and the decision weights in Definition 2.33, we get the objective function of the taxpayer under PT as

$$V(L) = w(1-p) [t(W-D)]^\gamma + w(p)(-\lambda) [(\theta t + s)(W-D)]^\gamma. \quad (3.20)$$

THE TAX EVASION DECISION UNDER EXPECTED UTILITY

Maximizing (3.18) by a choice of D , the solution to the declared income is

$$D^* = W \left[1 - (1-t) \left[(\theta t + s) + t \left(\frac{(\theta t + s)p}{t(1-p)} \right)^{\frac{1}{1-\gamma}} \right]^{-1} \right]. \quad (3.21)$$

Direct differentiation of (3.21) gives rise to all the comparative static results under EU, summarized in Proposition 3.29.

Proposition 3.29 *Under EU, tax evasion is decreasing in the probability of detection and conviction, p , the penalty rate, θ , and the rate of stigma, s . If preferences exhibit decreasing absolute risk aversion, then tax evasion is decreasing in the tax rate, t (Yitzhaki (1974) puzzle).³²*

Simple calculations give the following result.

Proposition 3.30 *Suppose that the taxpayer follows EU. Consider the set of (θ, p) points implicitly generated by the inequality*

$$\theta \geq \frac{1-p}{p} - \frac{s}{t}. \quad (3.22)$$

In (θ, p) space, (3.22) gives the loci of points such that a taxpayer with stigma $s \in [s, \bar{s}]$ reports the full amount of income. At all points below this loci, the taxpayer chooses to evade some strictly positive fraction of income.

Using (3.22), in the absence of stigma costs, $s = 0$, the taxpayer will evade income when $1 - p - p\theta > 0$, as claimed in (3.16).

THE TAX EVASION DECISION UNDER PROSPECT THEORY

The taxpayer maximizes the value function in (3.20) by an appropriate choice of D , given the probability weighting function $w(p)$. Rewriting (3.20),

$$V(L) = (W-D)^\gamma h(\theta, p, s, t, \lambda, \alpha, \gamma), \quad (3.23)$$

³² For the assumed utility function under EU, the coefficient of absolute risk aversion (for EU we need only consider the domain of gains) is given by $\frac{1-\beta}{\gamma}$ which is decreasing in γ . Hence, the Yitzhaki (1974) result applies.

where,

$$h = h(\theta, p, s, t, \lambda, \alpha, \gamma) = t^\gamma \left(w(1-p) - \lambda \left(\theta + \frac{s}{t} \right)^\gamma w(p) \right) \geq 0. \quad (3.24)$$

Since the value function in (3.23) is monotonic in D , the solution is given by:

$$D = \begin{cases} 0 & \text{if } h > 0 \Leftrightarrow \left(\frac{1}{\lambda} \right) \frac{w(1-p)}{w(p)} > \left(\theta + \frac{s}{t} \right)^\gamma \\ \in [0, W] & \text{if } h = 0 \Leftrightarrow \left(\frac{1}{\lambda} \right) \frac{w(1-p)}{w(p)} = \left(\theta + \frac{s}{t} \right)^\gamma \\ W & \text{if } h < 0 \Leftrightarrow \left(\frac{1}{\lambda} \right) \frac{w(1-p)}{w(p)} < \left(\theta + \frac{s}{t} \right)^\gamma \end{cases}. \quad (3.25)$$

(3.25) depicts a *bang-bang solution*, which might be descriptive of several forms of tax evasion that take the form of hiding certain activities completely from the tax authorities. For the general case considered in Dhimi and al-Nowaihi (2007), in which the probability of detection is endogenous and depends on the amount declared, one gets continuous dependence of the solution on the parameters of the model. The bang-bang solution arises in the special case of an exogenous and fixed probability of detection.

In (3.25), a large enough change in the parameters can push the solution from one case to the other. Starting from the case $D = 0$, the following factors are conducive to completely eliminating tax evasion ($D = W$). (1) Low tax rate, t , (2) high levels of stigma, s , and high penalties for tax evasion, θ , (3) high levels of loss aversion, λ , and (4) overweighting of the probability of a loss, p , which leads to a decrease in $\frac{w(1-p)}{w(p)}$.

Under EU and PT, tax evasion decreases with an increase in p , θ , and s , although, as we shall see below, the quantitative effects under PT are in accord with the evidence, while those under EU are not. There is also no counterpart in EU to the effect on tax evasion of (i) loss aversion, and (ii) overweighting of small probabilities. The main qualitative difference between EU and PT is in the predicted effect of the tax rate on the amount evaded. The result under EU is given in Proposition 3.29. However, PT predicts the empirically supported result that tax evasion increases with an increase in the tax rate. This is formally stated in Proposition 3.31 below (the simple proof is omitted).

Proposition 3.31 *Ceteris paribus, $\exists t = t_c \in [0, 1]$ such that the individual does not evade taxes if $t < t_c$ but evades taxes if $t > t_c$.*

A rough but useful intuition about the effect of the tax rate can be given as follows (the actual results are more subtle). An increase in the tax rate makes the taxpayer poorer. Hence, under decreasing absolute risk aversion, EU predicts a taxpayer would become more risk averse, and so evade less. By contrast, under PT the utility function is convex for losses. So, if the reference point is such that an audited taxpayer finds himself in the domain of losses (as is indeed the case), then an increase in the tax rate causes him to be poorer and, hence, more risk seeking. So he evades more.

A comparative static result similar to the one in Proposition 3.31 can be stated with respect to the stigma rate s (the simple proof is omitted). If stigma is high enough, then people do not evade any taxes; a similar result can easily be seen to hold for EU.

Proposition 3.32 *Ceteris paribus, $\exists s = s_c \in [0, 1]$ such that all individuals characterized by $s > s_c$ do not evade taxes, while all those with $s < s_c$ evade taxes.*

MODEL CALIBRATION

The analysis below provides simulation results in a calibrated model.³³ We use the Prelec probability function (see Definition 2.22) with $\alpha = 0.35$ and $\beta = 1$. For the utility function, we use the power form of utility in (2.20). From estimates in Tversky and Kahneman (1992), $\gamma \approx 0.88$ and $\lambda \approx 2.25$. Let us use a realistic tax rate of 30%, i.e., $t = 0.3$.

Based on TCMP (taxpayer compliance measurement program) data, Andreoni et al. (1998) report that about 40% of taxpayers report their incomes incorrectly in the US; see also Bernasconi (1998). Since these figures include those who unintentionally report incorrectly (about 7%), let us use the more conservative estimate that only about 30% of taxpayers who have a chance, do evade taxes. Assume that the density of the stigma rate, $\phi(s)$, is uniform. From Proposition 3.32, we know that under PT all individuals characterized by $s > s_c$ do not evade taxes, while all those with $s < s_c$ evade taxes. Given the assumption that the stigma rate is uniformly distributed over $[0, 1]$, the hypothesis that approximately 30% of taxpayers evade taxes corresponds to $s_c = 0.3$, which is the value we shall use for the calibration exercise.

We ask the following question. Given realistic magnitudes of tax evasion, about 30%, how close are the predicted θ, p values under EU and PT, respectively, to their actual values?³⁴

Under EU, using (3.22), and the calibration values, the locus of (θ, p) combinations that need to be consistent with the actual data is given by

$$\theta^{EU} = \frac{1-p}{p} - \frac{0.3}{0.3}, \quad (3.26)$$

where θ^{EU} may be taken to be the predicted value of θ under EU, conditional on all the other parameters of the model. Using (3.25), and the Prelec weighting function, a similar (θ, p) locus under PT is given by

$$\theta^{PT} = \left(\frac{1}{2.25} \right)^{\frac{1}{0.88}} \Gamma(p)^{\frac{1}{0.88}} - \frac{0.3}{0.3}, \quad (3.27)$$

where $\Gamma(p) = \exp [(-\ln p)^{0.35} - (-\ln(1-p))^{0.35}]$ and $\alpha = 0.35$. θ^{PT} may be taken to be the predicted value of θ under PT, conditional on all the other parameters of the model.

The numerical magnitudes of (θ, p) that correspond to the two loci in (3.26), (3.27) are shown in Table 3.1; in the top row, we use probabilities ranging from 0.005 to 0.050. For most realistic audit probabilities, i.e., $p \in [0.01, 0.03]$ the prediction of the penalty rate, θ , ranges from 0.66 to 1.21 for PT. This is consistent with actual values for the audit probabilities which range from 0.5 in the USA to 2.0 in Italy with several other Western countries in the middle (Bernasconi, 1998). On the other hand, EU predicts a penalty rate that is up to 100 times larger in this range and, on average, about 60 times higher.

It is sometimes argued that sufficiently high stigma can align the predictions of EU with the evidence. This is not correct. For instance, choose a middle probability of around 0.03 and increase the stigma rate from 30% (which forms the basis of the calculations in Table 3.1) to the maximum

³³ For robustness tests with respect to changes in the calibration values, such as the parameters of the Prelec function and alternative assumptions about the rate of stigma, s , the reader can consult Dhami and al-Nowaihi (2007). All the results go through.

³⁴ We could have equivalently posed our question in many different ways. For example, given actual (θ, p) combinations, what level of tax evasion does each theory predict?

Table 3.1 Comparison of the predicted value of penalty rates under EU and PT.

	.005	.010	.015	.020	.025	.030	.035	.040	.045	.050
θ^{EU}	197.7	97.7	64.3	47.7	37.7	31.0	26.2	22.7	19.9	17.7
θ^{PT}	1.6	1.2	1.0	0.9	0.8	0.7	0.6	0.5	0.5	0.4

possible rate, 100%. The new value of $\theta^{EU} = \frac{1-0.03}{0.03} - \frac{1}{0.3} = 29.0$, which is nowhere near the 0.5–2 range that is observed in actual practice.

On the other hand, in PT, all components of the theory (reference dependence, diminishing sensitivity, loss aversion, non-linear probability weighting) were needed in order to explain the qualitative and quantitative tax evasion puzzles. While the penalty rate and the probability of detection may appear low, PT decision makers overweight the small probability of being caught and suffer loss aversion, which magnifies the penalty rate. This provides strong vindication for the choice of PT in explaining actual parameters of policy choice relevant for the tax evasion problem. It is remarkable that the predicted magnitudes of (θ, p) are so close to the actually observed values when one considers that the parameter values used for the calibration exercise were obtained from independent experimental evidence applied to generic situations of risk. This model also shows that PT is quite simple and tractable to apply.

3.6 Explanation of Rabin's paradox using PT

Rabin's paradox for EU was described in Section 1.5.4. We now show that the concepts of reference dependence and loss aversion, that are central to PT, can explain Rabin's results, an explanation that Rabin (2000a) favored. Recall the three lotteries in Section 1.5.4, L_0, L_1, L_2 :

$$L_0 = (w, 1), L_1 = (w - 10, 0.5; w + 11; 0.5), L_2 = (w - 100, 0.5; w + m, 0.5), \quad (3.28)$$

where m is any positive reward level, no matter how high. Under PT, lotteries are defined in incremental form. Assume that initial wealth, w , is the reference point. Redefine the three lotteries, L_0, L_1, L_2 , in incremental form (or prospects) as follows

$$L_0 = (0, 1), L_1 = (-10, 0.5; 11; 0.5), L_2 = (-100, 0.5; m, 0.5). \quad (3.29)$$

Let us continue with Example 1.4 from Section 1.5.4 and show that Rabin's paradox can be explained with PT. For any level of wealth x , let $y = x - w$ be the wealth relative to the reference point (initial wealth level, w). Adapt the utility function in (1.44) to define the reference dependent utility function of the individual as

$$v(y) = \begin{cases} 1 - e^{-y/1000} & \text{if } y \geq 0 \\ -\lambda(1 - e^{y/1000}) & \text{if } y < 0 \end{cases}, \quad (3.30)$$

where $\lambda > 1$ is the parameter of loss aversion. Figure 3.7 gives a plot of this function for $\lambda = 2$, which is the parameter value we shall use in the calculations below. We wish to show that Rabin's paradox can be explained by using reference dependence and loss aversion only, so we do not

Figure 3.7 Plot of (3.30) for the case of $\lambda = 2$.

invoke non-linear probability weighting (but see Wakker (2005) who shows that the paradox can also be explained with non-linear probability weighting).

1. Let us first compare the two prospects in incremental form $L_0 = (0, 1)$ and $L_1 = (-10, 0.5; 11, 0.5)$ when the decision maker follows PT. The preference $L_1 \prec L_0$ (see Assumption A1 in Section 1.5.4) implies that

$$V(-10, 0.5; 11, 0.5) < V(0) = 0, \quad (3.31)$$

where V is the value function under PT. Using (3.30) and (3.31), we get

$$-(1 - e^{-.010}) + \frac{1}{2}(1 - e^{-.011}) < 0 \Leftrightarrow -4.4803 \times 10^{-3} < 0,$$

which is true. Thus, at all levels of initial wealth, a decision maker who follows PT prefers the prospect L_0 over L_1 .

2. Let us now compare the two prospects $L_1 = (-10, 0.5; 11, 0.5)$ and $L_2 = (-100, 0.5; \infty, 0.5)$ when the decision maker follows PT. Rabin's paradox will arise if one now observes the preference $L_2 \prec L_1$. We now show that the preference $L_2 \prec L_1$ cannot arise. Using (3.30), we get that

$$\begin{aligned} L_2 \prec L_1 : -(1 - e^{-0.1}) + \frac{1}{2}(1 - e^{-\infty}) &< -(1 - e^{-.010}) + \frac{1}{2}(1 - e^{-0.011}) \\ \Leftrightarrow 0.40484 &< -4.4803 \times 10^{-3}, \end{aligned}$$

which is false. Thus, a decision maker who follows PT prefers the prospect L_2 over L_1 , hence, Rabin's paradox does not arise for a decision maker who follows PT.

The Rabin paradox has elicited several responses. For a behavioral counter response, which argues that these responses are unsatisfactory, see Wakker (2005, 2010). Palacios-Huerta and

Serrano (2006) and Watt (2002) argued that the preferences $L_1 \prec L_0$ need not hold at all wealth levels (see Assumption A1 in Section 1.5.4) if the decision maker follows EU. They do so by estimating the parameters of the power form of utility that allow for Assumption A1. They find that some of the parameters are unreasonable. But this only illustrates the difficulty in accounting for plausible preferences under EU, a point that Rabin had already made.

Cox and Sadiraj (2006), Watt (2002), Rubinstein (2006), and Samuelson (2005) propose to solve Rabin's paradox, not by abandoning EU but by defining utility over income. But doing so immediately imposes reference dependence because income arises over and above current wealth and so this simply assumes the reference point to be current wealth. For this reason, Wakker (2005, 2010) argues that these authors provide the same explanation as Rabin (2000a).

Consider, for instance, the explanation by Cox and Sadiraj (2006). They assume the following utility function.

$$v(y) = \begin{cases} 0.9y + 0.1 & \text{if } y < 1 \\ y^{0.9} & \text{if } y \geq 1 \end{cases} \quad (3.32)$$

If we did not subtract the wealth level w from all the outcomes, then the relevant lotteries are given in (3.28). The variable y would then be the final wealth level. A simple calculation shows that this gives rise to Rabin's paradox under EU (as in Section 1.5.4). However, now suppose that utility in (3.32) is defined over income levels. So essentially, we subtract wealth, w , from all outcomes. This gives rise to the relevant lotteries in incremental form as in (3.29), exactly as under PT. Then, under EU, with the utility function in (3.32), the preference $L_1 \prec L_0$ implies that

$$0.5(0.9(-10) + 0.1) + 0.5(11^{0.9}) < v(0) = 0.1.$$

But $0.5(0.9(-10) + 0.1) + 0.5(11^{0.9}) = -0.12264 < 0.1$. Hence, the original preference $L_1 \prec L_0$ holds. Yet, a decision maker who has the utility function of income given in (3.32) will accept the lottery $(-1680, 0.5; 3412, 0.5)$ over the lottery $(0, 1)$, so $L_1 \prec L_0$ does not hold. But this means that Assumption A1 in Section 1.5.4 does not hold and Rabin's paradox does not arise in this case. Cox and Sadiraj propose an amendment to the expected utility function in which wealth directly enters the utility functions and attitudes to risk are dependent on initial wealth.

The Rabin paradox and the Cox and Sadiraj explanations are both results of the form, if A then B, and both results are technically sound. As we point out in the introduction to Part I, reference dependence is not inconsistent with the axioms of EU, so the Cox and Sadiraj explanation is a feasible one. However, once again, it illustrates the difficulty in accounting for plausible preferences under EU without imposing reference dependence. Furthermore, simply imposing reference dependence in EU without a theory of how the behavior of decision makers differs in the domains of gains and losses is not entirely satisfactory either.

Neilson (2001) and Safra and Segal (2008) show that Rabin's puzzle also applies to other decision theory models based on final wealth levels. However, it is not clear that these two papers are based on empirically plausible assumptions; see Wakker (2010, p. 245).

3.7 Goals as reference points

Under EU, one typically derives utility from final levels of outcomes such as wealth, or if there are reference effects, then there is no difference in behavior in the domain of gains and losses

(Remark 1.1). Thus, setting wealth targets or other goals should not, in the absence of auxiliary assumptions, have any influence on behavior. Yet, as we shall see below in Section 3.7.2, targets and goals influence human actions. The reason is that goals may serve as reference points and the decision maker may feel that he is in the domain of losses if he falls short of the goal. This may induce the decision maker to exert even greater effort to achieve his goal. These effects have been found for human and non-human subjects and for cognitive and non-cognitive tasks.³⁵ Such reasoning is consistent with PT but not necessarily with other theories that lack a reference point.

3.7.1 A theory of goals in prospect theory

We first organize these ideas into a formal model, using unpublished notes by al-Nowaihi and Dhami.³⁶ An individual can exert effort $e \in [0, \bar{e}]$ at a cost $c(e)$ to produce output according to the production function $y(e)$. The properties of these functions are:

$$c(e) \geq 0, c(0) = 0, c'(0) \geq 0, c''(e) > 0; y(e) \geq 0, y(0) = 0, y'(e) > 0, y''(e) \leq 0. \quad (3.33)$$

Thus the cost function is positive, increasing, and convex, while the production function is positive, increasing, and concave.

The exogenously given *goal* of the individual is to produce a level of output $y = g \geq 0$. We assume that:

$$\text{for each } g \geq 0, y(e) = g \text{ for some level of } e. \quad (3.34)$$

The utility function of the individual, v , is separable in output and effort, and is defined separately for the domain of gains and losses, depending on whether the outcome $y(e)$ is larger or smaller relative to the goal, g .

$$v = \begin{cases} v_+(e, g) = u(y(e) - g) - c(e) & \text{if } y(e) \geq g \\ v_-(e, g) = -\lambda u(g - y(e)) - c(e) & \text{if } y(e) < g \end{cases}; \lambda > 1. \quad (3.35)$$

We assume that the functions u, y, c have continuous second order partial derivatives. We make the following standard assumptions.

$$u(x) \geq 0 \text{ for } x \geq 0; u(0) = 0; u'(x) > 0 \text{ for } x > 0; u''(x) < 0 \text{ for } x > 0. \quad (3.36)$$

Further assumptions on the function u are as follows.

$$u'(x) \rightarrow \infty, \text{ as } x \rightarrow 0; u'(x) \rightarrow 0, \text{ as } x \rightarrow \infty. \quad (3.37)$$

We consider separately, the domain of gains and losses.

³⁵ See, for instance, Locke and Latham (1990) for a wide-ranging review of the laboratory and field studies in support of these stylized facts. For a more updated list of references see Heath et al. (1999).

³⁶ This model was constructed circa 2010 and has been used by one of our Ph.D. students in his empirical research.

I. Domain of gains: In the domain of gains, $y(e) \geq g$. Using (3.35), we get

$$\frac{\partial v_+}{\partial e} = y'(e) u'(y(e) - g) - c'(e), \quad (3.38)$$

$$\frac{\partial^2 v_+}{\partial e^2} = y''(e) u'(y(e) - g) + [y'(e)]^2 u''(y(e) - g) - c''(e) < 0. \quad (3.39)$$

Thus, v_+ is continuous and strictly concave in e . Since $e \in [0, \bar{e}]$ is a compact interval, so v_+ has a unique (local and global) maximum. Let $e_+^*(g)$ be the (unique) function that assigns to each $g \geq 0$, the unique local maximum, e_+^* , corresponding to g in the domain of gains. In the domain of gains, $y(e) \geq g$, and from (3.37), (3.38), a corner solution cannot exist, hence, $e_+^* > 0$. We summarize these results in the next lemma.

Lemma 3.2 Given $g \geq 0$, $\frac{\partial v_+}{\partial e} = 0$ at a unique maximum $e_+^* > 0$ and $y(e_+^*) > g$.

Implicitly differentiating (3.38) we get

$$\frac{\partial^2 v_+}{\partial e \partial g} = -y'(e) u''(y(e) - g) > 0, \quad (3.40)$$

and, hence,

$$\frac{de_+^*(g)}{dg} = - \left[\frac{\partial^2 v_+}{\partial e \partial g} / \frac{\partial^2 v_+}{\partial e^2} \right]_{e_+^*(g)} > 0. \quad (3.41)$$

II. Domain of losses: We now turn to an analysis of the domain of losses, $y(e) < g$. Using (3.35), $v_-(e, g) < 0$, and we would like to maximize this function. We get

$$\frac{\partial v_-}{\partial e} = \lambda y'(e) u'(g - y(e)) - c'(e). \quad (3.42)$$

$$\frac{\partial^2 v_-}{\partial e^2} = \lambda y''(e) u'(g - y(e)) - \lambda [y'(e)]^2 u''(g - y(e)) - c''(e). \quad (3.43)$$

$$\frac{\partial^2 v_-}{\partial e \partial g} = \lambda y'(e) u''(g - y(e)) > 0.$$

Unlike the domain of losses, we cannot sign the second derivative of v_- . Using (3.37), we get

$$\lim_{y(e) \uparrow g} \frac{\partial v_-}{\partial e} = \infty. \quad (3.44)$$

Since the domain of losses is defined by $y(e) < g$, and since y is continuous, it follows that the domain of losses is open, i.e., v_- is not defined over a compact domain. In conjunction with the fact there is no guarantee that v_- is concave or convex, the analysis of the optimal solution in the domain of loss is less direct.

Let e_-^* be a local maximum in the domain of losses. It then follows that, necessarily, $\left[\frac{\partial v_-}{\partial e} \right]_{e=e_-^*} = 0$. Since $\frac{\partial v_-}{\partial e}$ is continuous, it follows that the set of all e such that $\frac{\partial v_-}{\partial e} = 0$ is closed. Finally, since y is strictly increasing, the set of feasible effort levels is bounded (by 0 below and

$y^{-1}(g)$ above). Thus the set of all effort levels, e , such that $\frac{\partial v_-}{\partial e} = 0$ is closed and bounded, hence compact. It follows that, if this set is non-empty, then it contains a maximum. Choose the largest effort level associated with this maximum, and call it $e_-^*(g)$. If, in addition, $\left[\frac{\partial^2 v_-}{\partial e^2}\right]_{e=e_-^*(g)} < 0$, then

$$\frac{de_-^*(g)}{dg} = - \left[\frac{\partial^2 v_-}{\partial e \partial g} / \frac{\partial^2 v_-}{\partial e^2} \right]_{e=e_-^*(g)} < 0. \quad (3.45)$$

The existence of $e_-^*(g)$ is not guaranteed but $e_+^*(g)$ always exists. So we have two cases.

(1) For each $g \geq 0$, let $e^*(g) = e_+^*(g)$, if no $e_-^*(g)$ exist.

(2) Suppose one, or more, optimal effort levels exist in the domain of losses. By definition, each of these optimal effort levels give the same value of the objective function, hence, we need some tie breaking rule, which, given our convention, is to choose the highest of these, $e_-^*(g)$. In this case, let $e^*(g) = e_+^*(g)$ if $v_+(e_+^*(g), g) \geq v_-(e_-^*(g), g)$. Otherwise, set $e^*(g) = e_-^*(g)$.

From (3.41) we know that $\frac{de_+^*(g)}{dg} > 0$, and from (3.45) we know that $\frac{de_-^*(g)}{dg} < 0$. Define g^* , such that

$$v_+(e_+^*(g^*), g^*) = v_-(e_-^*(g^*), g^*),$$

in which case, given our convention, we would choose $e^*(g^*) = e_+^*(g^*)$. The next proposition shows that g^* is an optimal goal if the objective is to maximize the output y . The proof is left to the reader.

Proposition 3.33 *There exists a unique goal, g^* , such that the following holds.*

- (a) For $g < g^*$, $v_+(e_+^*(g), g) > v_-(e_-^*(g), g)$ and so $e^*(g) = e_+^*(g) < e^*(g^*)$.
- (b) For $g > g^*$, $v_+(e_+^*(g), g) < v_-(e_-^*(g), g)$ and so $e^*(g) = e_-^*(g) < e^*(g^*)$.
- (c) g^* is the goal that maximizes output, $y(e)$, when one restricts attention to the set of effort levels that maximize utility of the individual.

A number of lessons can be drawn from Proposition 3.33.

1. If the objective is to maximize the output produced by an individual, then there exists an optimal goal, g^* .
2. For goals in the interval $[0, g^*]$, the optimal effort level of the individual is $e_+^*(g)$, which places the individual in the domain of gains, so $y(e_+) - g \geq 0$. Thus, the individual exceeds the goals that he sets.
3. Over the range $[0, g^*]$, $\frac{de_+^*(g)}{dg} > 0$, so the individual responds to an increase in goals by increasing effort.
4. For any goal that is too ambitious, i.e., in the range, $g > g^*$, the individual flips from being in the domain of gains to being in the domain of losses, i.e., $y(e_-) < g$. Indeed, $e_-(g)$ rather than $e_+(g)$ is optimal for goals in this range. Thus, the individual falls below the goal that he sets. Furthermore, because $\frac{de_-^*(g)}{dg} < 0$, the individual (at least locally in the neighborhood of $e_-^*(g)$) responds to an increase in goals by putting in even less effort.

Table 3.2 Some simulations for optimal goals and effort levels.

g	$e_+^*(g)$	$e_-^*(g)$	$e^*(g)$

Remark 3.9 (*Predictions under EU and RDU*): Under EU and RDU, the utility function is defined over final levels of wealth (in this case $y(e)$) and is independent of g .³⁷ So goals are not predicted to have any effect on the effort levels of individuals. If goals do turn out to have an effect, then this finding would be inconsistent with EU and RDU.

We now report a few simulations in Table 3.2 that illustrate the conclusions of the model. Let us assume that the production function is linear, i.e., $y = e$. Let the utility function for gains and losses be defined respectively by the following.

$$v_+(y, g) = (y - g)^\beta - \frac{1}{2}y^2, y \geq g,$$

$$v_-(x, g) = -\lambda (g - y)^\beta - \frac{1}{2}y^2, \lambda > 1, x < g.$$

For simulation purposes, we use the values $\beta = 0.9$, $\lambda = 2$. We report for each value of the goal, g , the corresponding values of $e_+^*(g)$, $e_-^*(g)$, and $e^*(g)$. The reader can verify observations 1–4 above.

3.7.2 The evidence on goals

We now consider the evidence on goals, based on experimental results from Heath et al. (1999). The results in Table 3.2 were results based on the calculation of optimal effort levels. The experiments, on the other hand, present hypothetical information that is not necessarily based on a calculation of the optimal solution.

The number of subjects in an experiment is denoted by N . One implication of goals as reference points is that it is possible that an individual with a higher goal performs better than an individual with a lower goal, yet feels less happy. This is supported by the following problem.

Problem 1. [$N = 60$] Alice typically scores around 80 on weekly 100-point quizzes in one of her classes. One week she sets a goal of scoring 90. She scores 87. Betty typically scores around 80 on weekly 100-point quizzes in one of her classes. One week she decides to do her best. She scores 83. Overall, who will be more satisfied with her performance?

³⁷ Even if we allowed for reference dependence under EU and RDU, then identical behavior in gains and losses (Remark 1.1) ensures that this is not a fruitful exercise.

Alice's performance is better than Betty's but because of her higher goal, a statistically significant majority of people respond that Alice should be less satisfied with her performance. This indicates that goals partition the domain of outcomes into gains and losses akin to the role of reference points in prospect theory. This result, and the next experiment which illustrates the role of loss aversion, is in conformity with the framework of our theoretical model.

Problem 2. [$N = 48$] Sally and Trish both follow workout plans that usually involve doing 25 sit-ups. One day, Sally sets a goal of performing 31 sit-ups. She finds herself very tired after performing 35 sit-ups and stops. Trish sets a goal of performing 39 sit-ups. She finds herself very tired after performing 35 sit-ups and stops. Who is experiencing more emotion?

Of the subjects 29% answer, Sally, while the remaining 71% answer, Trish. One plausible interpretation is that because Trish falls below the goal of 39 she experiences more emotion, on account of loss aversion.

Problem 3. [$N = 73$] Charles and David both follow workout plans that usually involve doing 25 sit-ups. One day, Charles sets a goal of performing 30 sit-ups. He finds himself very tired after performing 34 sit-ups and, at most, has the energy to perform 1 more. David sets a goal of performing 35 sit-ups. He finds himself very tired after 34 sit-ups and, at most, has the energy to perform 1 more. Who will work harder to perform the 35th sit-up?

Of the respondents 82% give the answer as David, which supports the prediction of PT. This can be seen from (3.42). As $y(e) \rightarrow g$, the marginal returns to effort, $\lambda y'(e) u'(g - y(e))$ increase rapidly and in the limit, (3.37) ensures that this marginal return is infinite. In other words, by doing just one more sit-up David can avoid falling into the domain of losses, so he should work harder.

Problem 4. [$N = 76$] Charles and David both follow workout plans that usually involve doing 25 sit-ups. One day, Charles sets a goal of performing 30 sit-ups. He finds himself very tired after performing 42 sit-ups and, at most, has the energy to perform one more. David sets a goal of performing 40 sit-ups. He finds himself very tired after 42 sit-ups and, at most, has the energy to perform one more. Who will work harder to perform one final sit-up?

Of the respondents 69% give David as the answer.

Problem 5. Same as problem 4, with 42 sit-ups replaced by 28 sit-ups

Now 86% of the respondents give Charles as the answer.

In problem 4, both individuals exceed their goal. However, David has exceeded his goal by less than Charles. Since the effort level is held fixed for both (42 sit-ups), the marginal benefit for David of performing an extra sit-up is greater (because $u'(x) > 0$ $u''(x) < 0$). People exert greater effort when they are closer to their goals. The key is to invoke diminished sensitivity to gains and losses as one moves away from the reference point, a feature that is already incorporated into various versions of PT. The same reasoning explains the responses to Problem 5.

There are other emerging effects of goals that we have not touched on. For instance, there appears to be a strong effect of non-binding goals on performance and this effect appears to be much stronger for men relative to women (Smithers, 2015).

3.8 Why is it so hard to find a taxi on a rainy day in New York?

Consider the standard model of labor supply. Suppose that there is a small current transitory increase in wage. The decision maker would then smooth the transitory wage change over all future time periods so that income effects are negligible. In this case, we can concentrate solely on the substitution effects. Since wages are temporarily high, and so the opportunity cost of leisure is high, the individual engages in intertemporal substitution of labor, working relatively harder today. Hence, we can state the following well-known result.³⁸

Remark 3.10 *Transitory increases in the real wage are predicted, under neoclassical economic theory, to produce an increase in hours worked.*

In the labor economics literature, there is little empirical consensus on the magnitude and sign of the labor supply elasticity. There are two main problems with estimating labor supply elasticities. First, actual wage changes are often not transitory in nature. Second, individuals often have limited control over hours worked. The modern literature has tried to address these issues.

Camerer et al. (1997) ask: *Why is it harder to find a taxi on a rainy day in New York?* The situation for cab drivers in New York is particularly interesting. First, it is possible to identify transitory wage changes. Second, by deciding when to quit for the day, cab drivers make a real “hour’s worked” decision. The rate that cab drivers can charge per mile is fixed by law. However, on busy days, drivers have to spend less time searching for customers and, so, their (effective) real wage rate is higher.

Let h_{it} and Y_{it} denote hours worked and total daily earnings by driver i at date t . Hourly wage w_{it} is computed as Y_{it}/h_{it} . Let X_{it} denote a set of other independent variables; some are driver-specific, and others such as rain, temperature, and shift dummies, control for the difficulty of driving conditions and, hence, the opportunity cost of leisure. Camerer et al. (1997) estimate regression equations of the following form.

$$\log h_{it} = \beta_0 + \beta_1 w_{it} + \beta_2 X_{it} + \varepsilon_{it}, \quad (3.46)$$

where β_1 is a measure of labor supply elasticity and β_2 is a vector of coefficients. For the three sets of data in the sample, the inclusion of driver fixed effects gives the estimated labor supply elasticities to be respectively, -1.86 , -0.618 , -0.355 . These estimates suggest the presence of a *downward sloping labor supply curve* over the relevant range.

The construction of wages as $w_{it} \equiv Y_{it}/h_{it}$ raises two sets of issues. First, in the econometric model in (3.46), the labor supply decision responds to the average wage over the day, rather than fluctuations in the wage over the day. If the wage is negatively correlated over the day, then the intertemporal labor substitution model predicts that workers will work harder during the early part of the day when wages are relatively higher, and quit early. However, the authors find a positive autocorrelation in wages over the day, ruling out this problem. Second, h_{it} appears on the LHS as well as on the RHS because $w_{it} \equiv Y_{it}/h_{it}$. Hence, any model mis-specification or measurement errors will bias the estimates of β_2 downwards.

³⁸ For a simple, tractable, two-period model and discussion of these issues, see, for instance, Blanchard and Fischer (1989, section 7.2).

To control for these issues, the authors use the average daily wage rate of other drivers as an instrument. However, they find that this makes the estimate of β_1 even more negative. Another econometric issue is an identification issue. Are the authors picking out points along a downward sloping labor demand curve because of relatively greater variation in the labor supply curve? The authors report that they conducted personal interviews with cab drivers that led them to believe that the marginal cost of driving does not alter in a manner that might have an effect on the wage. However, the authors do not directly introduce an instrument for labor supply.

How does one explain the estimated labor supply elasticities? The authors favor an explanation that is based on reference dependence. Cab drivers have a daily target level of earnings. The target earnings level could be some fixed number (say, \$150 per day) or be linked to the costs of leasing the cab (such as, twice the daily leasing fee). Drivers dislike falling below the daily target and the probability of quitting for the day increases as they approach the target.

Explanations based on daily income targeting are supported by interviews that the authors conducted with the fleet managers. For instance, six fleet managers chose the following response: “Drive until they make a certain amount of money.” Five fleet managers chose: “Fixed hours.” Only one fleet manager chose a response that is consistent with the intertemporal substitution model: “Drive a lot when doing well; quit early on a bad day.” Daily income targeting is not a feature of standard labor economics models. However, it appears to be a sensible heuristic and is reminiscent of the short horizon of portfolio holders (1 year) in the Benartzi and Thaler (1995) model and of the literature on goals and targets. A daily income target is also simple and computationally easy, say, relative to a monthly or a weekly income target.

Does experience make a difference? For instance, experienced drivers might realize that it pays to work longer on busy days. It is possible to split up the cab drivers’ data into experienced drivers (greater than 3–4 year’s experience), and inexperienced drivers. The elasticity of labor supply for inexperienced drivers is generally close to -1 (which is consistent with a daily income target). The corresponding elasticity for experienced drivers is much larger, and positive.

We now present a simple model of reference dependent preferences in labor supply, due to Farber (2008). Section 2.8.2 considers the optimality of income targeting in a similar model with Köszegi–Rabin preferences. Suppose that Y is income, $\bar{Y}$ is reference income, h is hours worked, and w is the wage rate (such that $w = Y/h$). Suppose that the reference dependent utility function is given by

$$U(Y, \bar{Y}) = \begin{cases} (Y - \bar{Y}) - \frac{\theta}{1+\nu} h^{1+\nu} & \text{if } Y \geq \bar{Y} \\ -\lambda(\bar{Y} - Y) - \frac{\theta}{1+\nu} h^{1+\nu} & \text{if } Y < \bar{Y} \end{cases}, \quad (3.47)$$

where λ is the parameter of loss aversion, ν is the inverse of the elasticity of labor supply, θ is a parameter related to disutility of hours worked. Noting that $Y \equiv wh$, the conditions which separate the domain of income in (3.47) into losses and gains are

$$\begin{aligned} Y > \bar{Y} &\Leftrightarrow w > \bar{Y}/h \\ Y < \bar{Y} &\Leftrightarrow w < \bar{Y}/h \end{aligned} \quad (3.48)$$

When $Y > \bar{Y}$, a simple calculation gives the interior solution to the hours worked,

$$h = \left(\frac{w}{\theta} \right)^{1/\nu}. \quad (3.49)$$

Table 3.3 A summary of the solution to the simple labor supply problem in Farber (2008).

Wage	Hours	Elasticity
$w < w_1 \equiv \left(\frac{\theta \bar{Y}^\nu}{\lambda}\right)^{1/(1+\nu)}$	$h = \left(\frac{\lambda w}{\theta}\right)^{1/\nu}$	$1/\nu$
$w_1 \leq w \leq w_2 \equiv \left(\theta \bar{Y}^\nu\right)$	$h = \bar{Y}/w$	-1
$w_2 < w$	$h = \left(\frac{\lambda w}{\theta}\right)^{1/\nu}$	$1/\nu$

Analogously, when $Y \equiv wh < \bar{Y}$, from the second row of (3.47), a simple calculation gives the interior solution to the hours worked as

$$h = \left(\frac{\lambda w}{\theta}\right)^{1/\nu}. \quad (3.50)$$

When $Y \equiv wh = \bar{Y}$, the solution can be directly found as follows

$$h = \bar{Y}/w. \quad (3.51)$$

From (3.48), (3.49), (3.50), (3.51), we can summarize the solution in Table 3.3.

The labor supply curve has the following shape. For wage rates that are less than w_1 and those that are greater than w_2 , the labor supply curve is upward sloping with elasticity of labor supply given by $1/\nu$. However, for intermediate ranges of wage rates, between w_1 and w_2 , the individual finds that his income is at the reference point, so, as in (3.51), it is optimal simply to offset, one for one, an increase in the wage rate by the hours worked. Thus, the labor supply elasticity in the intermediate range is -1 .

Having fixed the basic ideas, we now give a brief overview of the empirical evidence. Oettinger (1999) examines the labor supply decision of vendors in baseball stadiums. The vendors have a choice of working during a particular game by giving prior notice of their decision to their employers. Vendors receive a commission for their sales during the game. The effective wage depends on the attendance at a particular game; greater attendance reduces the time needed to search for the next customer. The level of attendance is a “demand shock,” while the number of other vendors who have chosen to work at a particular game is the relevant “supply shock” for a vendor. Using instrumental variables for the attendance at any game, they find positive and statistically significant wage elasticities (ranging from 0.53 to 0.64). This evidence does not contradict either the standard neoclassical model (see Remark 10 above) or the reference dependence model because most of the equilibrium points could be along the positive sloping part of the labour supply curve.

Fehr and Goette (2007) look at the labor supply decision of bicycle messengers in Zurich who are paid a commission for each successfully delivered message. Bicycle messengers have to work a given number of fixed shifts during a month, but can voluntarily sign up for more shifts. There are two groups of messengers (groups A and B). Group A members are first offered a 25% increase in the commission rate for a period of one month after which they revert back to the old rate. In the following month, group B members are offered the same temporary increase in the commission rate for a month. Fehr and Goette (2007) find that the probability of working on a given day

is higher for the group that is currently a recipient of the increase in the commission rate. The wage elasticities are positive and have similar magnitudes to those in the Oettinger (1999) study, ranging from 0.72 to 0.82.

Fehr and Goette (2007) then regress the log of revenues earned by a messenger in each shift on a dummy for the treatment group that receives the 25% increase in commission rates. They also use other control variables that take account of daily fixed effects and individual fixed effects. They find that the revenues within a shift are lower for the group that has been offered the commission increase, and the implied labor elasticities are negative, ranging from -0.23 to -0.29 . These results are consistent with the reference dependence model.

The Fehr–Goette results are not only consistent with those of Camerer et al. (1997), they also control for some of the objections that were raised against those results. For instance, the source of the variation in wage (25% increase for the control group) is exogenous, so the issue of instruments for labor supply is not a concern. Similarly, messengers sorted themselves into one of the two groups (A or B) prior to the announcement of the increase in the wage, hence, selection issues are controlled for. In an insightful extension, the authors perform a follow-up experiment, designed to elicit the loss aversion parameter of the bicycle messengers. It is found that the effort elasticity is negative and statistically significant only for those messengers who also exhibit loss averse behavior (others do not exhibit an elasticity that is statistically different from zero). This provides much stronger confirmatory evidence of reference dependent preferences in labor supply.

Farber (2005) examines the within-day labor supply decision of New York cab drivers. He uses a hazard model of quitting to test the prediction of the reference dependence model that higher wages during the early part of the day induce earlier quits. In the simplest model, Farber finds that holding fixed the hours worked, the probability of quitting early increases when the earnings for the day up to that point are higher. This is consistent with the reference dependence model. Next, Farber adds controls for driver fixed effects, which alters the result of the simple model; the probability of quitting now does not depend on earnings so far during the day. However, one of the controls used is clock hours, which is the most predictable source of variation in hourly wages; average hourly wages are positively correlated over the day, peaking at evening rush time. This control eliminates an important source of information that could have identified the reference dependence model; for a discussion of these points, see Goette et al. (2004).

Goette and Huffman (2003), like Farber (2005), consider the within-day labor supply decisions of bike messengers based on US and Swiss data. They test the following prediction of the reference dependence model. Suppose that there is a windfall gain in the morning (e.g., a bike messenger gets lucky). Then, reference dependence should predict an increasing effort, followed by decreasing effort. The reason is that when messengers are below the target earnings, they have an increasing incentive to provide effort. However, once this target is exceeded, their incentive to provide effort, falls. In order to isolate just the effect of luck in the morning, they introduce messenger fixed effects, fixed effects to control for the effects of firm, day of the week, and clock hour. The residual variation in earnings of the messenger is on account of luck. The authors verify the prediction of reference dependence that they start out to prove.

Some of the concerns with Farber (2005) that prevented reference dependence to be identified are addressed in Farber (2008) in a model of reference dependent preferences and a reference point that is stochastic. The evidence supports a finding of reference dependence. The model in which income is targeted, performs much better than the standard neoclassical model. However, the reference point is found to fluctuate too much from day to day. The author concludes that this limits the power of reference dependence theory to explain labor supply.

Crawford and Meng (2011) raise two objections to the Farber (2008) results. (1) Farber finds that the probability of stopping increases when the income target is reached. While the individual decisions seem to have these kinks, the aggregate relation between stopping probability and income is too smooth. How can these results be reconciled? (2) The randomness in reference points is large but imprecisely estimated.

Crawford and Meng (2011) propose a model of reference dependent preferences that relies on the Köszegi–Rabin framework (see Section 2.8). In this model (and unlike Faber’s model) there are targets for both hours worked and income. These targets are determined endogenously as rational expectations equilibria. The rational expectations of the wage is operationalized by simply taking the average wage. As before, we denote hours worked by h , income by Y , the actual hourly wage rate by w and reference income by $\bar{Y}$. The new variables are average or expected wage (w^e), and reference numbers of hours worked ($\bar{h}$). Conditional on the reference points for income and hours ($\bar{Y}, \bar{h}$), which are themselves endogenous, the utility of the individual is given by a weighted combination of *consumption utility* and *gain–loss utility*, as follows.

$$U(Y, h, \bar{Y}, \bar{h}) = (1 - \eta) [u(Y) + v(h)] + \eta R(Y, h, \bar{Y}, \bar{h}); \eta \in [0, 1]. \quad (3.52)$$

In (3.52), consumption utility (first term) is additively separable in income and hours and given the weight $1 - \eta \geq 0$. There is positive marginal utility from consumption $u'(Y) > 0$, negative marginal utility from hours worked, $v'(h) < 0$, and $u(Y)$, $v(h)$ are both concave. Gain–loss utility, denoted by R , is the second term in (3.52), and it has weight $\eta \in [0, 1]$. This term is defined by partitioning all (Y, h) pairs into four domains. The income domain and the hours domain are both in gains when $Y > \bar{Y}$ and $h < \bar{h}$; both in loss when $Y < \bar{Y}$ and $h > \bar{h}$; one in loss and the other in gain if either of $Y < \bar{Y}$ and $h < \bar{h}$ or $Y > \bar{Y}$ and $h > \bar{h}$ holds. Formally

$$R = \begin{cases} [u(Y) - u(\bar{Y})] + [v(h) - v(\bar{h})] & \text{if } Y > \bar{Y}, h < \bar{h} \\ \lambda [u(Y) - u(\bar{Y})] + \lambda [v(h) - v(\bar{h})] & \text{if } Y < \bar{Y}, h > \bar{h} \\ \lambda [u(Y) - u(\bar{Y})] + [v(h) - v(\bar{h})] & \text{if } Y < \bar{Y}, h < \bar{h} \\ [u(Y) - u(\bar{Y})] + \lambda [v(h) - v(\bar{h})] & \text{if } Y > \bar{Y}, h > \bar{h} \end{cases}. \quad (3.53)$$

When drivers decide to work an extra hour, they know that their earnings are random. To simplify, it is assumed that drivers simply focus on the expected or average wage, w^e , and use it to compute their hourly earnings. w^a is determined by rational expectations. The objective of the driver is to maximize (3.52), subject to the budget constraint

$$Y = w^e h. \quad (3.54)$$

We motivate a diagrammatic solution. In each of the four domains listed in (3.53), the marginal rate of substitution (MRS) between Y and h is computed using (3.52) and (3.53); Table 3.4 summarizes these calculations.

Since the coefficient of loss aversion $\lambda > 1$, we get that $1 + \eta(\lambda - 1) > 1$. From Table 3.4, when both income and hours are either in the domain of gains or losses, then the MRS is given as in the standard neoclassical model. However, in the other two cases, when both outcomes are in different domains, this is no longer true. When income is in gains and hours are in losses, then

Table 3.4 Summary of the marginal rates of substitution between Y and h in various domains.

Income/Hours	Gain ($h < \bar{h}$)	Loss ($h > \bar{h}$)
Gain ($Y > \bar{Y}$)	$\frac{-v'(h)}{u'(Y)}$	$\frac{-v'(h)}{u'(Y)} (1 + \eta(\lambda - 1))$
Loss ($Y < \bar{Y}$)	$\frac{-v'(h)}{u'(Y)} \frac{1}{1 + \eta(\lambda - 1)}$	$\frac{-v'(h)}{u'(Y)}$

the MRS is magnified (i.e., the indifference curves are steeper). When income is in loss and hours in gain the MRS shrinks (indifference curves are flatter). Equilibrium labor supply can be found from the usual condition that equates MRS with the marginal rate of transformation, which from (3.54) is w^e , hence, $MRS = w^e$. Denote the actual wage of the taxi driver on trip by w^a .

Lemma 3.3 (a) Suppose that $w^a > w^e$, i.e., the actual wage is greater than the expected wage. Then the income target, $\bar{Y}$, is reached first, followed by the hours target, $\bar{h}$.
 (b) Conversely, if $w^a < w^e$, then the hours target is reached first.

Proof: By definition, on any trip, $w^a = Y/h$. Since $w^a > w^e$, we get $Y/h > w^e$. On account of rational expectations, $\bar{Y} = hw^e$, i.e., the endogenous reference income equals the expected income. Suppose that the hours target is reached, i.e., $h = \bar{h}$, then from $\bar{Y} = hw^e$ we get that

$$h = \bar{h} = \frac{\bar{Y}}{w^e}. \quad (3.55)$$

From (3.54), actual income is given by $Y = w^a h$. Substituting (3.55) we get

$$Y = w^a \frac{\bar{Y}}{w^e}.$$

But since $w^a > w^e$ we get that $Y > \bar{Y}$. Hence, when the hours target is reached, the income target is already exceeded. Part (b) of the lemma is analogously derived. ■

Figure 3.8 gives insights into the equilibrium in (Y_t, h_t) space, where the subscript t denotes the time of the day during the trip. On the vertical axis, we measure Y_t (increasing upwards) and along the horizontal axis, h_t (increasing leftward). The space is truncated into four quadrants I, II, III, IV, based on the reference income and reference hours level, $(\bar{Y}, \bar{h})$, as the origin.

The driver begins at his endowment point of $(Y, h) = (0, 24)$, assuming that the total time endowment is 24 hours. He begins with an expected wage w^e and then moves in the northeast direction along the line $Y = w^e h$. There are two possibilities, $w^a > w^e$ and $w^a < w^e$, both shown in the diagram. Having completed any single trip, the driver begins another trip starting from the last level of (Y, h) , again moving in a northeast direction along the line $Y = w^e h$.³⁹ The key insight comes from Lemma 3.3; when $w^a > w^e$, the driver first reaches the income target, and when $w^a < w^e$ the driver first reaches the hours target.

³⁹ In practice, the budget line is random (because the wage is random) but for exposition, we consider that the driver takes account of only the wage w^e .

Figure 3.8 An illustration of the equilibrium in the Crawford–Meng (2011) model.

Source: Crawford and Meng (2011) with permission from the American Economic Association.

Consider first the case $w^a > w^e$. We know from Table 3.4 that in quadrants I and III, the slope of the indifference curves is identical in neoclassical theory and in prospect theory with targets $(\bar{Y}, \bar{h})$ (PTT). In quadrant II, the indifference curves are relatively steeper under PTT as compared to neoclassical theory, while in quadrant IV, these indifference curves are relatively flatter. Let us concentrate only on quadrants I and IV.

Suppose that in the neoclassical model, the equilibrium is at point 1 (it could also be at other points such as 2, 3, and 4). However, because in this quadrant the indifference curves under PTT are flatter, so the equilibrium under PTT could be at point 2, as shown in the figure. Starting at point 2, the individual will not like to enter quadrant I if the marginal rate of substitution, $\frac{-v'(h)}{u'(Y)}$ (see (1, 1)th element in Table 3.4) exceeds the opportunity cost of leisure, w^e . Should this happen, then equilibrium is at point 2 and the income target is met before the hours target (see Lemma 3.3).

Conversely, when $w^a < w^e$, the relevant budget constraint is the lower of the two budget constraints in Figure 3.8. In this case, starting from the endowment point $(Y, h) = (0, 24)$, an individual using PTT may similarly find it optimal to be at point 5 (this turns out to be the empirically relevant case). But in this case, the hours target is reached before the income target.

Crawford and Meng (2011) estimate the probability of stopping, as in Farber (2005), with two main differences. First, targets are not treated as latent variables but rather as rational expectations (proxied by average sample realizations). Second, the sample is split into two parts $w^a > w^e$ and $w^a < w^e$, i.e., depending on whether the realized income is lower or higher than the (proxied) expected income. The authors find clear evidence of reference dependence.

The probability of stopping is heavily influenced by realized income when $w^a > w^e$. Conversely, when $w^a < w^e$, the probability of stopping is heavily influenced by hours worked. The cases $w^a > w^e$ and $w^a < w^e$ have almost equal weight in the sample. In the first case, the wage elasticity of hours is strongly negative, while in the second it is zero. Thus, in the aggregate, wage elasticity is negative, as in Camerer et al. (1997).

3.9 Some implications of inverse S-shaped weighting functions

Figure 2.5 in Section 2.3 considered the following important implication of inverse S-shaped probability weighting functions under rank dependent models. Extreme events (or tail events in finance) are more salient in the sense that such events are accorded higher decision weights. This is one possible explanation for why positively skewed portfolios and assets with positively skewed returns may be more attractive to investors, hence, driving up their prices (Barberis and Huang, 2008).⁴⁰ A related implication of a preference for positively skewed portfolios is that individuals may hold portfolios that are under-diversified; see Mitton and Vorkink (2007) for confirmatory evidence.

Another implication of the increased salience of tail events is that the decision maker is more averse to negatively skewed returns, which accords well with the actual shape of the average over-all returns in the market (Fehr-Duda and Epper, 2012). This produces an even higher level of the equity premium, beyond that which can be explained by loss aversion alone (De Giorgi and Legg, 2012). This illustrates, once again, the importance of using the entire machinery of PT, particularly when one wishes to explain quantitative phenomena.

Salience of tail events may also explain why the volume of retirement annuities purchased is lower than the predicted volume in neoclassical theory. Suppose that the retirement age is 65. Hu and Scott (2007) present the problem as one in which if someone dies early, within a few years of 65 (small perceived probability of the event, hence, this is a tail event), then the annuity is not very useful. However, if tail events are overweighted, then the desirability of annuities falls, in line with the evidence.

A basic feature of the inverse S-shaped weighting functions is that low probabilities are overweighted. This has been used to explain why people choose low deductibles in insurance⁴¹ even when the high deductibles are several times cheaper in expected value. In Sydnor (2010), potential insurees are given a menu of choices between four different levels of home insurance deductibles, \$100, \$250, \$500, \$1000. The most common choice was \$500. However, in order to reduce the deductible from \$1000 to \$500, consumers typically paid an extra cost, in terms of the premium, of \$100. The claim rate of this group of consumers was 5%. Thus, consumers are willing to pay an extra \$100 to reduce the expected loss by \$25. The implied coefficient of relative risk aversion is in triple and quadruple digits, which is unreasonably high. Sydnor's preferred explanation is that individuals must overweight the probability of tail events significantly, which is consistent with inverse S-shaped weighting functions.

The empirical tests in Barseghyan et al. (2013) discriminate among the Köszegi–Rabin framework, Gul's theory of disappointment aversion, and non-linear probability weighting. They show that it is non-linear probability weighting that accounts for the observed choice of low deductibles. Overweighting of low probabilities also explains the favorite long-shot *bias* in betting markets (e.g., in horse racing). This takes the form of over-betting on horses which have a small probability of winning and under-betting on horses which have a high chance of winning.⁴²

⁴⁰ For related empirical evidence, see Ang et al. (2006), Boyer et al. (2010), Green and Hwang (2012), and Conrad et al. (2013).

⁴¹ In the event of a loss, the loss of the consumer is capped at the level of the deductible that is chosen.

⁴² See, for instance, Jullien and Salanié (2000) who show that prospect theory outperforms expected utility in explaining this phenomena. Snowberg and Wolfers (2010) are able to distinguish between the role of convex utility and probability weighting and find the latter to be the main source of the explanation.

A quick look at the literature suggests that loss aversion based explanations are more predominant in the literature as compared to those based on non-linear probability weighting. Fehr-Duda and Epper (2012) make a strong case for redressing this imbalance. They argue that (p. 589): “Probability dependence is the more fundamental of the two [loss aversion and non-linear probability weighting] because it is observed for all types of prospects: pure gain prospects as well as pure loss and mixed prospects. In contrast, loss aversion is effective for mixed prospects only. It is our impression that probability-dependent risk preferences have not received as much attention as loss aversion has, however.”

3.10 Contracts as reference points

Suppose that a buyer and a seller write a contract at an initial stage in which the future cannot be perfectly anticipated. Hence, any contracts that they write have to be necessarily incomplete. At the initial stage, both parties (or just one party) sink relation-specific investment. Once the relevant uncertainty is resolved at a future date, then the two parties can renegotiate the terms of the contract. Under the assumptions of Coasian bargaining, renegotiation allows them to achieve an efficient outcome.

Renegotiation entails sharing, ex-post, the benefits of the relation-specific investment. Anticipating this hold up problem in the renegotiation stage, at the initial stage, each party invests an inadequate amount. This highlights an important *transaction cost* of using the market. The solution to the problem is the allocation of ownership rights and *residual control rights* in such a way that facilitates *efficient investment* (Grossman and Hart, 1986; Hart and Moore, 1990). Indeed, one possible solution is the *formation of firms* and entering into *long-term contracts*.

This account of the theory of the firm is restrictive in scope, because ex-ante investment in non-contractible relation-specific investments is the main driver in the formation of firms. In contrast, we often observe the existence of firms when such factors are absent. This explanation also does not shed light on the *internal organization of the firm* and the explanation of *authority, hierarchy, and delegation*.

In this section, we consider an alternative view of the firm, one that is based on the idea of reference dependence in prospect theory.

In a reference dependence-based explanation of firms, contracts establish a *reference point of entitlements* for the contracting parties. Initial contracts are typically written among parties chosen from a competitive pool of buyers and sellers. Hence, each party to the contract is likely to believe that the terms of the contract capture the market beliefs about its entitlement. Competition is critical to establishing entitlements. Lack of competition does not establish entitlements, hence, contracts that are signed in non-competitive conditions may not serve as a reference point; see Fehr et al. (2009) for the empirical evidence.

At a future date, once ex-ante uncertainty is resolved, parties to the contract evaluate the current outcomes, relative to the ex-ante entitlements established by the initial contract. If the outcomes are inferior to the entitlements, parties feel *aggrieved* and may *shade* their ex-post performance. Both parties need not share the same beliefs about their respective entitlements. For instance, there could be a *self-serving bias*, which leads each party to confound fairness with its selfishly preferred outcome. This self-serving bias in entitlements is analyzed in the context of bargaining models in Chapter 12 (Babcock and Loewenstein, 1997).

Why is it typically difficult to specify ex-post performance in the ex-ante contract? Hart and Moore (2008) distinguish between *perfunctionary performance* and *consummate performance*.

The former refers to conformity with the *letter* of the contract (e.g., number of hours worked) and the latter with the *spirit* of the law (e.g., care and attention exercised during working hours). Perfunctionary performance is observable and verifiable to a third party, so it can be specified in the ex-ante contract. By contrast, consummate performance is observable to both parties, but not verifiable to a third party, so it cannot be written down in the contract. Hence, the ex-post actions of the parties are only *partially contractible*. If, ex-post, parties to a contract feel aggrieved, based on a comparison with their entitlements based on the initial contract, then they can lower their consummate performance. This is the sense in which *shading of performance*, to the detriment of the other parties to a contract, can take place. In this framework, there is no loss aversion and there is no renegotiation.

In a buyer–seller framework, shading by the seller can take the form of reducing quality, or not agreeing to reasonable requests by the buyer that greatly enhance the utility of the buyer at zero or very low cost to the seller. Buyers can also engage in shading by, say, delaying payments, engaging in discourteous behavior, and writing bad references for future potential buyers.

These elements of the theory can be used to determine the choice between *rigid contracts* and *flexible contracts*. A rigid contract, such as an *employment contract*, rigidly fixes the wage at the initial stage in a competitive environment, and allows no ex-post flexibility in altering the wage. Hence, ex-post, parties have no opportunity to be aggrieved. However, such a contract lacks the ex-post flexibility to adapt to changing states of nature. For instance, demand might turn out to be surprisingly low, but the initially fixed wage cannot be lowered. By contrast, a flexible contract offers ex-post flexibility in adapting to the realized state of the world. However, it also creates an opportunity for aggrievement. As one of the parties adapts to the state of the world, the other party may feel unfairly treated relative to the entitlements and retaliate by reducing its consummate performance. This trade-off governs the choice between the rigid contract and the flexible contract. Under certain conditions that we specify below, the rigid contract may be optimal.

3.10.1 A simple model

Hart and Moore (2008) consider the following simple model of a long-term relation between a buyer, B, and a seller, S. A competitive pool of buyers and sellers meet at date 0. A matched buyer–seller pair then sign a contract at date 0, which structures their interaction at date 1. Once the two parties are matched, the competitive pool of market participants reduce to a bilateral monopoly situation; this is Williamson’s well-known *fundamental transformation*. Both parties are risk neutral, all information is symmetric, there are no wealth constraints, and there are no non-contractible relation-specific investments.

There is potential uncertainty when parties sign contracts at date 0, but all uncertainty is resolved by date 1. At date 1, the parties act, in each state, as per the instructions in the date 0 contract. For instance, if the date 0 contract is a rigid contract, then parties make no active decisions. On the other hand, if the date 0 contract is a flexible contract, it might require one of the parties to the contract to choose a date 1 price, depending on which state of the world is realized. Trade then occurs and the two parties choose their consummate performance. In order to measure the degree of aggrievement, we make the simplifying assumption that each party feels entitled to the best outcome that can arise for it in the date 0 contract (say, on account of self-serving bias).

Denote by Π_B, Π_S , the set of gross payoffs that are contractually feasible and let $\bar{u}_j = \max \Pi_j$ be the maximum possible payoff to party j as dictated by the date 0 contract. Suppose that at date 1, the gross payoffs of the buyer and seller are, respectively, u_B and u_S . Let the buyer and the seller be indexed, respectively, by $j = B, S$. The aggrievement of player j is given by

$$a_j = \bar{u}_j - u_j, u_j \in \Pi_j. \quad (3.56)$$

Being aggrieved causes a drop in consummate performance that causes a monetary loss to the other party (effort shading). Denote the monetary loss caused by the buyer and the seller, respectively, to the other party, on account of aggrievement, by l_B and l_S . The respective utilities of the buyer and the seller, U_B and U_S , are given by

$$U_B = u_B - l_S - \max\{\theta a_B - l_B, 0\}, \quad (3.57)$$

$$U_S = u_S - l_B - \max\{\theta a_S - l_S, 0\}, \quad (3.58)$$

where $\theta \in (0, 1]$. The third term on the RHS in each of (3.57) and (3.58) shows that being aggrieved leads to a loss in utility, the extent of which depends on θ . However, causing a monetary loss to the other party shades this loss in utility; this is viewed as “just retribution” inflicted on the other party when one perceives oneself to be unfairly treated. However, shading can never be used to increase one’s own utility, although one can shade enough such that all aggrievement disappears (i.e., if $\theta a_B = l_B$ or $\theta a_S = l_S$). Each party simultaneously chooses l_j , $j = B, S$. Clearly, the utility maximizing choice of each party is $l_B = \theta a_B$ and $l_S = \theta a_S$. Substituting this solution in (3.57) and (3.58), the equilibrium utilities of the buyer and seller are, respectively,

$$U_B = u_B - \theta a_S \text{ and } U_S = u_S - \theta a_B. \quad (3.59)$$

Let us use this framework to find the optimal contracts for the following simple case. A buyer would like to enter into a date 0 contract with a seller to supply 1 unit of an object at date 1. It is common knowledge that the buyer’s utility is $u_B = 100 - p$, where p is the date 1 price at which the object is exchanged. The seller’s cost is zero, so $u_S = p$. The total surplus is $u_B + u_S = 100$. There are no ex-ante non-contractible investments. The results for this simple case are listed in the next proposition.

Proposition 3.34 (i) *In the neoclassical framework, the solution is identical in the absence or presence of an ex-ante contract.*

(ii) *In the “contracts as reference points” framework, the total surplus is given by $(1 - \theta) 100$, which is independent of p and there is a deadweight loss of 100θ .*

(iii) *Ex-post Coasian renegotiation does not alter the result in (ii).*

(iv) *A mechanism that gives residual control rights to the buyer to choose a date 1 price does not alter the result in (ii).*

(v) *Suppose that there is a competitive market for sellers or buyers. Consider a rigid contract at date 0 that fixes a date 1 price, p , determined by competitive contracts. Such a contract achieves a social surplus of 100.*

(vi) *Suppose that the date 0 market is imperfectly competitive and the contracting parties agree on some price interval $[\underline{p}, \bar{p}]$ for the date 1 trading price, such that $0 < \underline{p} < \bar{p} < 100$. Then the shading costs of aggrievement are $\theta(\bar{p} - \underline{p}) < 100\theta$.*

Proof: (i) Consider the neoclassical framework in which there is absence of aggrievement and shading. Assume that there is a competitive supply of sellers but only one buyer, and lump-sum transfers are allowed. Suppose that the buyer writes a contract with one of the sellers from the competitive pool of sellers at date 0. All parties know that at date 1, there is bilateral monopoly between the contracting parties, so that the date 1 price is determined by bargaining. The total

surplus from trading is $u_B + u_S = 100$, arising entirely from the buyer's valuation, because the seller's cost is zero.

Assume symmetric Nash bargaining among the two parties at date 1, thus, $p = 50$ and the gains from trade are shared equally. However, at date 0, since there is a competitive pool of sellers, the single buyer must get all the surplus. Anticipating ex-post opportunism, the seller who gets the contract at date 0, pays a lump-sum transfer to the buyer, equal to 50. Thus, the date 1 payoffs of the seller and the buyer are $u_B = 100$, $u_S = 0$. On the other hand if the parties had waited for date 1 to write a contract, then competition among the sellers would have driven the price to $p = 0$ so that $u_B = 100$, $u_S = 0$, which is identical to the outcome under a date 0 contract.

This result can also be shown to hold for other market configurations such as one buyer and one seller or many competitive buyers and one seller.

(ii) Consider one buyer and one seller. Suppose that the two parties do not write a date 0 contract and both realize that they will agree on some price p at date 1. At date 1, the maximum possible payoff of the buyer, as dictated by the date 0 contract, is $\bar{u}_B = 100$, so the buyer feels aggrieved if $p > 0$. Analogously, for the seller, $\bar{u}_S = 100$, so the seller feels aggrieved if $p < 100$. Thus, for any $0 < p < 100$ both parties will shade their consummate performance.

Since $a_j = \bar{u}_j - u_j$, $j = B, S$, we have that $a_B = 100 - (100 - p) = p$ and $a_S = 100 - p$. Thus, the buyer shades by $l_B = \theta a_B = \theta p$, and the seller shades by $l_S = \theta a_S = \theta(100 - p)$. Using (3.59), the final utilities of the buyer and the seller are, thus,

$$U_B = 100 - p - \theta(100 - p) = (1 - \theta)(100 - p).$$

$$U_S = p - \theta p = (1 - \theta)p.$$

The total surplus is $W = U_B + U_S = (1 - \theta)100$, which is independent of p . Thus, there is a deadweight loss of 100θ that is increasing in the weight that the two parties put on aggrievement.

(iii) Suppose that at date 1, the buyer pays an amount x to the seller to reduce the seller's shading. The seller will find that a_S falls (see (3.56)), so he indeed shades less. However, the buyer will find that a_B goes up, so he feels more aggrieved, thus, he will shade more. On net, given the linear, additive, structure of the model, there is no change to the result in (ii).

(iv) Part (ii) holds for any arbitrary date 1 price, p and there is a deadweight loss of 100θ , which is independent of p . In particular, this result holds for $p = 0$. In part (iv) we have a particular price p chosen by the buyer who makes a take it or leave it offer to the seller, hence, $p = 0$. So we get the same deadweight loss and same total surplus as in part (ii).

(v) Suppose that there is a competitive pool of suppliers and one buyer, so that the buyer has all the bargaining power. Then a rigid contract at date 0 must fix a date 1 price of $p = 0$. Conversely, if there are a large number of buyers and one seller, this price must be $p = 100$. Once the price is fixed at date 0, none of the parties feels aggrieved at date 1 from the implementation of the date 0 price. Since the date 0 price was competitively determined, each party realizes that this price fixes an objective, market determined, entitlement. Thus, no shading of consummate performance occurs and the total surplus is $100 - p + p = 100$.

(vi) In this case, given the definition of $\bar{u}$, the buyer feels entitled to $\bar{u}_B = 100 - \underline{p}$ and the seller feels entitled to $\bar{u}_S = \bar{p}$. Suppose that trade takes place at some $p \in [\underline{p}, \bar{p}]$. Then $a_B = (100 - \underline{p}) - (100 - p) = p - \underline{p}$. Thus, the buyer shades his effort by $\theta a_B = \theta(p - \underline{p})$. For the seller, $a_S = \bar{p} - p$, thus, the seller shades by $\theta a_S = \theta(\bar{p} - p)$. Total shading is given by $\theta(p - \underline{p}) + \theta(\bar{p} - p) = \theta(\bar{p} - \underline{p}) < 100\theta$ because $0 < \underline{p} < \bar{p} < 100$. Hence, the deadweight loss in this case is lower and the social surplus is higher. ■

Proposition 3.34 shows that rigid contracts that determine the date 1 terms of trade at date 0 are preferable to flexible contracts that leave price determination to date 1. This is because they lead to lower aggrievement and lower shading of effort. An extension of these results to the case of non-contractible ex-ante investment can be found in Hart (2009).⁴³

In general, Proposition 3.34 need not hold when either the buyer's valuation of the object, v , or the seller's cost, c , are uncertain. Suppose that trading at date 1 is voluntary and a date 0 contract specifies a no-trade price p_0 (paid by the buyer to the seller in the event of no-trade) and a trade price, p_1 , if trade occurs at date 1. We allow lump-sum transfers between the two parties and no renegotiation of contracts at date 1. Let $q = 1$ if trade occurs at date 1, and $q = 0$ if no trade occurs. The buyer and the seller voluntarily engage in trade at date 1 if, respectively, $v - p_1 \geq 0 - p_0$ and $p_1 - c \geq p_0$, which can be summarized by

$$q = 1 \Leftrightarrow v \geq p_1 - p_0 \geq c. \quad (3.60)$$

We normalize $p_0 = 1$ because lump-sum transfers are allowed. Thus, the relevant trade condition is $v \geq p_1 \geq c$. One may compare this with the first best condition for trade:

$$q = 1 \Leftrightarrow v \geq c. \quad (3.61)$$

Since condition (3.60) is more restrictive than (3.61), thus, in the second best, trade takes place less often as compared to the socially optimal level.

Suppose that we consider a slightly more general contract in which:

- (i) p_1 is not a point price but it can be chosen from the interval $[\underline{p}, \bar{p}]$, and
- (ii) the contract gives the buyer the right to choose the date 1 price, once any uncertainty has resolved.

In this case, a generalized version of (3.60) can be written as

$$q = 1 \Leftrightarrow \exists p_1 \in [\underline{p}, \bar{p}] : v \geq p_1 - p_0 \geq c. \quad (3.62)$$

Normalizing $p_0 = 0$, a sufficient condition for (3.62) to hold for all $p_1 \in [\underline{p}, \bar{p}]$ is

$$q = 1 \Leftrightarrow v \geq \bar{p} \text{ and } c \leq \underline{p}. \quad (3.63)$$

This condition holds irrespective of whether the buyer or the seller has residual control rights to choose $p_1 \in [\underline{p}, \bar{p}]$.

Assume that each party recognizes that due to the voluntary trade assumption, they cannot get more than 100% of the trade surplus. Thus, each party feels an entitlement up to the maximum surplus within the contract, conditional on trade taking place. So long as they achieve this level of entitlement, they feel no aggrievement.

Definition 3.63 *An 'optimal contract' maximizes ex-ante expected surplus, net of shading costs.*

⁴³ For an extension of the Hart-Moore framework to renegotiation, see Halonen-Akatwijuka and Hart (2013) and for an application to the scope of the firm, see Hart and Holmstrom (2010).

	s1	s2
v	9	20
c	0	10

Figure 3.9 Valuations and costs in two states of the world.

	s1	s2	s3
v	9	20	20
c	0	10	0

Figure 3.10 Valuations and costs in three states of the world.

Example 3.26 Suppose that there are two possible states of the world at date 1, s_1 and s_2 , but at date 0 it is not known which state will arise. The buyer's valuation, v , and the seller's cost, c , are given in Figure 3.9. Suppose first that p_1 is a point price. Then, we need to find a single value for p_1 at date 0 such that $v \geq p_1 \geq c$ in each state (see (3.60) when $p_0 = 0$). From Figure 3.9 there exists no such price.

Now consider a contract that specifies $p_1 \in [\underline{p}, \bar{p}] = [9, 10]$. Recall that the buyer has the right to choose the date 1 price, once the state of the world is known. In state s_1 , the buyer picks $p_1 = 9$. Since this is the lowest possible price in the range of feasible prices $[9, 10]$, the buyer does not feel aggrieved. The seller too does not feel aggrieved because any higher price will exceed the buyer's valuation and prevent trade from taking place. When the state of the world is s_2 , the buyer picks $p_1 = 10$, which is the upper bound of the feasible set of prices. The buyer does not feel aggrieved because any lower price will lead to no trade. The seller does not feel aggrieved because he gets his maximum possible entitlement within the contract. Thus, in each state, we obtain an efficient outcome.

The outcome under uncertainty about v, c need not always be efficient (although it is efficient in Example 3.26). Consider, for instance, Figure 3.10, which augments an extra state to Example 3.26.

We leave the proof of the following proposition as an exercise.

Proposition 3.35 Consider Figure 3.10 and suppose that the three states, s_1, s_2 , and s_3 occur with respective probabilities π_1, π_2 , and π_3 . In all states, $v > c$ so it is socially optimal to trade. Consider three possible contracts A, B, and C. In contract A, $\underline{p} = \bar{p} = 9$. In contract B, $\underline{p} = \bar{p} = 10$. In contract C, $\underline{p} = 9, \bar{p} = 10$.

- (i) In contracts A and B, there is inefficient amount of trade.
- (ii) Contract A is optimal if π_2 is small, contract B is optimal if π_1 is small, and contract C is optimal if π_3 is small or θ is small.

In Proposition 3.35, a contract is more likely to be optimal if the probability of the state in which it does not allow trade is also low. Of the available contracts, contract C allows trade in all states, yet in state 3, there are aggrivement costs, hence, contract C is likely to be optimal if state 3 is less likely and if aggrivement costs are small.

3.10.2 Empirical evidence for contracts as reference points

Fehr et al. (2011) test if ex-ante competition serves to create entitlements via the reference point effect, using a version of the Hart and Moore (2008) model with payoff uncertainty. Their aim is not to test if players choose their contracts optimally, but rather to test if the behavioral assumptions of the Hart–Moore framework are empirically relevant.

Groups of 2 sellers and 2 buyers interact over 15 periods; groups are randomly rematched in each round to minimize reputational concerns. Each seller can sell up to 2 units, while each buyer needs only 1 unit at date 1, so there is seller competition. Parties are matched at date 0. At date 1, the contracted seller not only supplies the contracted quantity of 1 unit, but also determines the quality, q , which can take two possible values, normal (q_n) or low (q_l). There are two states of the world, the good state ($s = s_g$) that occurs with probability 0.8 and the bad state ($s = s_b$) that occurs with probability 0.2.

The production cost of the seller at date 1 is given by $c(q, s)$, where s is the state of the world and $c(q_n, s) < c(q_l, s)$, i.e., it is more costly to produce low quality in any state. The intuition is that it might be costly to alter the production process to produce an altered, and shaded level of consummate effort that results in a lower quality. The seller's costs are higher in the bad state, relative to the good state, so $c(q, s_g) < c(q, s_b)$. The payoffs of the buyer and the seller are given, respectively, by

$$u_B = v(q) - p \text{ and } u_S = p - c(q, s),$$

where v gives the buyer's valuation, and $v(q_n) > v(q_l)$, i.e., the buyer prefers normal to low quality. The outside option of the seller for any unit that he is unable to sell is $x_s = 10$. The payoff relevant data used in the experiments is shown in the self-explanatory Figure 3.11.

The buyers choose among contracts. They can choose either a rigid contract (r), or a flexible contract (f). These contracts are then auctioned off to sellers. In a *rigid contract*, the contract price $p_r \in [c(q_l, s_g) + x_s, 75] = [35, 75]$ is determined in an auction where the sellers bid against each other. The lower bound of 35 ensures that in the good state, even with the low quality, the

	s_g		s_b	
	q_n	q_l	q_n	q_l
c	20	25	80	85
v	140	100	140	100

Figure 3.11 Quality dependent valuation and cost data in two states of the world.

Source: Fehr et al. (2011) with permission from the American Economic Association.

seller does not make losses by trading, relative to getting an outside option price of $x_s = 10$ for unsold units. The upper limit ensures that the seller is always better off exercising his outside option price of $x_s = 10$ if the state is bad, rather than engaging in trade. This captures the idea that contract rigidity does not allow the parties to adapt well, ex-post, to changes in circumstances.

A *flexible contract* vests residual control rights in the hands of the buyer to choose the price p_f at date 1, once the state of the world is revealed. In the good state, s_g , the price $p_f \in [\underline{p}, \bar{p}]$, where $\underline{p} \in [35, 75]$ as in the rigid contract, and $\bar{p} = v(q_n) = 140$. In the bad state, s_b , the buyer chooses a price $p_f \in [c(q_l, s_b) + x_s, v(q_n)] = [95, 140]$. This ensures that in the bad state, the buyer's price does not let the seller make a loss by trading relative to exercising the outside option of $x_s = 10$. Unlike a rigid contract, a flexible contract permits trade to take place in both states of the world.

In each of the two contracts, sellers observe the price and then choose their quality. If they decide to choose a lower quality, they incur an extra cost of 5 units (see Figure 3.11).

Let us first summarize the results for the case of purely self-regarding preferences. In this case, bygones are bygones, so each seller will always choose the normal quality to avoid reducing their own payoff by 5 units. Anticipating that the seller never engages in shading of consummate performance, buyers choose the smallest price allowed in their respective contracts. In the rigid contract, buyers choose a price of 35 in each state of the world. Thus, the buyer's payoff equals 105 in the good state but 0 in the bad state because at a price of 35, the seller prefers to exercise the outside option. By contrast, in the flexible contract, in the good state, the buyer chooses 35 (so his payoff is 105) but in the bad state the buyer is restricted to choose no lower than 95, so his payoff is 45. Clearly, the flexible contract dominates the rigid contract because the payoffs are identical in the good state but relatively higher in the bad state under a flexible contract. These results do not depend on the presence of ex-ante competition.

Now consider the predictions in the “contracts as reference points” framework. In the rigid contract, the prices are fixed up-front, so the seller does not feel aggrieved ex-post, thus, no shading takes place. Therefore, we do not expect low quality to be chosen. In a flexible contract, by contrast, both parties have different entitlements, so shading by the seller does take place. Such shading is personally not very costly for the seller (a loss of 5 units in terms of the cost), however, it is costly for the buyer (a loss of 40 units in terms of the valuation in each state). The higher the price, the lower is the expected shading on the part of the seller. In response, buyers will attempt to increase the price to reduce shading by the seller. But increasing the price reduces the buyer's profits under flexible contracts, so they might end up preferring rigid contracts.

Recall that in a flexible contract, in the bad state, $p_f \in [95, 140]$. In an additional treatment, buyers are restricted to choose the date 1 price in the interval $[95, 95]$. Since there is no ex-post flexibility for the buyer in this case, we expect lower shading by the seller. Yet another treatment eliminates ex-ante seller-competition. In the absence of seller-competition, the sellers may increase their entitlements, so they may engage in more shading.

The empirical results confirm the predictions of the Hart–Moore model that are outlined above, but reject the model of purely self-regarding preferences. The results are summarized in Table 3.5.

The *competitive price* is simply the cost of the seller plus the outside option. Since trade never takes place in the bad state under rigid contracts, the competitive price in a rigid contract is 35 in the good state. Analogously, in a flexible contract that allows trade in the bad state, the competitive price is 95. From Table 3.5, the average prices in rigid and fixed contracts are 40.7 and 40.2, respectively, which are not statistically different.

Table 3.5 Summary of the results for rigid and flexible contracts.

Contract type	Rigid contract		Flexible contract	
	Good	Bad	Good	Bad
Average price	40.7	—	51.1	98.4
Relative frequency of normal quality	0.94	—	0.75	0.70
Average auction outcome	40.7		40.2	
Average profit buyer (per state)	96.8	10	78.9	29.7
Average profit seller (per state)	20.4	10	29.8	16.9
Average profit buyer (over both states)	77.9		68.9	
Average profit seller (over both states)	18.1		27.2	
Relative frequency of contract	0.50		0.50	

Source: Fehr et al. (2011).

Looking at the results in each state, although the lower bound for price is only 35 in the good state of a flexible contract, buyers use their residual control right over prices to offer a price of 51.1. This is significantly higher than the price of 40.7 in the good state of a rigid contract where no shading can occur. In a flexible contract, 75% of the prices are above the lower bound. The difference between actual prices and the lower bound is significant, stable, and persists over time. This is consistent with the prediction that in a flexible contract, buyers offer a higher price to take account of the possibility of shading by the sellers.

Sellers rarely shade in the rigid contract in the good state (no trade takes place, by design, in the bad state) and in 94% of the cases, sellers choose normal quality. However, the corresponding figure for flexible contracts is 75%. A non-parametric signed rank test confirms that the difference between the two figures is significant. This is consistent with the hypothesis that sellers are aggrieved when they receive a payoff below their entitlements.

As noted above, if all parties had self-regarding preferences, then buyers should always prefer the flexible contract. However, in the Hart–Moore framework, buyers may get a higher payoff from the rigid contracts on account of the shading behavior of sellers in a flexible contract. The data confirms this prediction. Average profit over both states in the rigid contract is 77.9, while it is 68.9 in the flexible contract. By contrast, the average profits of sellers are higher in the flexible contract relative to the rigid contract. It would seem that buyers may have conceded a higher price that more than offsets the higher costs of the sellers from shading in the flexible contracts.

Possibly in response to these differences in profits, on average, buyers choose the rigid contract in 50% of the cases. Over time, the share of rigid contracts increases from 38% in round 1 to 56% by the last round (round 15) and the time trend is statistically significant. These results provide insights about why some forms of rigid contracts such as the employment contract may be preferred in many cases.

3.11 Moral hazard, loss aversion, and optimal contracts

Consider a simple principal–agent model in which the principal is risk neutral and the agent has prospect theory preferences (de Meza and Webb, 2003, 2007). The outside option of the agent

is zero. The agent chooses an action $a \in \{0, 1\}$. Each action probabilistically determines one of three observable output levels, $0 \leq y_L < y_M < y_H$. Let P and Q be the distribution functions, respectively, under $a = 1$ and $a = 0$. Under action $a = 1$, the probability of outcome y_i is p_i , $i = L, M, H$, while under action $a = 0$, the corresponding probability is q_i . We make two assumptions about the probability distribution of outcomes.

- A1. The distribution of outcomes under $a = 1$ first order stochastically dominates the distribution under $a = 0$, so $P_i \leq Q_i$ for $i = L, M, H$.
- A2. The *monotone likelihood ratio property* (MLRP) holds, so

$$\frac{p_L}{q_L} < \frac{p_M}{q_M} < \frac{p_H}{q_H}.$$

Thus, the probability of a higher outcome under the higher action is higher. In other words, a higher output is more likely to have come from a higher effort level.

The only observable and verifiable signal of the agent's effort is the output level produced. Hence, the principal conditions the agent's reward scheme on the observed output level. The agent receives a wage w_i when the observed output level is y_i . The agent has limited liability ($w_j \geq 0$) and there is no renegotiation of contracts. For pedagogical ease, let the *reference wage* of the agent be w_M . Since the MLRP holds, the optimal wage is increasing in the observed output level, so w_M will also be the median wage. The utility function of the agent from the wage w_i and action a , is given by

$$v(w_i | w_M, a) = \begin{cases} u(w_i) - a & \text{if } w_i > w_M \\ u(w_i) - \lambda (w_M - w_i) - a & \text{if } w_i \leq w_M \end{cases},$$

where $u' > 0$, $u'' < 0$, and $\lambda > 0$ is the coefficient of loss aversion. Thus, when $w_i \leq w_M$ the decision maker suffers disutility from loss aversion that is linear in the distance $w_M - w_i$. This formulation is similar to the Köszegi–Rabin framework in which the individual derives consumption utility and gain–loss utility, except that here we only capture disutility from losses. In order to ensure an interior solution, we impose the Inada condition, $\lim_{x \rightarrow 0} u'(x) = -\infty$.

A contract is given by four parameters, (w_L, w_M, w_H, a) , where w_i is the contractible wage level if the observed output is y_i , and a is the *non-contractible, desired action*. We assume that the principal always wishes to induce the higher action, $a = 1$. Thus, we wish to focus attention on contracts of the form $(w_L, w_M, w_H, 1)$ in which the principal optimally chooses w_L, w_M, w_H . Let $u_i = u(w_i)$ and define the expected utility of the agent and expected cost of the principal under the distribution P by

$$\bar{u}(P) = p_H u_H + p_M u_M + p_L u_L, \bar{C}(P) = p_H w_H + p_M w_M + p_L w_L. \quad (3.64)$$

One can analogously define $\bar{u}(Q)$ and $\bar{C}(Q)$ under the distribution Q . Define

$$\Delta \bar{u}(P) = \bar{u}(P) - \bar{u}(Q), \Delta p_i = p_i - q_i, \Delta w_M = w_M - w_L; i = L, M, H.$$

With this definition, we can write the MLRP in Assumption A2 as

$$\frac{\Delta p_L}{p_L} < \frac{\Delta p_M}{p_M} < \frac{\Delta p_H}{p_H}. \quad (3.65)$$

The expected utility of the agent when he chooses the action $a = 1$ and induces the distribution P over outcomes can be written as

$$E_P v(w_i | w_M, 1) = \bar{u}(P) - p_L \lambda \Delta w_M - 1.$$

Similarly, the agent's expected utility when he takes action $a = 0$ and induces the distribution Q over outcomes is

$$E_Q v(w_i | w_M, 0) = \bar{u}(Q) - q_L \lambda \Delta w_M.$$

In order to implement the action $a = 1$, the principal chooses w_L, w_M, w_H to solve Problem 1:

$$\text{Min } \bar{C}(P)$$

subject to:

$$\begin{aligned} 0 &\leq w_L \leq w_M. & (\text{NDW}) \\ E_P v(w_i | w_M, 1) &\geq 0 \Leftrightarrow \bar{u}(P) - p_L \lambda \Delta w_M - 1 \geq 0. & (\text{IR}) \\ E_P v(w_i | w_M, 1) &\geq E_Q v(w_i | w_M, 0) \Leftrightarrow \Delta \bar{u}(P) - \Delta p_L \lambda \Delta w_M - 1 \geq 0. & (\text{IC}) \end{aligned}$$

The first constraint restricts attention to non-decreasing wage schemes (NDW); this is motivated by the MLRP assumption. The *individual rationality constraint* (IR) requires that the agent earns at least his outside option of zero when he takes the action $a = 1$. Since the reference point is w_M , the agent only experiences a loss when he receives a wage w_L . The *incentive compatibility constraint* (IC) requires that the agent gets at least as much expected utility from taking the action $a = 1$ as he does from the action $a = 0$. Setting $\lambda = 0$ recovers the no loss aversion case.

Letting $\phi \geq 0, \gamma \geq 0, \mu \geq 0$ be the Lagrangian multipliers on the constraints, NDW, IR, and IC, respectively, the Lagrangian for the minimization problem, Problem 1, can be written as:

$$\Gamma = \bar{C}(P) + \gamma [-\bar{u}(P) + p_L \lambda \Delta w_M + 1] + \mu [-\Delta \bar{u}(P) + \Delta p_L \lambda \Delta w_M + 1] - \phi \Delta w_M. \quad (3.66)$$

Our assumptions on preferences and constraints ensure that the Kuhn–Tucker conditions are necessary and sufficient for a minimum. The Kuhn–Tucker conditions are as follows.

$$\frac{\partial \Gamma}{\partial w_H} = p_H - \gamma p_H u'_H - \mu \Delta p_H u'_H \geq 0. \quad (3.67)$$

$$\frac{\partial \Gamma}{\partial w_M} = p_M - \gamma (p_M u'_M - p_L \lambda) - \mu (\Delta p_M u'_M - \Delta p_L \lambda) - \phi \geq 0. \quad (3.68)$$

$$\frac{\partial \Gamma}{\partial w_L} = p_L - \gamma (p_L u'_L + p_L \lambda) - \mu (\Delta p_L u'_L + \Delta p_L \lambda) + \phi \geq 0. \quad (3.69)$$

$$\frac{\partial \Gamma}{\partial \gamma} \leq 0; \quad \frac{\partial \Gamma}{\partial \mu} \leq 0; \quad \frac{\partial \Gamma}{\partial \phi} \leq 0. \quad (3.70)$$

$$w_i \frac{\partial \Gamma}{\partial w_i} = 0, i = L, M, H. \quad (3.71)$$

$$\gamma \frac{\partial \Gamma}{\partial \gamma} = 0; \mu \frac{\partial \Gamma}{\partial \mu} = 0; \phi \frac{\partial \Gamma}{\partial \phi} = 0. \quad (3.72)$$

The first order conditions with respect to the state-contingent wages are given in (3.67)–(3.69). The condition (3.70) recovers the three constraints. The two complementary slackness conditions are given in (3.71) and (3.72). Given the Inada condition, $\lim_{x \rightarrow 0} u'(x) = -\infty$, it must be the case that $w_i > 0$, $i = L, M, H$, otherwise, $\frac{\partial \Gamma}{\partial w_i} < 0$, which is not possible. But if $w_i > 0$, then we get from (3.71) that $\frac{\partial \Gamma}{\partial w_i} = 0$, $i = L, M, H$.

The decision maker feels loss averse whenever $\Delta w_M > 0$. On the one hand, as in classical agency theory, $\Delta w_M > 0$ helps the principal to counter the moral hazard problem by providing higher incentives for better outcomes. However, because the agent is loss averse, this also requires a higher wage compensation to the agent in order to fulfill his IR condition. The size of this compensation is directly proportional to the loss aversion parameter, λ . Indeed, if λ is high enough, the second effect is likely to dominate the first effect, and the firm may find it optimal to set $\Delta w_M = 0$. In this case, the agent does not face any downside risk. De Meza and Webb (2007) conjecture that this case applies to CEO salary compensation that takes the form of stock options, which protect the CEO from downside risk. The next proposition formalizes this idea.

Proposition 3.36 *There exists a critical value of the parameter of loss aversion, λ_c , such that $\lambda \geq \lambda_c$ is necessary and sufficient for $\Delta w_M = w_M - w_L = 0$.*

Proof: Here we prove the if part. Suppose that $\Delta w_M = w_M - w_L = 0$, so $u'_L = u'_M$. Recall that $\frac{\partial \Gamma}{\partial w_i} = 0$, $i = L, M, H$. Thus, from (3.67) we must have

$$\frac{1}{u'_H} = \gamma + \mu \frac{\Delta p_H}{p_H}. \quad (3.73)$$

Adding (3.68), (3.69), noting that $\Delta w_M = 0$ and $u'_L = u'_M$, and dividing by $p_L + p_M$ we have

$$\frac{1}{u'_M} = \gamma - \mu \frac{\Delta p_H}{1 - p_H}. \quad (3.74)$$

First we show that in this case, $\gamma > 0$ and $\mu > 0$. Suppose not. If $\gamma = 0$, then from (3.74) we get $u'_M < 0$, which is a contradiction. If $\mu = 0$, then, from (3.73), (3.74), we have $u'_M = u'_H$. Thus, in this case $w_L = w_M = w_H$. However, if the agent is paid a fixed wage, then this destroys incentives and he will choose the minimum action, $a = 0$.⁴⁴ This contradicts the desired implementation of $a = 1$. Thus, it follows that $\gamma > 0$ and $\mu > 0$.

From (3.69), $\frac{\partial \Gamma}{\partial w_L} = 0$ implies that

$$1 + \frac{\phi}{p_L} = (u'_L + \lambda) \left(\gamma + \mu \frac{\Delta p_L}{p_L} \right). \quad (3.75)$$

⁴⁴ The IC then gives $-1 \geq 0$, which is a contradiction.

When $\phi = 0$, (3.75) implies $\lambda = \lambda_c = \left(\gamma + \mu \frac{\Delta p_L}{p_L}\right)^{-1} - u'_L$. Thus, when $\lambda = \lambda_c$ it is optimal for the principal to choose $\Delta w_M = 0$ in the absence of the NDW constraint. But for any $\phi > 0$, (3.75) implies that $\lambda > \lambda_c$ to ensure that our maintained assumption, $\Delta w_M = 0$, holds. Thus, for all $\lambda \geq \lambda_c$ we have $\phi > 0$, so $\phi \frac{\partial \Gamma}{\partial \phi} = 0$ implies $\frac{\partial \Gamma}{\partial \phi} = -\Delta w_M = 0$, or $\Delta w_M = 0$. We leave the if and only if part to the reader. ■

Corollary 3.3 $\lambda < \lambda_c$ is necessary and sufficient for $\Delta w_M = w_M - w_L > 0$.

Proof: Proposition 3.36 shows that $\lambda \geq \lambda_c \Leftrightarrow \Delta w_M = 0$. Thus, if $\lambda < \lambda_c$, then $\Delta w_M \neq 0$. But $w_M < w_L$ would violate the MLRP when used in conjunction with (3.68), (3.69). So the only possibility is $\Delta w_M > 0$. ■

Classical moral hazard theory predicts *high-powered incentives*, i.e., wage schemes that are very sensitive to the observed and verifiable outcomes. In real life, one typically observes incentives that are *low-powered*, relative to these predictions.⁴⁵ High enough loss aversion, by leading to flat segments in the optimal incentive scheme ($\Delta w_M = 0$; see Proposition 3.36) provides one potential explanation.

In Proposition 3.36, the incentive scheme is flat at the bottom of the outcome range. However, when there are more than three states of the world, then it is possible that the incentive scheme may be flat in the intermediate ranges. Consider, for instance, four possible states of the world, in which the output levels are $0 \leq y_S < y_L < y_M < y_H$. In all other respects, the model is identical to the one with three states. In this case, suppose that the principal wishes to implement the high action, $a = 1$. Then the optimal contract specifies the wage levels (w_S, w_L, w_M, w_H) . The main result is summarized in the next proposition. The proof is similar to that of Proposition 3.36, so we leave it as an exercise.

Proposition 3.37 (de Meza and Webb, 2003): *There exist critical values of the parameter of loss aversion, $\lambda_1 \geq \lambda_2 \geq 0$, such that:*

- (i) $\lambda \geq \lambda_1$ is necessary and sufficient for $w_S = w_L = w_M$.
- (ii) $\lambda_1 \geq \lambda \geq \lambda_2$ is necessary and sufficient for $w_L = w_M$ but $w_S < w_L$.
- (iii) $\lambda_1 \geq \lambda_2 \geq \lambda$ is necessary and sufficient for $w_S < w_L < w_M < w_H$.

The main insight of this analysis is that, relative to the predictions of the classical agency model, loss aversion may lead to low-powered incentive schemes. This insight helps to explain several interesting economic phenomena. Herweg and Mierendorff (2013) show that if loss aversion of consumers is high enough, then a monopolist risk-neutral seller finds it optimal to offer a two-part tariff to the consumer. This involves a fixed charge to be paid by the consumer, and a variable charge that depends on the number of units consumed. The authors argue that their framework provides the rationale for a fixed payment in situations where the competing explanations are not very persuasive.

Heidhues and Köszegi (2005, 2008) consider a model of monopolist competition in which consumers are loss averse and have a reference price. If the price is higher than the reference price, they suffer a gain–loss disutility. Thus, at prices that exceed the reference point, firms compete more aggressively in prices. The reason is that lowering prices towards the reference price contributes greatly to an increase in consumer utility by avoiding expensive loss aversion. The reference point might then serve as a *focal point* around which firms compete. Loss aversion, thus, leads to non-responsiveness of prices to changes in economic circumstances, particularly when

⁴⁵ See Chapter 8 for the empirical evidence.

the desired price exceeds the focal reference price. Interestingly, a single focal price may exist even when firms are asymmetric. Spiegel (2012) considers a simplified version of this model. See Spiegel (2011, Chapter 9) for a further discussion of optimal contracts under loss aversion.

Herweg et al. (2010) consider another implication of loss aversion. They seek to explain why most real-world incentive schemes are of a binary nature, i.e., they have a fixed wage and a bonus payment that is conditional on the observed outcome exceeding a certain threshold. They consider a principal–agent framework with moral hazard on the part of the agent. The agent has Köszegi–Rabin preferences; see Section 2.8 above. As in de Meza and Webb (2007), Herweg et al. (2010) show that loss aversion leads to lower-powered incentive schemes. However, the main insights of their paper arise from the manner in which it is optimal for the principal to bundle different signals of the agent’s effort level, when providing a bonus. While it is not possible to give an exposition of their model without a fuller specification of the details, we consider below a simple example of the sorts of issues that can arise; the interested reader should pursue the much richer model in Herweg et al. (2010).

Suppose that the observable and verifiable output levels are $0 \leq y_1 \leq y_2 \leq \dots \leq y_n$. The principal is interested in eliciting a particular effort level from the agent that gives rise to a probability distribution P over outcomes. So the outcomes $y_1, y_2, \dots, y_n$ occur with the respective probabilities $p_1, p_2, \dots, p_n$. In order to explain the intuition behind the results, let us restrict attention to the case of increasing wage schemes, so $0 \leq w_1 \leq w_2 \leq \dots \leq w_n$. Assume also that the material utility is given by $m(x) = x$ and gain–loss utility, μ , is linear and is operative only for losses as in (2.77). Suppose that the realized state is i , with the associated wage w_i . Then, the Köszegi–Rabin utility of the agent (see Section 2.8) is

$$u(w_i | r) = w_i - \sum_{j=i+1}^n p_j \lambda (w_j - w_i).$$

Thus, given $m(x) = x$ and (2.77), the expected Köszegi–Rabin utility of the agent, prior to the realization of the state of the world is

$$Eu = \sum_{j=1}^n p_j u(w_j | r) = \sum_{j=1}^n p_j w_j - \lambda \sum_{i=1}^{n-1} p_i \sum_{j=i+1}^n p_j (w_j - w_i). \quad (3.76)$$

We now consider a sequence of hypothetical incentive schemes to illustrate the intuition behind the results. Suppose that we begin with an initial fixed wage contract, $w_j = w, j = 1, 2, \dots, n$; we call this the *baseline contract*. In the baseline contract, there is no gain–loss utility, so the Köszegi–Rabin utility, in (3.76), denoted by Eu_0 , is

$$Eu_0 = w.$$

The baseline contract illustrates the classic conflict between insurance and incentives. By putting zero risk on the agent, the contract eliminates incentives completely, so a self-regarding agent will put in the least amount of effort. In other words, this contract is not incentive compatible. Starting from the baseline contract, consider a $n - 1$ *perturbed contract* that offers the following incentive structure

$$w_1 = w \text{ and } w_j = w + b, j = 2, 3, \dots, n,$$

where $b > 0$ is a credible bonus payment. Recall that the distribution function of outcomes for the desired effort level is P . The expected Köszegi–Rabin utility, in (3.76), for the $n - 1$ *perturbed contract*, Eu_1 , can be written as

$$Eu_1 = w + b(1 - P_1)(1 - \lambda P_1),$$

where $P_1 = \text{Prob}(y \leq y_1)$. Now consider a $n - 2$ perturbed contract

$$w_1 = w_2 = w \text{ and } w_j = w + b, j = 3, 4, \dots, n.$$

The expected Köszegi–Rabin utility, (3.76), for this incentive scheme, Eu_2 , can be written as

$$Eu_2 = w + b(1 - P_2)(1 - \lambda P_2),$$

where $P_1 = \text{Prob}(y \leq y_2)$. These calculations reveal the pattern of recursion. In general, for any $n - k$ perturbed contract

$$w_1 = w_2 = \dots = w_k = w \text{ and } w_{k+1} = w_{k+2} = \dots = w_n = w + b,$$

we have that the expected Köszegi–Rabin utility is

$$Eu_k = w + b(1 - P_k)(1 - \lambda P_k), \quad (3.77)$$

where $P_k = \text{Prob}(y \leq y_k)$.

In the absence of loss aversion ($\lambda = 0$), bonus payments always increase the expected utility of the agent, hence, they serve to loosen the individual rationality constraint of the agent. The exact bonus payment may be calculated in such a manner that the individual rationality constraint always holds. Now consider the presence of loss aversion ($\lambda > 1$). If loss aversion is low enough, in the sense that $\lambda < \frac{1}{P_k}$ for all $1 < k \leq n$, then using (3.77), bonuses for performance that exceeds some threshold always improve expected utility.

The more interesting situation arises when $\frac{1}{P_{k+1}} < \lambda < \frac{1}{P_k}$. In this case, offering bonuses for equalling or exceeding the output threshold of y_{k+1} (a $n - (k + 1)$ perturbed contract) reduces the expected utility of the agent. This result is contrary to that obtained in the standard model. Thus, once this threshold is reached, the principal will have to increase the fixed wage, w , of the agent to implement the desired effort. On the other hand if the performance threshold is chosen to be below y_{k+1} , say at y_k then bonuses for performance that exceeds y_k increase the expected utility of the agent. Such an incentive scheme loosens the individual rationality constraint and makes implementation of the desired effort easier. On the other hand if k is very high, then $1 - P_k$ is very low, which reduces the marginal impact on the agent's utility from an increase in the bonus payment. For a characterization of the optimal contract under these sorts of considerations, see Herweg et al. (2010).

3.12 Renegotiation, long-term contracts, and loss aversion

In the traditional theory of the firm, once the state of the world is realized, parties that are bound by some initial contract use Coasian bargaining to renegotiate to an efficient outcome. Suppose that the terms of the initial contract serve to form a reference point for loss averse contracting parties, as in Hart and Moore (2008). However, parties write a contract with each other before the realization of state of nature. Once the state of nature is realized, the contracting parties can renegotiate the ex-ante reference contract to an efficient ex-post contract.

Figure 3.12 Sequence of moves in a bilateral trade model with renegotiation.

Source: Herweg, F. and Schmidt, K. M., "Loss aversion and inefficient renegotiation," *Review of Economic Studies* (2015) 82(1): 297–332, by permission of Oxford University Press.

An ex-post change in the terms of the contract through renegotiation may improve the payoff of one of the parties, but reduce the payoff of the other party. If the harmed party is loss averse, the extent of the harm is magnified. The party that benefits may be able to compensate the harm caused to the other party, but might not be able to compensate the scaled-up harm that arises on account of loss aversion. In this case, ex-post renegotiation may successfully alter the original contract only partly towards the efficient outcome.

Furthermore, this might lead to sticky ex-post renegotiation; such renegotiation may take place only for a restricted range of states of nature, while for all other states, it completely breaks down. Anticipating these ex-post problems, the parties may not wish to write long-term contracts, preferring instead to use the spot market, particularly if the spot market is fairly competitive. We consider below these issues in a model due to Herweg and Schmidt (2013).

Consider a buyer (B) and a seller (S) who agree at date 0 on two contractual features of one unit of a good/widget that they might trade in the future. These features are: a specification $x \in X$ of the good and a price $p \in P$, where X is a compact, possibly multidimensional, space and P is some non-negative closed real interval.

The sequence of moves is shown in Figure 3.12. At date 0, the two parties sign a contract $(\bar{x}, \bar{p})$. At date 1, a state of the world, $\theta \in \Theta$ is realized. This state determines which specification $x \in X$ of the traded good is most appropriate. At date 0, the two parties know that θ is distributed with the distribution function $F(\theta)$. They also know that ex-post, the state of the world is not verifiable to a third party, so they cannot write state-contingent contracts at date 0. Having observed the state at date 1, the parties can renegotiate to another feasible contract, $(\hat{x}, \hat{p})$, at date 2. If they fail to renegotiate, the default contract, $(\bar{x}, \bar{p})$ is implemented. The valuation of the buyer and the cost of the seller are, respectively, $v(x, \theta)$ and $c(x, \theta)$. Their respective payoffs are $v(x, \theta) - p$ and $p - c(x, \theta)$, which are realized at date 3.

Define the joint surplus of the two parties as

$$W(x, \theta) = v(x, \theta) - c(x, \theta), x \in X, \theta \in \Theta.$$

We assume that $W(x, \theta)$ is strictly concave, so the first order conditions are sufficient. In any given state $\theta \in \Theta$, denote the socially optimum specification found by maximizing W with respect to $x \in X$ by $x^*(\theta)$. This is given by the solution to the following equation.

$$\frac{\partial W}{\partial x} = \frac{\partial v(x^*(\theta), \theta)}{\partial x} - \frac{\partial c(x^*(\theta), \theta)}{\partial x} = 0. \quad (3.78)$$

Both parties have Köszegi–Rabin utilities. Define gain–loss utility by

$$\mu(z) = \begin{cases} 0 & \text{if } z > 0 \\ \lambda z & \text{if } z \leq 0 \end{cases}, \quad (3.79)$$

then the Kőszegi–Rabin utilities of the buyer and the seller from the contract $(\hat{x}, \hat{p})$, conditional on the state of the world $\theta \in \Theta$ are given, respectively, by

$$U_B(\hat{x}, \hat{p}; \theta) = v(\hat{x}, \theta) - \hat{p} + \mu(\bar{p} - \hat{p}) + \mu(v(\hat{x}, \theta) - v(\bar{x}, \theta)). \quad (3.80)$$

$$U_S(\hat{x}, \hat{p}; \theta) = \hat{p} - c(\hat{x}, \theta) + \mu(\hat{p} - \bar{p}) + \mu(c(\bar{x}, \theta) - c(\hat{x}, \theta)). \quad (3.81)$$

The original contract $(\bar{x}, \bar{p})$ establishes the relevant entitlements that determine the subsequent gains and losses of the two parties. We assume a common or universal gain–loss function, so that the form of μ is identical for each party and in each dimension (price, valuation, or cost). Moreover, we assume that gain–loss utility from price variation and value/cost variation is additively separable. The buyer feels a loss if the renegotiated price is higher than the date 0 price and the seller suffers a loss if it is lower. The buyer suffers a loss if the value of the renegotiated specification is lower than the date 0 specification and the seller suffers a loss if the cost of this specification is higher.

Clearly, if the original contract is not renegotiated, then there is no gain–loss utility, so

$$U_B(\bar{x}, \bar{p}; \theta) = v(\bar{x}, \theta) - \bar{p} \text{ and } U_S(\bar{x}, \bar{p}; \theta) = \bar{p} - c(\bar{x}, \theta). \quad (3.82)$$

Using (3.80)–(3.82) the buyer and the seller would wish to renegotiate if

$$B : v(\hat{x}, \theta) - v(\bar{x}, \theta) + \mu(v(\hat{x}, \theta) - v(\bar{x}, \theta)) \geq \hat{p} - \bar{p} - \mu(\bar{p} - \hat{p}). \quad (3.83)$$

$$S : c(\bar{x}, \theta) - c(\hat{x}, \theta) + \mu(c(\bar{x}, \theta) - c(\hat{x}, \theta)) \geq \bar{p} - \hat{p} - \mu(\hat{p} - \bar{p}). \quad (3.84)$$

Conditional on any initial contract, $(\bar{x}, \bar{p})$, the set of contracts $(\hat{x}, \hat{p})$ that satisfies (3.83), (3.84) is said to be *individually rational*. For a given initial contract, $(\bar{x}, \bar{p})$, let the set of all individually rational contracts be denoted by $I(\bar{x}, \bar{p})$. The *renegotiation set*, R , is simply the set of specifications of the good that the parties wish to voluntarily renegotiate to at some mutually agreed price, i.e.,

$$R(\bar{x}, \bar{p}) = \{\hat{x} \in X : \exists \hat{p} \in P \text{ and } (\hat{x}, \hat{p}) \in I(\bar{x}, \bar{p})\}.$$

The next proposition summarizes the renegotiation possibilities.

Proposition 3.38 Consider an initial contract $(\bar{x}, \bar{p})$ at date 0, and the realization of a state $\theta \in \Theta$ at date 1. Then the renegotiation set $R(\bar{x}, \bar{p})$ at date 2 is characterized as follows:

- (i) For some $\hat{x} \in X$, if $v(\bar{x}, \theta) \leq v(\hat{x}, \theta)$ and $c(\bar{x}, \theta) \geq c(\hat{x}, \theta)$, then $\hat{x} \in R(\bar{x}, \bar{p})$.
- (ii) For some $\hat{x} \in X$, if $v(\bar{x}, \theta) \leq v(\hat{x}, \theta)$ and $c(\bar{x}, \theta) \leq c(\hat{x}, \theta)$, then $\hat{x} \in R(\bar{x}, \bar{p})$ if and only if

$$v(\hat{x}, \theta) - v(\bar{x}, \theta) \geq (1 + \lambda)^2 [c(\hat{x}, \theta) - c(\bar{x}, \theta)]. \quad (3.85)$$

- (iii) For some $\hat{x} \in X$, if $v(\bar{x}, \theta) \geq v(\hat{x}, \theta)$ and $c(\bar{x}, \theta) \geq c(\hat{x}, \theta)$, then $\hat{x} \in R(\bar{x}, \bar{p})$ if and only if

$$c(\bar{x}, \theta) - c(\hat{x}, \theta) \geq (1 + \lambda)^2 [v(\bar{x}, \theta) - v(\hat{x}, \theta)]. \quad (3.86)$$

Proof: (i) If there is a specification such that at date 2, the valuation of the buyer is higher and the cost of the seller is lower, then each party benefits by agreeing to renegotiate to this specification even if they kept the initial price $\bar{p}$, unchanged.

(ii) Since renegotiation is voluntary, the buyer will have to offer $\hat{p} \geq \bar{p}$ in order to cover the higher costs of the seller. Thus, the buyer suffers a loss in the price domain and a gain in the valuation domain. The seller suffers a loss in the cost domain and a gain in the price domain. From (3.83), (3.84) we get that

$$v(\hat{x}, \theta) - v(\bar{x}, \theta) \geq (1 + \lambda)(\hat{p} - \bar{p}) \Leftrightarrow \hat{p} \leq \bar{p} + \frac{v(\hat{x}, \theta) - v(\bar{x}, \theta)}{1 + \lambda}. \quad (3.87)$$

$$(1 + \lambda)(c(\bar{x}, \theta) - c(\hat{x}, \theta)) \geq \bar{p} - \hat{p} \Leftrightarrow \hat{p} \geq \bar{p} - (1 + \lambda)(c(\bar{x}, \theta) - c(\hat{x}, \theta)). \quad (3.88)$$

Hence, we get

$$\bar{p} - (1 + \lambda)(c(\bar{x}, \theta) - c(\hat{x}, \theta)) \leq \bar{p} + \frac{v(\hat{x}, \theta) - v(\bar{x}, \theta)}{1 + \lambda}. \quad (3.89)$$

Simplifying (3.88), we get (3.85), as claimed. Thus, $\hat{x} \in R(\bar{x}, \bar{p})$ for any $\hat{x}$ satisfying (3.85).

(iii) In this case, the seller must offer a price reduction to the buyer in order to induce him to voluntarily renegotiate. Thus, the buyer faces a loss in the value dimension and the seller faces a loss in the price dimension. Using (3.83), (3.84) and proceeding as in the proof of part (ii), an easy calculation gives rise to the claimed result. ■

Proposition 3.38 illustrates at least two ideas:

1. In the absence of loss aversion ($\lambda = 0$) each of the renegotiation conditions (3.85) and (3.86) is easier to satisfy. Consider, for instance, (3.85). It might be the case that $v(\hat{x}, \theta) - v(\bar{x}, \theta) \geq c(\hat{x}, \theta) - c(\bar{x}, \theta)$ but $v(\hat{x}, \theta) - v(\bar{x}, \theta) < (1 + \lambda)^2 [c(\hat{x}, \theta) - c(\bar{x}, \theta)]$. Hence, the presence of loss aversion may create stickiness in renegotiation.
2. The results in Proposition 3.38 are independent of prices. This is because the utilities are quasilinear in prices and specifications.

Next, we need to specify how the two parties bargain at date 2. Herweg and Schmidt (2013) assume that the two parties bargain by using generalized Nash bargaining.⁴⁶ For expositional ease, we consider instead the two polar extremes in which either the buyer or the seller have all the bargaining power. In what follows, we consider the case where the buyer has all the bargaining power (as an exercise, the reader can work through the case where the seller has all the bargaining power).

To make further progress, let us consider the following example.

$$v(x, \theta) = \theta x, \quad c(x, \theta) = \frac{1}{2}x^2 + \frac{1}{3}\theta. \quad (3.90)$$

Using (3.78), we get the unique socially optimal (or first best) state-contingent solution

$$x^*(\theta) = \theta. \quad (3.91)$$

⁴⁶ For various bargaining solutions, and the empirical evidence, see Part 4 of the book.

Suppose that the two parties have agreed to a contract $(\bar{x}, \bar{p})$ at date 0. For simplicity, let us normalize $\bar{x} = 1$. Define $\bar{\theta}$ such that

$$\frac{\partial v(1, \bar{\theta})}{\partial x} = \frac{\partial c(1, \bar{\theta})}{\partial x},$$

so, using (3.91), $\bar{\theta} = 1$.

Suppose that at date 1, the realized state of the world is $\theta_H > 1$. How should the two parties renegotiate at date 2? There are two possibilities.

I. For any $\hat{x} > 1$, $v(1, \theta_H) < v(\hat{x}, \theta_H)$ and $c(1, \theta_H) < c(\hat{x}, \theta_H)$. The buyer experiences an increase in value and the seller experiences an increase in cost. This is the case described in Proposition 3.38(ii), hence, $\hat{x} \in R(1, \bar{p})$ if and only if (3.85) holds. Using (3.90), we can write (3.85) as

$$\theta_H(\hat{x} - 1) \geq (1 + \lambda)^2 \frac{1}{2} (\hat{x}^2 - 1) \Leftrightarrow \lambda \leq \sqrt{\frac{2\theta_H}{(\hat{x} + 1)}} - 1. \quad (3.92)$$

In the absence of loss aversion ($\lambda = 0$), the condition in (3.92) is more likely to be satisfied. However, if loss aversion is high enough, then no renegotiation can take place. Using (3.92), $\hat{x} \in R(\bar{x}, \bar{p})$ if

$$\theta_H \geq \frac{(1 + \lambda)^2}{2} (\hat{x} + 1). \quad (3.93)$$

Thus, when, say, $\lambda = 1$, θ_H must exceed the critical value of 4 before any renegotiation can occur. So, we have that at date 3, $x = \bar{x} = 1$ for $1 \leq \theta \leq 4$. However, for any θ in this range, the socially efficient outcome is $x^*(\theta) = \theta$. Thus, loss aversion leads to rigidity in contract renegotiation, in the sense that there is a set of states for which it is socially optimal to renegotiate but privately suboptimal.

Since the buyer is assumed to have all the bargaining power, he ensures that the individual rationality constraint of the seller in (3.88) holds with equality. Thus,

$$\hat{p}(\hat{x}) = \bar{p} + (1 + \lambda) \frac{1}{2} (\hat{x}^2 - 1). \quad (3.94)$$

II. For any $\hat{x} < 1$ we have $v(1, \theta_H) > v(\hat{x}, \theta_H)$ and $c(1, \theta_H) > c(\hat{x}, \theta_H)$. The buyer's value falls and the seller's cost also falls, so this is the case in Proposition 3.38(iii), hence, $\hat{x} \in R(1, \bar{p})$ if and only if (3.86) holds. Using (3.90), we can write (3.86) as

$$\frac{1}{2} (1 - \hat{x}^2) \geq (1 + \lambda)^2 \theta_H (1 - \hat{x}) \Leftrightarrow \lambda \leq \sqrt{\frac{(1 + \hat{x})}{2\theta_H}} - 1. \quad (3.95)$$

Since λ is non-negative, $\hat{x} < 1$ and $\theta_H > 1$, so (3.95) cannot hold. Thus, following a realization of any state $\theta_H > \bar{\theta} = 1$, the two contracting parties never reduce the specification of the good that they trade. The only relevant case, therefore, is Case I.

Substitute $\hat{p}(\hat{x})$ from (3.94) into (3.80) and use the assumed functional forms in (3.90) to get

$$U_B(\hat{x}, \hat{p}(\hat{x}); \theta_H) = \theta_H \hat{x} - \hat{p}(\hat{x}) - \lambda (\hat{p}(\hat{x}) - \bar{p}); 1 < \theta_H \in \Theta. \quad (3.96)$$

The buyer experiences a loss in the price dimension (last term in (3.96)) and a gain in the value dimension, but given (3.79), the gain is set to zero. Since the buyer has all the bargaining power, the ex-post solution $\hat{x} = \hat{x}^*$ maximizes $U_B(\hat{x}, \hat{p}(\hat{x}); \theta_H)$.

$$\frac{\partial U_B(\hat{x}, \hat{p}(\hat{x}); \theta_H)}{\partial \hat{x}} = \theta_H - (1 + \lambda)^2 \hat{x}.$$

It is immediate that U_B is strictly concave and the first order condition is sufficient. Thus,

$$\hat{x}^* = \frac{\theta_H}{(1 + \lambda)^2}. \quad (3.97)$$

There are two noteworthy features of the renegotiated solution under loss aversion. First, the socially optimal solution requires $x^*(\theta) = \theta$. But when renegotiation takes place, we have $\hat{x}^* < x^*$, i.e., the specification is lower than the socially optimal specification. Second, the socially optimal solution requires a one for one adjustment of the specification to θ (because $x^*(\theta) = \theta$), while the renegotiated solution in (3.97) exhibits a less than one for one adjustment to θ . Coupled with the fact that renegotiation takes place for only some values of θ (see (3.93)) it follows that in the presence of loss aversion, renegotiation is inefficient and sluggish.

Substituting $\hat{x}^*$ in (3.94) gives the optimal solution for the renegotiated price, $\hat{p}^* = \hat{p}(\hat{x}^*)$. Thus, the utility of the buyer from the long-term contract in any state of the world, $\theta_H > 1$, is given by $U_B(\hat{x}^*, \hat{p}^*; \theta_H)$. One can proceed analogously to find the utility of the buyer from a long-term contract for any $\theta_L < 1$. Integrating over all states $\theta \in \Theta$ gives the expected utility of the buyer from a long-term contract, U_B^{LT} .

The other possibility is that the parties may not sign a long-term contract, but following the realization of θ at date 1, choose to trade on the spot market. Should the buyer prefer spot markets? The answer depends on three factors.

1. The degree of competition in the spot market: the greater the competition, the lower is the spot price, so the higher is the utility of the buyer.
2. Reference point of the buyer in the spot market: In a long-term contract, the initial contract serves as an entitlement. However, adjustment to the realized state is easier in a spot contract because there is no initial contract. In a simple class of models this may be mathematically similar to having a lower value of loss aversion in spot market contracts (see Herweg and Schmidt, 2013).
3. The degree of loss aversion in long-term contracts. The greater the loss aversion, the higher is the inefficiency and sluggishness of renegotiation in long-term contracts, which reduces their attractiveness.

We refer the reader to Herweg and Schmidt (2013) for a more detailed analysis of these factors.⁴⁷

⁴⁷ The interested reader can also consult Herweg et al. (2014) for an application of the UPE concept to the incomplete contracts problem.

CHAPTER 4

Human Behavior under Ambiguity

4.1 Introduction

Ambiguity arises when individual choices depend on the *source* of the uncertain information, but within each source, the individual possesses reasonable subjective probabilities (non-negative probabilities that add to one). This is sometimes also referred to as *source-dependent uncertainty*. Ambiguity is a major topic, and deserves a book length treatment in its own right. However, the discussion in this chapter is relatively brief.¹ The reason is that the approach of most of the modern literature on ambiguity does not appear behavioral enough. A troubling feature of several of these models is that under pure risk they simply reduce to expected utility theory, which is not supported by the evidence.

For this reason, we have split this chapter into two parts. Section 4.3 outlines *neoclassical models of ambiguity*, and Section 4.4 considers *behavioral models of ambiguity*. There is, by no means, a neat or established separation between the two sets of models. However, the main difference is that all the models in Section 4.4 do not reduce to EU under pure risk, while many of the models in Section 4.3 do.² In order to maintain brevity of discussion, we focus almost exclusively on the *Ellsberg paradox* and consider its resolution in the different models.

In Section 4.2, we consider the classic Ellsberg paradox that illustrates the phenomenon of ambiguity in lab experiments. Suppose that one urn, the *known urn*, is known to have 50 red and 50 black balls. Another urn, the *unknown urn*, has 100 balls of only two colors, red and black, but their exact composition is unknown. As a first pass, one may appeal to the *principle of insufficient reason* to argue that the prior probability of a red and a black ball from the unknown urn is 0.5 each. Indeed, when individuals are asked to bet *separately* on the two urns, the evidence suggests that they assign equal probabilities to drawing either a red or a black ball from either urn. This is the sense in which they have reasonable subjective beliefs about each urn. However, individuals are unwilling to exchange a bet on any color on the known urn with the same bet on the unknown urn. This is the sense in which the subjective beliefs across the two urns are not reasonable. The decision maker is then said to have a preference for avoiding ambiguity (or source-dependent

¹ The reader can also consult chapter 17 in Gilboa (2009), chapter 11 in Wakker (2010), Etner et al. (2012), and Machina and Siniscalchi (2014) for more details.

² This is not true of several models. For instance, Choquet expected utility (CEU) that is considered in Section 4.3 does not reduce to EU for the case of risk.

uncertainty) associated with the unknown urn.³ Thus, SEU cannot be applied because no consistent subjective probabilities exist. The Ellsberg paradox is also a violation of *probabilistic sophistication* (Definition 1.13).

Section 4.3 gives a brief discussion of the neoclassical models of ambiguity and outlines their explanation for the Ellsberg paradox. Section 4.3.1 discusses *non-additive probability measures* (or *capacities* or *Choquet capacities*). Choquet capacities are different from probabilities in that they need not be additive.⁴ This framework gives rise to *Choquet expected utility* (CEU) and is able to explain the Ellsberg paradox.

Section 4.3.2 describes the *multiple priors model*. In this class of models, decision makers have probability distributions over their prior beliefs that reflect their uncertainty about the true model of the world (Gilboa and Schmeidler, 1989). We describe the *maximin model* and its two main axioms. The maximin model has a pessimistic attitude to uncertainty. Among the set of minimum outcomes achieved through all actions, the decision makers choose the action with the maximum outcome. None of the axioms used in deriving such a preference representation gives any explicit clue about this extreme degree of pessimism. We also describe another popular multiple priors model, the α -MEU model (Hurwicz, 1951; Ghirardato et al., 2004).⁵ This class of models can also explain the Ellsberg paradox.

Section 4.3.3 considers the *failure of the reduction of compound lotteries axiom* as an explanation of the Ellsberg paradox in a *two-stage recursive model* (Segal, 1987, 1990). Section 4.3.4 considers the *smooth ambiguity aversion model* (Klibanoff et al., 2005). Unlike some models of multiple priors, such as the *maximin model*, the objective function here is differentiable. The two-stage recursive models and the smooth ambiguity aversion models are both multiple priors models. However, the main difference between the two is that the smooth ambiguity aversion model uses a different utility function at each stage. Ambiguity is captured by the concavity of the second stage utility function and the burden of explaining risk and ambiguity attitudes in this model lies with the utility function.

Section 4.3.5 gives a brief account of other models that can account for the Ellsberg paradox. Section 4.3.6 shows that the empirical evidence for neoclassical models of ambiguity aversion is mixed (Hey et al., 2010; Conte and Hey, 2013). No single model can account for all the experimental results. What causes ambiguity aversion? Some experimental evidence suggests that *fear of negative evaluation by others* and one's competence in the problem could be important explanations (Curley et al., 1986; Trautmann et al. 2008).

Section 4.4 considers the small literature on behavioral models of ambiguity. None of these models reduce to EU under pure risk. In Section 4.4.1, we consider promising work that was conducted in the 1990s on *support theory* but was ignored by the subsequent literature in economics. This work is associated most with the names of Amos Tversky and his collaborators. In *support theory*, the support for one hypothesis over another depends on how the two hypotheses are framed and how events are subdivided. For instance, the probability that one assigns to death by homicide in an area might be lower than the sum of probabilities that one assigns to homicide by friends and homicide by strangers, although classically the two answers should be identical. Splitting the event into its components, brings more such instances to mind (as in the

³ It is possible to define ambiguity generally as a preference for information from one source relative to another; see Definition 11.1.1 in Wakker (2010).

⁴ Lack of additivity means that for two disjoint events, E_i, E_j , in some well-defined sample space, the subjective probability $\mu(E_i \cup E_j)$ need not equal $\mu(E_i) + \mu(E_j)$.

⁵ Luce and Raiffa (1957) already discuss multiple priors (maximin EU) and the α -maximin model (see their Ch. 13 on ambiguity, with §13.5 pp. 304–5). I am grateful to Peter Wakker for pointing this out.

availability heuristic), hence, increasing its perceived probability. In support theory, in the first stage, individuals form beliefs about events by using such considerations. Once these beliefs are formed, then one evaluates the uncertain situation using PT.

Section 4.4.2 considers the possibility that decision makers perceive information from different *sources* of uncertainty in a fundamentally different manner (Abdellaoui, Baillon et al., 2011). Applied to the Ellsberg paradox, in this view, each urn is a different source of uncertainty. This accounts for the unwillingness of decision makers to exchange bets on the known urn (first source) with bets on the unknown urn (second source). Empirical results presented by the authors confirm this view, although they also reveal a rich diversity in the attitudes of individuals to uncertainty. In particular, the differences in the two Ellsberg urns cannot be ascribed to differences in the utility functions but rather to the elicited probability weighting functions (or source functions) across them. In an important study that applies these concepts, PT outperforms all others in a 11-way horse race (Kothiyal et al., 2014). This strengthens the case for PT to apply to risk, uncertainty, and ambiguity, which is a central theme that runs through Wakker (2010).

The explanation of ambiguity in these behavioral models is different from neoclassical models, such as the smooth ambiguity aversion model. The neoclassical models locate the source of ambiguity aversion in the shape of the utility function. This is analogous to the feature of EU under risk and uncertainty, which places the entire burden of risk attitudes on the shape of the utility function; a finding that is rejected by the evidence. On the other hand, non-EU theories such RDU and PT rely jointly on the shapes of the utility function and the probability weighting function in capturing attitudes to risk; a finding that is consistent with the evidence.

4.2 A problem for SEU: The Ellsberg paradox

Under uncertainty, there is no problem in applying EU, RDU, or PT (see Sections 1.3, 2.3.2, and 2.4) provided that decision makers have well-defined subjective probabilities. However, evidence suggests that this assumption might not always hold. The most famous example of this is the Ellsberg (1961) paradox. We present two variants of the Ellsberg paradox below; the two-colors and the three-colors experiment.

Example 4.27 (*Two-colors experiment*): Consider the simplest demonstration of the Ellsberg paradox, the two-colors experiment. Urn 1 has 50 red and 50 black balls, while Urn 2 contains 100 balls that are an unknown mixture of red and black balls.

- (1) Suppose that subjects are asked to bet on a color (a red or a black ball) for each urn and they receive a monetary prize, z , if a ball of their chosen color is drawn. Subjects reveal, through their choices, that they are indifferent among the two colors for each urn.⁶ Thus, they appear to assign equal probabilities to the two colors in both urns.
- (2) Now suppose that subjects, in addition, are also asked which urn they would like to bet on. Irrespective of their chosen color, they typically choose Urn 1 over Urn 2. Let p_r and p_b represent the subjective probabilities of a red and a black ball, respectively, in Urn 2 such that $p_r + p_b = 1$. Then, the indifference in (1) implies that $p_r = 0.5$. However, if the chosen color is red, the preference for Urn 1 implies that $0.5u(z) > p_ru(z) \Leftrightarrow p_r < 0.5$. Analogously if the chosen color is black, the stated

⁶ The original Ellsberg experiments were not incentivized and are thought experiments. However, once these potential drawbacks are addressed by modern experimental methods (see below) the results still survive.

Table 4.1 Description of the four Savage acts in the three-colors experiment.

	r	b	y
f_1	100	0	0
f_2	0	100	0
f_3	100	0	100
f_4	0	100	100

preference implies $0.5u(z) > p_b u(z) \Leftrightarrow p_b < 0.5$. This contradicts $p_r = p_b = 0.5$ from (1). Hence, the subjects do not hold reasonable subjective beliefs.⁷ Furthermore, this violates probabilistic sophistication (see Definition 1.13).

Example 4.28 (Three-colors experiment) In the three-colors experiment, subjects are told that an urn contains 90 balls of 3 different colors: red, black, and yellow. There are 30 red balls and the remaining balls are either black or yellow. One ball is drawn at random from the urn. Let r, b, y be the events: red ball, black ball, and yellow ball. The minimum “reasonableness” that we might expect from subjective beliefs is that they should satisfy an additive probability measure, q , such that

$$q(r) = \frac{1}{3}, q(b) = 1 - p - \frac{1}{3}; q(y) = p; p \in [0, 2/3]. \quad (4.1)$$

The decision maker is offered a choice between the following two pairs of lotteries or Savage acts (see Section 1.3).

$$f_1 = (r, 100; b, 0; y, 0), f_2 = (r, 0; b, 100; y, 0), \quad (4.2)$$

$$f_3 = (r, 100; b, 0; y, 100), f_4 = (r, 0; b, 100; y, 100). \quad (4.3)$$

Thus, for instance, the Savage act f_2 is the lottery that pays \$100 if a black ball turns up but \$0 if any other color comes up. Analogously, the Savage act f_4 is the lottery that pays \$100 if either a black or a yellow ball is drawn and \$0 if a red ball comes up. This information is summarized in Table 4.1.

Subjects in experiments, typically express the preferences $f_1 \succ f_2$ and $f_4 \succ f_3$. Assuming SEU preferences (see Section 1.3), these preferences imply the following inequalities.

$$f_1 \succ f_2 \Leftrightarrow \frac{1}{3}u(100) > \left(1 - p - \frac{1}{3}\right)u(100) \Leftrightarrow p > \frac{1}{3}. \quad (4.4)$$

$$f_4 \succ f_3 \Leftrightarrow \frac{1}{3}u(100) + pu(100) < \left(1 - p - \frac{1}{3}\right)u(100) + pu(100) \Leftrightarrow p < \frac{1}{3}. \quad (4.5)$$

From (4.4) and (4.5), the decision maker does not assign consistent subjective probabilities. This is illustration of the Ellsberg paradox.

⁷ This problem was also discussed by Keynes (1921).

The examples suggest the following observations.

1. The preferences $f_1 \succ f_2$ and $f_4 \succ f_3$ suggest that the decision maker tries to search for greater certainty in the probability of the outcome. For instance, the preference $f_1 \succ f_2$ may suggest that the decision maker wishes to avoid the possibility that the probability of the black ball is very small or zero. Similarly, in the preference $f_4 \succ f_3$, the decision maker knows that the probability of getting a prize of 100 under f_4 is $2/3$, while under f_3 it might just be $1/3$. This is the sense in which the individual is *ambiguity averse*.
2. From Table 4.1, the outcomes under the two Savage acts f_1, f_2 are identical if a yellow ball comes up but $f_1 \succ f_2$. Similarly, the outcomes under the two Savage acts f_3, f_4 are identical if a yellow ball comes up. If Savage's *sure thing principle* (see Definition 1.11) is applied we should observe $f_3 \succ f_4$. However, we observe $f_4 \succ f_3$. Hence, the Ellsberg paradox is essentially a violation of the sure thing principle. For this reason, explanations of the Ellsberg paradox have typically tried to relax this principle.
3. The Ellsberg paradox violates probabilistic sophistication (Definition 1.13). For instance, in the two-colors experiment in Example 4.27 above, for each urn, separately, $p_r = 0.5$ but when the two urns are compared, the decision maker does not behave as if $p_r = 0.5$. It is as if the probabilities depend on the act itself.⁸ Suppose that an individual bets on the color red when presented with each urn separately. Let x_i denote the event that the a ball of color $x = \text{Red, Black}$ is drawn from urn $i = 1, 2$. Then for each urn, the expressed preference is $(\text{Red}1, z; \text{Black}1, 0) \sim (z, 0.5, 0, 0.5)$ and $(\text{Red}2, z; \text{Black}2, 0) \sim (z, 0.5, 0, 0.5)$, where $\sim$ is the indifference relation, so probabilistic sophistication holds for each urn separately. But $(\text{Red}1, z; \text{Black}1, 0) \succ (\text{Red}2, z; \text{Black}2, 0)$, so $(z, 0.5, 0, 0.5) \succ (z, 0.5, 0, 0.5)$, where $\succ$ is the strict preference relation; this is a contradiction of probabilistic sophistication.

We now consider alternative explanations of the Ellsberg paradox within two classes of models. The neoclassical approach and the behavioral approach.

4.3 Neoclassical models of ambiguity

In this section, we consider models of ambiguity that are based on the neoclassical tradition. There is no clear dividing line between models in the neoclassical and the behavioral traditions, so any such division is necessarily arbitrary. However, in the presence of pure risk, many of the models in this section collapse to expected utility, but clearly some such as Choquet expected utility do not. Given the refutations of EU (see Chapter 1), this is clearly a troublesome feature of many of these models (Wakker, 2010); and some may argue, a direct refutation of these models. By contrast, the behavioral models of ambiguity (see Section 4.4) do not typically reduce to EU under risk. Furthermore, the main difference between the neoclassical and the behavioral models of ambiguity is that, in the behavioral models, ambiguity is *source-dependent*.

The following two comments on this class of models illustrate the reservations that many behavioral economists have with the neoclassical approach to ambiguity, despite its immense popularity and widespread acceptance. Hey (2014, p. 838) writes: "We remain agnostic as to whether these can be really considered as models of ambiguity." Kothiyal et al. (2014, p. 3) write: "Since 1990, quantitative ambiguity models have become available (Gilboa 1987;

⁸ Probabilistic sophistication was originally introduced by Machina and Schmeidler (1992). For subsequent developments, see Grant (1995) and Chew and Sagi (2006). See also the exposition in Wakker (2010).

Gilboa & Schmeidler 1989; Schmeidler 1989), and many extensions have been proposed . . . These models were all normatively motivated . . . assuming expected utility for risk, backward induction in an Anscombe-Aumann (1963) model, and (with α -maximin excepted) universal ambiguity aversion. These assumptions, even if accepted normatively, fail descriptively.” For this reason, we provide a relatively brief treatment of these models, focusing mainly on their approach to the Ellsberg paradox.

4.3.1 Choquet expected utility

One resolution to the Ellsberg paradox is to employ non-additive probability measures. Consider a sample space, S and a sigma algebra Σ of the subsets of S .

Definition 4.64 A sigma algebra Σ corresponding to a sample space S is a set of subsets of S such that the following hold. (i) The empty set $\emptyset \in \Sigma$. (ii) If $A \in \Sigma$, then $A^c \in \Sigma$, where A^c is the complement of A . (iii) For countably many sets $A_1, A_2, \dots, A_n, \dots \in \Sigma$, the union $A_1 \cup A_2 \cup \dots \cup A_n \cup \dots \in \Sigma$.

The non-additive measure, $\varsigma : \Sigma \rightarrow [0, 1]$, also sometimes called a *capacity* or *Choquet capacity*, has the following properties.

1. $\varsigma(\emptyset) = 0$, where $\emptyset$ is the empty set.
2. If $A \subseteq B$, then $\varsigma(A) \leq \varsigma(B)$; $A, B \in \Sigma$.
3. $\varsigma(S) = 1$.

Thus, as with probability measures, the probability assigned to the empty set, $\emptyset$, is zero, while the probability assigned to the entire sample space, S , is one. However, the main difference lies in the weaker requirement in Property 2. For an additive probability measure, say, p , and for disjoint events A, B , $p(A \cup B) = p(A) + p(B)$. However, Property 2 does not impose any such condition for a non-additive probability measure. The triple (S, Σ, ς) is known as the *capacity space*.

Recall that for any partition of a sample space, S , into a set of *mutually exclusive* events $\{E_1, E_2, \dots, E_n\}$, a Savage act $f : S \rightarrow X$. Suppose that the outcomes or prizes corresponding to the events $E_1, E_2, \dots, E_n$ are, respectively, $z_1, z_2, \dots, z_n$. We assume that the events are arranged, so that $0 < z_1 < z_2 < \dots < z_n$ and $f = \{E_1, z_1; E_2, z_2; \dots; E_n, z_n\}$. Let F be the set of all Savage acts (or lotteries) under consideration. For non-additive measures, the Riemann integral is not adequate (Gilboa, 2009, pp. 148–9). The *Choquet integral* that we define next, turns out to be useful in this regard.

Definition 4.65 (*Choquet integral*): Consider the capacity space (S, Σ, ς) . Define a Savage act $f = \{E_1, z_1; E_2, z_2; \dots; E_n, z_n\}$, $0 < z_1 < z_2 < \dots < z_n$, over a sigma algebra, Σ , of the sample space S . The Choquet integral of f with respect to the Choquet capacity ς is given by:

$$\int_S f d\varsigma = \sum_{j=1}^n z_j \left[\varsigma \left(\bigcup_{k=j}^n E_k \right) - \varsigma \left(\bigcup_{k=j+1}^n E_k \right) \right]. \quad (4.6)$$

If ς were additive, then $\varsigma \left(\bigcup_{k=j}^n E_k \right) = \sum_{k=j}^n \varsigma(E_k)$, so (4.6) can be written as

$$\int_S f d\varsigma = \sum_{j=1}^n z_j \varsigma(E_j),$$

which is simply the Riemann integral.

Definition 4.66 (Comonotonicity): Consider two Savage acts $f = (s_1, z_1; \dots; s_n, z_n)$, and $g = (s_1, x_1; \dots; s_n, x_n)$. Then f and g are comonotonic if for all i, j

$$f(s_i) < f(s_j) \Rightarrow g(s_i) < g(s_j),$$

where $f(s_i) = z_i$ and $g(s_j) = x_j$ for all $i, j = 1, \dots, n$.

For our next definitions, we need to define mixtures over horse-roulette acts. Hence, we introduce the following terminology (Machina and Siniscalchi, 2014). Recall that we represented a lottery under objective probabilities in the *one-stage form* as $L = (x_1, p_1; \dots; x_n, p_n)$. Consider a partition $E_1, \dots, E_m$ of the sample space. A *horse-roulette act* or an *Anscombe–Aumann act* (or an *objective–subjective prospect*) takes the form, $(L_1, E_1; \dots; L_m, E_m)$ with the interpretation that the decision maker plays the objective lottery L_i if the event E_i takes place. Thus, horse-roulette acts are mappings from the sample space to the objective, single-stage, lotteries. These sorts of lotteries were used by Anscombe and Aumann (1963) in providing an axiomatic derivation of subjective expected utility (SEU) that is simpler than the axiomatization in Savage (1954).

Recall that mixtures over objective one-stage lotteries are defined as follows. If $L_1 = (x_1, p_1; \dots; x_n, p_n)$ and $L_2 = (y_1, q_1; \dots; y_m, q_m)$, then for $\alpha \in (0, 1)$ the $\alpha : (1 - \alpha)$ probability mixture of L_1 and L_2 , is denoted by

$$\alpha L_1 + (1 - \alpha) L_2 = (x_1, \alpha p_1; \dots; x_n, \alpha p_n; y_1, (1 - \alpha) q_1; \dots; y_m, (1 - \alpha) q_m).$$

If the reduction of compound lotteries axiom holds, then one can reduce the mixture lottery to an objective one-stage lottery such that for any common prize, $x_i = y_i$, in the two lotteries L_1 and L_2 , the corresponding probability is $\alpha p_i + (1 - \alpha) q_i$.

In most models of ambiguity aversion, preferences are defined over horse-roulette acts (or simply “acts”). Probability mixtures over such acts are constructed as follows. Suppose that we have a common partition $\{E_1, \dots, E_n\}$ of the sample space. For two acts $f = (L_1, E_1; \dots; L_n, E_n)$ and $g = (L'_1, E_1; \dots; L'_n, E_n)$, and $\alpha \in (0, 1)$, the $\alpha : (1 - \alpha)$ mixture of f and g , is defined as

$$\alpha f + (1 - \alpha) g = (\alpha L_1 + (1 - \alpha) L'_1, E_1; \dots; \alpha L_n + (1 - \alpha) L'_n, E_n).$$

Definition 4.67 (Comonotonic independence): Consider three acts f, g, h that satisfy pairwise comonotonicity and let $\succeq$ denote the decision maker’s preference relation. Then comonotonic independence implies that

$$f \succeq g \Leftrightarrow \alpha f + (1 - \alpha) h \succeq \alpha g + (1 - \alpha) h \text{ for all } \alpha \in (0, 1).$$

Schmeidler (1986, 1989) demonstrated axiomatically that if the relevant notion of independence is comonotonic independence, then,

$$f \succeq g \Leftrightarrow \int_S u(f) d\zeta \geq \int_S u(g) d\zeta,$$

where the relevant notion of integration is Choquet integration (Definition 4.65), ς is a capacity and u is a non-constant function such that $u : X \rightarrow \mathbb{R}$. $\int_S u(f) d\varsigma$ is termed as the Choquet expected utility (CEU) of the act, f .⁹

Allowing for subjective, non-additive, beliefs raises problems for the Pareto criterion in welfare economics. Consider, for instance, the following hypothetical problem posed by Gilboa et al. (2004). In an age of chivalry, two gentlemen, A and B , are considering a resolution of a nagging dispute by engaging in a duel. The objective probability that A wins is p and that B wins is $1 - p$. However the two gentlemen do not know the objective probabilities. Given their tastes, each prefers to engage in the duel if their respective probability of winning is greater than 0.8. Suppose that A and B assign respective subjective probabilities of their winning the duel at 0.9. It is, therefore, privately optimal for each to fight the duel. However, there is no pair of objectively shared probabilities $p, 1 - p$ such that it is optimal to fight. Hence, it may not seem justified for society to accept the individual preferences for a duel, knowing that at least one of the gentlemen has got his beliefs wrong.

Let us now give an explanation of the preferences observed in the three-colors experiment in Example 4.28. Under the four acts in Example 4.28, the sample space is

$$S = \{\{r\}, \{b\}, \{y\}, \{r, b\}, \{r, y\}, \{b, y\}\}.$$

Suppose that we assign the following capacities to these events

$$\varsigma(r) = \varsigma(rb) = \varsigma(ry) = \frac{1}{3}; \varsigma(b) = \varsigma(y) = 0; \varsigma(by) = \frac{2}{3},$$

which satisfy the conditions for a capacity. Let us now compute the CEU corresponding to the two preferences and let $u(0) = 0$.

$$\begin{aligned} \int_S u(f_1) d\varsigma - \int_S u(f_2) d\varsigma &= \frac{1}{3}u(100) - 0 > 0 \Leftrightarrow f_1 \succ f_2. \\ \int_S u(f_3) d\varsigma - \int_S u(f_4) d\varsigma &= \frac{1}{3}u(100) - \frac{2}{3}u(100) < 0 \Leftrightarrow f_4 \succ f_3. \end{aligned}$$

Thus, we are able to explain the observed preference patterns in the Ellsberg paradox if we allow for non-additive probability measures.

4.3.2 Models of multiple priors

Multiple priors models offer one way of capturing ambiguity. Instead of point estimates of the prior probability, decision makers might assign a probability distribution over the prior probabilities. This could arise because decision makers may not fully trust any particular prior or they may have many possible models of the world in mind, each model having some probability of being the true one.

⁹ For other axiomatizations of CEU, see Gilboa (1987), Sarin and Wakker (1992), Nakamura (1990), Ghirardato et al. (2003), and Lehrer (2009).

Gilboa and Schmeidler (1989) propose the following axiomatized model, which can explain the Ellsberg paradox.¹⁰ Consider some act $f \in F$, where F is the set of all acts under consideration. Suppose that the state space is $S = \{s_1, s_2, \dots, s_n\}$ and let Δ be the set of possible subjective probability distributions over S . Let Λ be some closed and convex subset of Δ and denote a typical element of Λ by $\rho = (\rho(s_1), \rho(s_2), \dots, \rho(s_n))$. The set Λ captures all priors that the decision maker has about the set of states; each prior may be taken to denote a different model of the world. Now consider two acts f, g . Then, under certain conditions (see below), Gilboa and Schmeidler (1989) showed that:

$$f \succeq g \Leftrightarrow \min_{\rho \in \Lambda} \int_S u(f(s)) d\rho(s) \geq \min_{\rho \in \Lambda} \int_S u(g(s)) d\rho(s), \quad (4.7)$$

where $u : X \rightarrow R$ is a non-constant function. In words, (4.7) says the following. For each possible act, compute the minimum expected utility for that act from the set of all possible priors under consideration. Then choose the act which gives the maximum utility from the set of minimum expected utilities obtained in the first step. This is also called as the *maximin expected utility model* (MEU).¹¹

In order to derive the representation in (4.7), Gilboa and Schmeidler (1989) weakened the independence axiom in the Anscombe–Aumann framework to *C-independence*, and they also required a notion of *uncertainty aversion*. We now define these concepts.

Definition 4.68 (*C-independence*): Suppose that f, g are two acts and h is some constant act that gives the same outcome in each state of the world. Then *C-independence* requires that

$$f \succeq g \Leftrightarrow \alpha f + (1 - \alpha)h \succeq \alpha g + (1 - \alpha)h \text{ for all } \alpha \in (0, 1).$$

Notice the difference between *C-independence* and comonotonic independence: the acts here are not required to be pairwise comonotonic and h is a constant act.

Definition 4.69 (*Uncertainty aversion*): Suppose that the decision maker is indifferent between two acts f, g , i.e., $f \sim g$, then

$$\delta f + (1 - \delta)g \succeq f \text{ for all } \delta \in (0, 1).$$

Roughly speaking, uncertainty aversion requires that the decision maker would like to hedge bets by preferring a combination of two equivalent acts to any one of the acts.

The representation in (4.7) exhibits extreme pessimism because the decision maker focuses on the worst possible expected utility under each prospect. However, the two conditions, *C-independence* and *uncertainty aversion*, do not directly suggest such pessimism.

Consider now the three-color Ellsberg experiment in Example 4.28. For the four lotteries in (4.2), (4.3), using the most pessimistic subjective probability distribution, we get that for $p \in [0, 2/3]$ (the joint probability of a black and yellow ball) the minimum expected utility for each of the four acts, f_1, f_2, f_3, f_4 is:

¹⁰ There are several axiomatizations of the multiple priors model. See also, Bewley (2002), Klibanoff et al. (2005), Maccheroni et al. (2006a,b).

¹¹ For a generalization of the maximin criteria, see Chateauneuf and Faro (2009). These authors restrict the set of allowable priors to only those on which the decision maker can put a certain minimum degree of confidence. One undesirable feature of MEU models is that they violate monotonicity (see exercise 11.10.1 in Wakker, 2010).

$$\begin{cases} f_1 : & \frac{1}{3}u(100) \\ f_2 : & (1 - p - \frac{1}{3})u(100) = 0 \text{ for } p = 2/3 \\ f_3 : & [\frac{1}{3}u(100) + pu(100)] = \frac{1}{3}u(100) \text{ for } p = 0 \\ f_4 : & [(1 - p - \frac{1}{3})u(100) + pu(100)] = \frac{2}{3}u(100) \text{ for } p = 0 \text{ or } p = 2/3 \end{cases}$$

It is clear from these calculations that

$$\min_{\rho \in \Lambda} \int_S u(f_1(s))d\rho(s) \geq \min_{\rho \in \Lambda} \int_S u(f_2(s))d\rho(s), \text{ so } f_1 \succ f_2,$$

$$\min_{\rho \in \Lambda} \int_S u(f_4(s))d\rho(s) \geq \min_{\rho \in \Lambda} \int_S u(f_3(s))d\rho(s), \text{ so } f_4 \succ f_3,$$

which is in agreement with the observed choices: f_1 over f_2 and f_4 over f_3 .

The models of multiple priors and the MEU approach has also been applied to macroeconomics in the work of Hansen and Sargent (2001a,b). Roughly speaking, the idea is as follows. Suppose that a policymaker has uncertainty about which model best describes the real world. For instance, the policymaker could be uncertain about the relevant coefficients of the expectations augmented Phillips curve. The policymaker must make a choice between $n > 1$ alternative policies. Then the policymaker computes, first, the maximum loss that could arise by using each of the policies. At the second stage, the policymaker chooses the policy that gives the least loss from among the set of losses computed in the first step. For more on the precise link between *robust control methods* of this sort on the one hand and the maximin model, see Maccheroni et al. (2006b).

Some of the assumptions behind the MEU model have been relaxed. For instance, Maccheroni et al. (2006a) relax C-independence. By relaxing the assumption of uncertainty aversion (Definition 4.69 above) in the MEU model, Ghirardato et al. (2004) obtained the α -MEU model. In this model, any act f is evaluated in the following manner:

$$V(f) = \alpha(f) \min_{\rho \in \Lambda} \int_S u(f(s))d\rho(s) + [1 - \alpha(f)] \max_{\rho \in \Lambda} \int_S u(f(s))d\rho(s) \quad (4.8)$$

where Λ is some closed and convex subset of the set of possible probability distributions, Δ , over the set of states. The parameter $\alpha(f) \in [0, 1]$ depends on the act, f , and it captures the decision maker's *ambiguity aversion* for the act. For $\alpha(f) = 1$, this is simply the MEU model. For $\alpha(f) = 0$, this representation turns out to be the same as that for a special case of incomplete preferences as in Bewley (2002), which we examine in Section 4.3.5. In this case, it is sometimes known as the maximax EU model. It has recently been shown that the preference foundations for the α -MEU model are quite restricted. Eichberger et al. (2011) show that the proposal by Ghirardato et al. (2004) holds only for $\alpha = 0$ and $\alpha = 1$. Siniscalchi (2006) shows that α cannot be interpreted as a parameter of ambiguity aversion.

We note that (4.8) is reminiscent of the *Arrow–Hurwicz criterion*, which preceded the axiomatic developments. Arrow and Hurwicz (1972) generalized in turn, the Wald criterion. The latter advocated looking at the worst possible outcome of an act. The generalization of Arrow–Hurwicz was to advocate a weighted average of the worst and best outcome under each act.

4.3.3 Two-stage recursive models and failure of compounding

Segal (1987, 1990) provided an explanation for the Ellsberg paradox within the class of two-stage recursive models where subjects violate the reduction of compound lotteries axiom.¹² Consider the following simplified Ellsberg setup.

Example 4.29 Suppose that there are two urns. Urn 1 is known to contain 5 red and 5 black balls. Urn 2 has 10 balls that are either red or black, but their composition is not known. In this sense, as in the original setup of the Ellsberg paradox, there is ambiguity associated with Urn 2, while Urn 1 involves known risks.

The decision maker is offered a monetary prize, z , if a red ball comes up in a random draw. No prize is given if a black ball comes up. Suppose that the decision maker uses RDU. Then, the utility from betting on a red ball from Urn 1, denoted by RDU_1 , is

$$RDU_1 = u(z)w(0.5), \quad (4.9)$$

where $w(p)$ is a probability weighting function. Suppose that the decision maker has the following mental models of the color composition of Urn 2.

Definition 4.70 With probability $\rho > 0$, Urn 2 has 10 red balls (Model 1). With probability ρ , Urn 2 has 0 red balls (Model 2). Finally, with the complementary probability $1 - 2\rho$, Urn 2 has 5 red and 5 black balls (Model 3). We denote Model i by M_i , $i = 1, 2, 3$.

The probability of a red ball in the three models is, respectively, ρ , 0, $(1 - 2\rho)/2$. A decision maker who respects the reduction axiom, computes the total probability of a red ball to be $\rho + 0 + (1 - 2\rho)/2 = 0.5$, and the total probability of a black ball to be 0.5. Thus, such a decision maker evaluates Urn 2, based on his mental model in Definition 4.70, as the lottery

$$L = (0, 0.5; z, 0.5). \quad (4.10)$$

If a decision maker who follows RDU did respect compounding, then he would evaluate the lottery in (4.10) drawn from Urn 2, and based on the mental models in Definition 4.70, as $RDU(L) = u(z)w(0.5)$.

Suppose now that the decision maker does not respect the reduction axiom, so is unable to reduce compound lotteries in the usual manner. Further, the decision maker follows RDU. Segal (1987, 1990) provided the following formalization of the departure from compounding, in the context of RDU. Assume that $w(p)$ is convex.¹³ The certainty equivalent of the lottery $L = (0, 1 - p; z, p)$ is a prize, c , earned with probability 1, such that

$$u(c) = u(z)w(p). \quad (4.11)$$

$$\Rightarrow c = u^{-1}(u(z)w(p)). \quad (4.12)$$

¹² For a list of two-stage models that preceeded the work of Segal and suggest giving up compounding so as to model ambiguity, see the annotated bibliography on Peter Wakker's homepage under the heading "second-order probabilities to model ambiguity."

¹³ Convexity of the weighting function has certain desirable properties under RDU. For instance, it is a necessary condition for risk aversion (see Chew et al., 1987). For other desirable properties, see Segal (1987).

The decision maker essentially faces a two-stage lottery when considering the draw of a ball from Urn 2. In the first stage, there is risk on account of three possible mental models described in Definition 4.70 (these occur with respective probabilities $\rho, 0, 1 - 2\rho$). For each mental model, in the second stage, he faces another risky situation because the prize z is won with some probability (only in the first mental model is it won with certainty).

The decision maker violates the reduction axiom in the following manner. For each mental model, he replaces the second stage lottery by its certainty equivalent, which violates compounding. Denote by $c_i, i = 1, 2, 3$, the certainty equivalent in model M_i , then

$$\begin{cases} c_1 = u^{-1}(u(z)w(1)) = u^{-1}(u(z)) = z, \\ c_2 = u^{-1}(u(z)w(0)) = u^{-1}(0) = 0, \\ c_3 = u^{-1}(u(0)[1 - w(0.5)] + u(z)w(0.5)) = u^{-1}(u(z)w(0.5)). \end{cases}$$

By replacing the second stage lottery by its certainty equivalent, and rolling back the decision tree, the individual faces the following lottery. The outcomes are arranged in an increasing order, as required by RDU (w is convex, so $u^{-1}(u(z)w(0.5)) < u^{-1}(u(z)) = z$).

$$(0, \rho; u^{-1}(u(z)w(0.5)), 1 - 2\rho; z, \rho). \quad (4.13)$$

We can now compute the utility of a RDU decision maker, when faced with the lottery in (4.13). This is the utility of the decision maker from betting on a red ball from Urn 2 (the ambiguous urn in the classical terminology), when he employs the mental models in Definition 4.70, and reduces lotteries in the manner described above. Under RDU, this utility, denoted by RDU_2 , is:

$$\begin{aligned} RDU_2 &= u(u^{-1}(u(z)w(0.5))) [w(1 - \rho) - w(\rho)] + u(z)w(\rho) \\ &= u(z) [w(0.5)w(1 - \rho) + w(\rho)(1 - w(0.5))]. \end{aligned} \quad (4.14)$$

Using the assumed convexity of the weighting function we get that

$$\begin{aligned} w(0.5)w(1 - \rho) + w(\rho)(1 - w(0.5)) &< w(w(0.5)(1 - \rho) + (1 - w(0.5))\rho) \\ &= w(w(0.5)(1 - 2\rho) + \rho) \\ &< w(w(0.5)(1 - 2\rho)) \quad (\because w \text{ is increasing}) \\ &< w(w(0.5)) \quad (\because (1 - 2\rho) \in (0, 1)) \\ &< w(0.5) \quad (\because w(0.5) < 0.5). \end{aligned} \quad (4.15)$$

From (4.14), (4.15), and using (4.9), we get that

$$RDU_2 < u(z)w(0.5) = RDU_1. \quad (4.16)$$

From (4.16), the decision maker prefers to bet on a red ball from Urn 1 rather than Urn 2. Hence, using the classical terminology, one can explain a preference for the risky urn relative to the ambiguous urn, solely by a failure of a decision maker, using RDU, to understand or invoke compounding, when the decision maker has more than one model of the world as in Definition 4.70.

Halevy (2007) found evidence consistent with the predictions of models that allow for a failure of compounding. These models include those of Segal (1987, 1990), Klibanoff et al. (2005), and

Halevy and Feltkamp (2005). Halevy found that most subjects in experiments who were able to reduce compound lotteries were ambiguity neutral. Conversely, most subjects who were ambiguity neutral were able to reduce compound lotteries. Over the entire population of subjects in experiments, none of the existing theories can explain all the experimental findings. However, the results do strongly suggest that the reduction of compound lotteries must be an important part of the explanation of the Ellsberg paradox.

4.3.4 The smooth ambiguity aversion model

The *smooth ambiguity aversion model* proposed by Klibanoff et al. (2005) belongs to a similar class of models as Segal (1987, 1990). The main differences are the nature of lotteries in the two frameworks (objective versus subjective lotteries) and the nature of preferences in the two stages (identical versus different preferences). Consider the three-colors Ellsberg experiment in Example 4.28. The decision maker has a set of priors, or initial belief, or *first order beliefs*, given in (4.1). These are given by the distribution function Q^1 with the associated probabilities: $q^1(r) = \frac{1}{3}$, $q^1(b) = \frac{2}{3} - p$; $q^1(y) = p$; $p \in [0, 2/3]$. There are an infinite number of such priors because $p \in [0, 2/3]$. Suppose that the decision maker has *second order beliefs* captured by the distribution Q^2 about the set of possible priors $p \in [0, 2/3]$.

Preferences over the initial or first order beliefs are represented by a von Neumann–Morgenstern utility function, u , and $u(0) = 0$. Preferences over second order beliefs are represented by an increasing transformation, ϕ , of u , i.e., $\phi(u) : \mathbb{R} \rightarrow \mathbb{R}$. Then, the observed preferences in the Ellsberg paradox (i.e., $f_1 \succ f_2$ and $f_4 \succ f_3$) are represented by:

$$f_1 \succ f_2 \Leftrightarrow \phi\left(\frac{1}{3}u(100)\right) > \int_{-\infty}^{\infty} \phi\left(\left(\frac{2}{3} - p\right)u(100)\right) dQ^2, \quad (4.17)$$

$$f_4 \succ f_3 \Leftrightarrow \phi\left(\frac{2}{3}u(100)\right) > \int_{-\infty}^{\infty} \phi\left(\frac{1}{3}u(100) + pu(100)\right) dQ^2. \quad (4.18)$$

In this framework, u captures the individual's attitudes to risk. However, ϕ measures attitudes to ambiguity, i.e., the uncertainty faced by the decision maker about the set of priors. Ambiguity aversion is associated with concavity of ϕ , i.e., $\phi' > 0$, $\phi'' < 0$. The preferences expressed in (4.17), (4.18) are reasonable; this is shown in the next example.

Example 4.30 (Machina and Siniscalchi, 2014): Suppose that $u(100) = 1$, $u(0) = 0$, $\phi(u) = \sqrt{u}$. The distribution Q^2 assigns a probability 0.5 each to one of two possible Q^1 distributions. In the first distribution, $p = \frac{2}{3}$, and the second, $p = 0$. We can now rewrite (4.17), (4.18) as follows.

$$\begin{aligned} f_1 \succ f_2 &\Leftrightarrow \phi\left(\frac{1}{3}\right) > \frac{1}{2}\phi\left(\frac{2}{3}\right) \Leftrightarrow 0.5774 > 0.4083. \\ f_4 \succ f_3 &\Leftrightarrow \phi\left(\frac{2}{3}\right) > \frac{1}{2}\phi(1) + \frac{1}{2}\phi\left(\frac{1}{3}\right) \Leftrightarrow 0.8165 > 0.7887. \end{aligned}$$

Hence, there is no paradox in this case.

More generally, let the initial priors over the set of states in the sample space, S , be captured by the distribution, Q^1 . An ambiguity averse decision maker's preferences over two acts f, g in the smooth ambiguity aversion model are represented by:

$$f \succ g \Leftrightarrow \int_{\Lambda} \phi \left(\int_S u(f(s)) dQ^1 \right) dQ^2 > \int_{\Lambda} \phi \left(\int_S u(g(s)) dQ^1 \right) dQ^2, \quad (4.19)$$

where u is a von Neumann–Morgenstern utility function, $\phi''(u) < 0$, the distribution Q^1 defined over S , captures prior beliefs, and the distribution Q^2 defined over Λ , captures uncertainty about prior beliefs. In a sense, the decision maker applies subjective expected utility twice; once over the prior distribution with von Neumann–Morgenstern preferences given by u and then over the posterior distribution with preferences given by $\phi(u)$.

In contrast to the MEU model of Gilboa and Schmeidler (1989), where the objective function is not differentiable, here it is differentiable. For this reason, when ϕ is smooth, the Klibanoff et al. (2005) model is sometimes known as the *smooth ambiguity aversion model*. Insofar as expected utility is applied at each of the two stages, within each stage, the model is susceptible to the criticisms that have already been made of EU. Furthermore, the burden of explaining risk and ambiguity attitudes in this model lies on the utility function; in contrast the evidence indicates that the shape of the probability weighting function plays an important role in risk attitudes. Finally, the theory is not easy to test because second order acts are difficult to observe. Wakker (2010) gives a more detailed discussion of these criticisms; see also Baillon et al. (2012) for a further critical evaluation.

Related models can be found in Nau (2006) and Ergin and Gul (2009). The idea in Nau (2006) is that the state space can be partitioned in such a manner that each partition has a similar degree of uncertainty. In a similar framework, Ergin and Gul (2009) obtain a representation that is similar to (4.19). Epstein (2009) has criticized the smooth ambiguity aversion model of Klibanoff et al. (2005), raising concerns about its very foundations and interpretations. He also contests the claim that the model provides a separation between attitudes to ambiguity and to what one would reasonably agree to be an ambiguous situation.¹⁴

4.3.5 A brief note on the related literature

Bewley (2002) allowed for the possibility that one might not have complete preferences over acts. Thus, in the Ellsberg paradox, some of the acts may not be comparable. In this model, let Λ be the set of acts over which the preferences are complete. Then, using the same terminology that was used in (4.7),

$$f \succeq g \Leftrightarrow \int_{\Lambda} u(f(s)) d\rho(s) \geq \int_{\Lambda} u(g(s)) d\rho(s) \text{ for all } \rho \in \Lambda,$$

otherwise (for $\rho \notin \Lambda$), the acts f, g are simply non-comparable. In any non-comparable situation, it is assumed that the status quo is chosen. This framework can also be used to explain the Ellsberg paradox.

A range of other proposals can explain the Ellsberg paradox. We briefly note some of these. Siniscalchi (2009) proposes a model of *vector expected utility*. In this model, for any act, the individual computes his expected utility using a baseline probability distribution. However, the individual also makes an adjustment to utility which depends on a comparison of the act with similar

¹⁴ The criticisms also apply to the related representation by Ergin and Gul (2009). For a reply, see Klibanoff et al. (2009) who argue that Epstein's thought experiments either strengthen their smooth ambiguity aversion model, or point shortcomings that apply to a much wider range of ambiguity models.

acts, using a measure of statistical similarity. Maccheroni et al. (2006b) propose a representation that they call the *variational representation of preferences*. This is based on a weakening of C-independence (Definition 4.68). Their main axiom, *weak certainty independence*, requires that preferences over acts be invariant to changes in location, but not scale of utilities. Cerreia-Vioglio et al. (2011) propose a general model that provides a unified account of MEU and smooth ambiguity aversion models. Gul and Pesendorfer (2013) propose an axiomatization of their model, *expected uncertain utility*. Chew and Sagi (2006, 2008) propose a theory of “small worlds.” The idea here is to divide the domain of possible events into groups of events. The decision maker has a good idea of probabilities within a group. However, he/she reveals ambiguity when asked to compare across the groups.

We have already considered some definitions of ambiguity aversion. In Definition 4.69, we considered Schmeidler’s definition. In Section 4.3.3 we considered the definition of ambiguity aversion given by Klibanoff et al. (2005). In the α -MEU model of Ghirardato et al. (2004) considered above, the magnitude of α is used to capture the degree of ambiguity (although we have also noted the problems with this approach). These definitions depend on the shape of the utility function. However, it is also possible to give definitions of ambiguity aversion that are independent of the shape of the utility function.¹⁵

Yet another definition of ambiguity aversion is due to Chateauneuf and Tallon (2002). Suppose that there are n acts $f_1, f_2, \dots, f_n$ and the decision maker is indifferent between them, i.e., $f_1 \sim f_2 \sim \dots \sim f_n$. Suppose also that there exist n real numbers $\alpha_1, \alpha_2, \dots, \alpha_n$ with the property that $\sum_{i=1}^n \alpha_i = 1$ and $\sum_{i=1}^n \alpha_i f_i = x \in X$, the set of outcomes. Notice that x could be considered to be a hedged bet relative to any of the acts, f_i . Then, ambiguity aversion requires that $x \succ f_i$, $i = 1, 2, \dots, n$. This definition is similar in idea to Schmeidler’s definition. It too relies on a taste for diversification; the decision maker prefers a hedged bet to an unhedged bet.

Some other definitions of ambiguity aversion include those by Epstein (1999) and Ghirardato and Marinacci (2002). An issue with these definitions is that they do not fully separate attitudes to ambiguity from attitudes to risk. For one such separation of ambiguity and risk preferences, see Gajdos et al. (2008).¹⁶

4.3.6 Some empirical evidence on ambiguity aversion

The experimental results in Section 4.4.1 question some of the underlying premises of the modern ambiguity aversion literature; for a survey, see Trautmann et al. (2016). For instance, ambiguity disappears in Ellsberg style experiments when individuals bet on one urn at a time rather than across both urns. Knowledge/expertise in the sorts of questions asked could even create ambiguity-seeking behavior that is problematic for the modern theoretical models of ambiguity aversion. Furthermore, in the presence of losses or lower probabilities with which events occur, we may observe ambiguity neutrality or even ambiguity-seeking behavior.

Hey et al. (2010) use an experimental setup that modifies the one in Halevy (2007). The authors argue that the original Ellsberg paradox is subject to one important criticism. Namely, that the urn with the unknown composition of balls invites *suspicion*. Subjects in experiments could be suspicious that the experimenter wishes to reduce their total monetary payoff and could somehow

¹⁵ See, for instance, Epstein and Zhang (2001), Nehring (2001), Ghirardato et al. (2004), and Ghirardato and Siniscalchi (2012). Tversky and Wakker (1995) define ambiguity aversion as source preference for risk, which does not involve any utility.

¹⁶ Klibanoff et al. (2005) also claim a separation between attitudes to risk and to ambiguity. This claim is contested in Epstein (2009).

have rigged the urns in his favor. Hence, the “ambiguous urn” could turn into a “suspicious urn”. Subjects might even use the heuristic that they are playing a game against a *malevolent nature*. The very fact that someone offers you a bet, could make you suspicious. For instance, you might wonder if the other party has access to some information that you do not have.

The solution proposed by Hey et al. (2010) for the suspicious urn problem is to use a bingo-blower. This is a rectangular device with transparent glass walls that has a collection of balls being spun around in a continuous motion. In order to draw a ball from the box, the box is tilted and a ball is ejected randomly, and transparently, through a transparent tube. In this case, the balls can be seen, but their proportions cannot be calculated on account of the continuous motion of the balls. The authors argue that this enables them to term the urn as “ambiguous” rather than “suspicious.”

Hey et al. (2010) examine 12 alternative specifications. These include expected utility, the decision field theory (DFT) of Busemeyer and Townsend (1993), MEU and α -MEU models, the Hurwicz criterion, Choquet expected utility, a form of prospect theory that is not PT,¹⁷ and minimum regret. Theories with second order beliefs (see, for instance, Sections 4.3.3 and 4.3.4) are not included because the experiments do not have the multiple stages required to test them. DFT and OPT emerge as the two best theories out of the 12. There is support for Gilboa and Schmeidler’s (1989) MEU model and Ghirardato et al.’s (2004) α -MEU models.

Ahn et al. (2014) find greater support for multiple priors models and rank dependent models relative to smooth ambiguity aversion models. Hayashi and Wada (2010) reject multiple priors models on the grounds that priors that lead to intermediate values of expected utility also play a critical role. By contrast, from (4.8), only those priors that lead to maximum and minimum expected utility should matter.

Conte and Hey (2013) employ a new experimental setup that allows for the testing of theories that employ second order beliefs. They use a mixture model that considers five different theories. They find that the choices of 22% of the subjects are consistent with EU, 53% are consistent with the smooth ambiguity aversion model, 22% are consistent with the rank dependent model and 3% with the α -MEU model. There are vexed econometric issues in interpreting the results from any of these studies; see Hey (2014) for a discussion.

Recall that the Ellsberg paradox poses problems for Savage’s SEU, because it rules out well-defined subjective probabilities in the sense of SEU. Machina (2009) proposes two-urn problems that give rise to a similar problem for models based on Choquet expected utility and axiomatized, for instance, by Gilboa (1987) and Schmeidler (1989).¹⁸ Baillon et al. (2011) show in fact that Machina’s results falsify four main models: maximin expected utility, variational preferences, α -maximin and the smooth model of ambiguity aversion.¹⁹

Gilboa et al. (2009) illustrate a shortcoming of the Bayesian approach by asking the following hypothetical question. Suppose that you were to hear the title of a seminar in a University: “Are all cydophines, also abordites?” What probability do you assign to the event? As the authors say: “For all you know these could be enzymes, grammatical structures in an ancient language, or Abelian groups.” So you cannot justifiably assign any probability. Using the principle of insufficient reason

¹⁷ It is an extension of OPT but Kothiyal et al. (2014) express reservations about using this variant in the domain of lotteries that they consider.

¹⁸ Recall that models based on Choquet expected utility violate *event separability* because the Choquet capacities involve other events on account of the cumulative treatment of events. A particular kind of separability, *tail separability*, still remains in such models. Machina (2009) exploits the notion of tail separability for his results.

¹⁹ The vector expected utility model of Siniscalchi (2009) is, however, not subjected to the anomalies pointed out by Machina (2009).

is not fully satisfactory either. The authors conclude: “The Bayesian approach is lacking because it is not rich enough to describe one’s degree of confidence in one’s assessments. For any probability question it requires a single probability number as an answer, excluding the possibility of replies such as ‘I don’t know’ or ‘I’m not so sure.’” In a similar vein, Gilboa et al. (2009) ask readers, what is the probability that the US President, six years from now, will be a Democrat?

These arguments rule out other possible solutions, particularly expert advice and the option value of waiting for uncertainty to resolve. For instance, suppose that instead a non-economics scholar at a university were to see a seminar titled “Are Hicksian cross partial derivatives negative?” The scholar could ask a friend in the economics department for advice. In many situations of interest in real life, if it were terribly important for you to know the relevant probabilities, you would often ask someone who knows better. For instance, you would ask an expert for financial/insurance information. Or perhaps you might rely on some institutional solution; for instance you need not figure out the probability that the saturated fat content of a jar of powdered milk drink is high or low, you simply read information about the contents, which must be provided by law in most countries.

But in some situations, nobody might currently know the relevant probabilities, not even experts. The modern ambiguity aversion literature requires decision makers to form an immediate probability assessment of an event. In many relevant situations of interest to economics, there is substantial *option value of waiting*. The reason is that ambiguity can resolve as time passes. If you are not sure that you have met the right person for marriage, or you are not sure if this is the right time for having a child, or divorcing your partner, you can rationally wait for more information to unravel. Similarly, if you are not sure that this is the right time to make a particular investment, you can wait to see how events unfold. Countries might put off having a common currency, e.g., the euro, or defer on the death penalty, if they are not sure about the probabilistic merit of the case.

The findings of Halevy (2007), Hey et al. (2010), and Kothiyal et al. (2014) cast sufficient empirical doubt about some of the modern ambiguity aversion theories. The findings of Amos Tversky and colleagues that we outline in Section 4.4.1, question some of the central assumptions in all neoclassical theories of ambiguity.

The empirical literature on ambiguity aversion till about the mid 1990s is considered in Camerer (1995). We can summarize his stylized facts on ambiguity aversion as follows. First, subjects’ aversion to more ambiguous choices does not vanish if one gives them written arguments to illustrate their paradoxical choices. Second, ambiguity and attitudes to risk are not correlated. So, for instance, someone who is more risk averse is not necessarily more ambiguity averse. Third, compound lotteries are considered to be more ambiguous, i.e., subjects are more keen to bet on lotteries with some unknown probability rather than a probability distribution over an unknown probability. Fourth, as one widens the domain of the probability distribution of unknown events (for instance, the range of probabilities p in Example 4.28), choices are considered by subjects to be more ambiguous. Fifth, ambiguity aversion is not caused by a belief on the subjects’ part that the odds are stacked against them in the ambiguous choice.

There is also some evidence that ambiguity aversion might be more relevant in the domain of gains rather than in the domain of losses (Cohen et al., 1987). Similar findings can be found in Du and Budescu (2005) who find decision makers to be nearly ambiguity-neutral in the loss domain. Furthermore, while there appears to be some correlation between risk and ambiguity attitudes in the domain of gains, there is none in the domain of losses (Chakravarty and Roy, 2009). Gender differences in ambiguity aversion have also been documented. Women are relatively more ambiguity averse in situations where the degree of ambiguity is high (Borghans et al., 2009). Using

data from trainee truck drivers, Burks et al. (2008) find that attitudes to risk and ambiguity can be separated in their data. Furthermore, indices of ambiguity aversion are found to be negatively correlated with cognitive skills (measured through, say, non-verbal IQ tests).

Several field experiments illustrate the effect of ambiguity aversion in real-world choice. Investors have a home country bias, investing far more in home country securities relative to diversifying by using international securities (French and Poterba, 1991). Referees are more willing to accept papers when refereeing is single-blind rather than double-blind (Blank, 1991).²⁰ Insurance contracts can charge an ambiguity premium (Hogarth and Kunreuther, 1992). Furthermore, even professionals such as actuaries and insurance underwriters exhibit ambiguity aversion (Hogarth and Kunreuther, 1989; Kunreuther et al., 1995).

What causes ambiguity aversion? This remains an intriguing question. One possible explanation is that people take account of the negative evaluation of others, of their decision (Curley et al., 1986). Hence, if they are being directly observed by others, they are found to be more ambiguity averse. This is sometimes referred to as the *fear of negative evaluation*, FNE. When the perception is that others are more competent, then FNE (and, hence, ambiguity aversion) might be enhanced even more.²¹ Trautmann et al. (2008) introduce an experimental design which is able to control for FNE. They find that this leads to the disappearance of ambiguity aversion. The authors conjecture that FNE might be a necessary condition for the presence of ambiguity aversion.

4.4 Behavioral models of ambiguity

In this section, we consider behavioral models of ambiguity. Under pure risk, this class of models does not reduce to EU. We consider two classes of models. The common theme running through these models is that the individual's attitudes towards ambiguity are influenced by the *source of information*.

4.4.1 *Support theory*

In a series of papers, Amos Tversky and several collaborators examine the nature of ambiguity within and outside the Ellsberg context. We now examine this line of work which is influential in psychology, and its decision theoretic foundations have recently been articulated by Ahn and Ergin (2010).²²

Fox and Tversky (1998) begin with the observation that subjective expected utility (SEU) determines beliefs and tastes in one fell swoop. SEU is agnostic on what the decision maker forms first: beliefs or preferences. However, beliefs may precede preferences. For instance, a punter might bet on team A rather than on team B because he believes the former is more likely to win. Punters do not, however, infer this belief from a observation that they prefer betting on team A.

In the first step, individuals form beliefs about events using the *support theory* of Tversky and Koehler (1994). The starting point of support theory is the empirical observation that *procedure*

²⁰ These experiments used data on referees from the *American Economic Review*. In single blind refereeing, the identity of the author is known to the referee (but not vice versa). In double blind refereeing, the identity of each is private knowledge (so this is a more ambiguous situation).

²¹ See for instance, Heath and Tversky (1991), Fox and Tversky (1998), and Fox and Weber (2002).

²² These authors derive a partition dependent expected utility representation of preferences. The same sample space can be finely or coarsely partitioned. The decision maker then has non-additive weights over events in any partition. Also see Cohen and Jaffray (1980) for an earlier attempt along this direction.

invariance is violated when one elicits beliefs using different methods. Suppose that $E_1, E_2, \dots, E_n$ are disjoint events, then we typically observe the following form of subadditivity (Fischhoff et al., 1978; Teigen, 1974).

$$P(E_1 \cup E_2 \cup \dots \cup E_n) < P(E_1) + P(E_2) + \dots + P(E_n).$$

Motivated by this finding, support theory assumes that individuals do not attach probability to events, but rather to the “description of events” or “hypotheses.” So depending on how the same event is described or framed, the individual could assign different probabilities to it.

If only two possible hypotheses, A and B , hold, then the subjective probability that A rather than B holds, denoted by $P(A, B)$, is given by:

$$P(A, B) = \frac{s(A)}{s(A) + s(B)} \in [0, 1], \quad (4.20)$$

where, for any hypothesis, A , $s(A) \geq 0$ is the “support value” of the hypothesis. This reflects the strength of evidence for this hypothesis. It is obvious from (4.20) that $P(A, B) + P(B, A) = 1$; this is known as *binary complementarity*. For $A = A_1 \cup A_2$, the support value satisfies:

$$s(A) \leq s(A_1 \text{ or } A_2) \leq s(A_1) + s(A_2). \quad (4.21)$$

The first inequality in (4.21) implies that by unpacking an event into its constituent parts increases the support for the event. The second inequality implies that this, in turn, is dominated by the sum of support for the individual constituents. The idea behind this kind of *subadditivity* is that by breaking an event into its sub-parts, one increases the salience of the event; quite possibly, one might be able to recall a greater number of instances of the event. For instance, it is likely that the support value for homicide (event A) is lower than the support value for the two constituent events, homicide by strangers (A_1) and homicide by acquaintances (A_2), simply because the latter two might bring to mind more instances of such events and thereby increase their salience. This intuition is borne out by evidence, which includes field studies of the behavior of experienced physicians.²³

Once beliefs consistent with (4.20), (4.21) are allowed for, one transforms an uncertain situation (what is the probability of events A and B that lack an objective probability?) into a risky one (well-defined probabilities $P(A, B)$, $P(B, A)$ can be formed). Such probabilities are said to be consistent with support theory.

For n possible events $E_1, E_2, \dots, E_n$ that represent a partition of the sample space S , denote the associated subjective probabilities that are consistent with support theory by $p_1, p_2, \dots, p_n$. One can then move on to the second stage. In this stage, the decision maker simply uses prospect theory to evaluate what has become a risky prospect.

Tversky and Wakker (1995) extend the weighting function under risk, $w(p)$, to uncertainty, $W(E)$, as follows.

1. (Weight on extreme events) $W(\phi) = 0$, $W(S) = 1$.
2. (Bounded subadditivity) Denote by E_i, E_j , two events in the sample space such that $i, j = 1, 2, \dots, n$, $i \neq j$ and $E_i \cap E_j = \phi$, then:²⁴

²³ For the evidence, see, for instance, Tversky and Koehler (1994) and Rottenstreich and Tversky (1997). For the specific case of experienced physicians exhibiting the ideas in (4.21), see Redelmeier et al. (1995).

²⁴ Support for the bounded subadditivity hypothesis can be found in Tversky and Fox (1995).

- 2a. (Possibility effect or lower subadditivity) $W(E_i) \geq W(E_i \cup E_j) - W(E_j)$ whenever $W(E_i \cup E_j) \leq W(S - E)$ for some event E . The possibility effect captures the idea that increasing the probability of winning a prize from 0 to p has a larger effect than increasing the probability from $q > 0$ to $q + p \leq 1$. This is seen by considering successively the cases $E_j = \phi$ (where the inequality binds) and $E_j \neq \phi$ (where it need not bind).
- 2b. (Certainty effect or upper subadditivity) $W(S) - W(S - E_i) \geq W(E_i \cup E_j) - W(E_j)$ whenever $W(E_j) \geq W(E')$ for some E' . The certainty effect shows that the impact of an event E_i is greater when it is subtracted from a certain event (S) rather than an uncertain event.

Consider simple prospects of the form (E_i, x) that offer a monetary prize x if the event E_i occurs. Denote the reference point as $\bar{x}$. Then the value of the prospect (E_i, x) is given by

$$V = v(x - \bar{x})W(E_i) = v(x - \bar{x})w(p_i),$$

where p_i is the subjective probability associated with the event E_i and it is consistent with support theory. The function $v(x - \bar{x})$ is as defined in prospect theory.

Heath and Tversky (1991) introduce the *competence hypothesis*. The competence hypothesis requires that an individual's propensity to bet on a lottery depends on how knowledgeable or competent the individual feels in that context. Several cognitive explanations for this hypothesis are suggested. For instance, people learn from experience that they perform better in challenges where they have better knowledge, skill, or competence. Another possibility is that in addition to the monetary consequences from betting, there are also psychic consequences, e.g., credit or blame for an outcome, lowered or improved self esteem, and approval or condemnation from others. In pure games of chance, one does not expect these psychic payoffs to be very important. However, in games involving skill, judgment, or knowledge, they are likely to be far more important. Competent people can take credit when they succeed in games of skill and can sometimes be insulated from blame ("the expert's prediction was incorrect but the expert is very competent, so it must be a very noisy environment, making predictions too difficult"). On the other hand, if a non-expert gets it correct he gets no credit ("succeeded by chance") and if he fails he might get the blame ("he had no expertise; failure was expected"). Hence, we would expect people with the relevant knowledge and competence to be more likely to bet on games that involve knowledge/competence.

In the context of the Ellsberg paradox, people might dislike betting on the "vague" urn for fear of being shown up to be less knowledgeable or competent. Indeed, Curley et al. (1986) show that aversion to ambiguity increases if others can observe one's decision and the actual outcome ("fear of negative evaluation"). The Ellsberg paradox is not, however, a particularly good application of the competence hypothesis because it is not clear what knowledge or competence is involved.

Fox and Tversky (1995) made the important observation that the literature following the Ellsberg paradox typically invoked a *within-subjects design* of experiments. In these experiments, subjects always compared clear and vague bets; for instance, a comparison of two urns, one with a known composition of balls and another with an unknown composition. They propose, instead, a *between-subjects design* in which subjects compare either one or the other urn at a time. Their main experimental finding is that ambiguity aversion no longer exists in a between-subjects design.

Consider, for instance, the following experiment reported in Fox and Tversky (1995). Bag A has 50 red chips and 50 black chips. Bag B has 100 red and black chips, but the exact proportion is unknown. A "ticket" to a bag entitles the holder to play the following game. First, choose a color,

Table 4.2 Results from the Fox and Tversky (1995) study.
Standard errors in parantheses.

	Clear bet	Vague bet
Comparative condition	\$24.34 (2.21)	\$14.58 (1.80)
Non-comparative condition	\$17.94 (2.50)	\$18.82 (2.87)

then draw randomly a chip from the bag. If the chip is of the same color as the chosen color, then the ticket holder wins \$100, otherwise he/she wins nothing. Experimental subjects are asked how much they would pay for a “ticket” to each bag?

Two conditions were identified and the subjects were split roughly evenly between the two conditions. In the *comparative condition* (67 subjects) the two bags were simultaneously presented to the subjects and they had to state a price they were willing to pay for a ticket for each bag. The other half of the subjects (74 subjects) played the *non-comparative condition* and they were split into two groups. One group (35 subjects) had to state the price they were willing to pay for the ticket to Bag A only and the remaining (39 subjects) had to state the price they were willing to pay for Bag B only.

The results are show in Table 4.2 for the case of the *clear bet* (betting on bag A) and the *vague bet* (betting on bag B). The results are in line with the conjecture made by the authors. Ambiguity aversion, as traditionally understood, arises in the comparative condition; subjects are willing to pay significantly more for a ticket to Bag A. However, in the non-comparative condition, such ambiguity aversion completely disappears. This result is unaltered when the authors introduce real monetary stakes.

Subjects do seem aware that relevant information is missing in the case of Bag B. However, unless there is a direct comparison between the clear bet and the vague bet, ambiguity aversion does not arise, so missing information is not a sufficient condition for ambiguity aversion. These results are problematic for neoclassical theories of ambiguity.

4.4.2 Prospect theory, source-dependent uncertainty, and ambiguity

We have briefly alluded to the work of Chew and Sagi (2008) above. They partition the domain of events into groups such that there is homogeneity in uncertainty within each group, yet heterogeneity between the groups. Section 4.4.1 also alluded to the *source of information* in influencing the beliefs of individuals about uncertain events (Tversky and Fox, 1995; Fox and Tversky, 1995).

In an important breakthrough, Abdellaoui, Baillon et al. (2011) formalize some of these ideas and also present evidence for their insights. The central idea is that the decision maker distinguishes between information from difference *sources* of uncertainty. The authors (p. 699) give an informal definition of a *source*: “A source of uncertainty concerns a group of events that is generated by a common mechanism of uncertainty.” Consider the two-colors example of the Ellsberg paradox (Example 4.27) in which there is a known urn (K) and the unknown urn (U). Decision makers are indifferent between the two colors in each urn when the urns are presented separately. Yet, they are not willing to exchange a bet on a color in urn K with a bet on the same color in urn U . Thus, it appears that each urn constitutes a separate source of uncertainty.

We have outlined PT under uncertainty in Section 2.4.1. We now employ similar machinery to develop the ideas here. Let $f = (E_1, x_1; E_2, x_2; \dots; E_n, x_n)$ be a Savage act, as in (1.6), that gives

a prize x_i if event E_i occurs and $\cup_{i=1}^n E_i = E$, where E is the universal event. The decision maker does not know which of the n events will occur. Let $P(E_i)$ be the subjective probability of the event E_i , which can be elicited from the choices made by the subjects. Suppose that the decision maker has complete and transitive preferences $\succeq$ over F , the set of all Savage acts. Under SEU (see Section 1.3) the decision maker evaluates the act f by the functional

$$SEU(f) = \sum_{i=1}^n P(E_i)u(x_i), \quad (4.22)$$

where u is a continuous and strictly increasing utility function.

In the empirical tests undertaken by Abdellaoui, Baillon et al. (2011), $n = 2$. Thus, they have prospects of the form $(E_1, y; E_2, x)$, where $y \leq x$. The reader should have no problems with the next two definitions.

Definition 4.71 (*Weighting function for uncertainty*): A weighting function under uncertainty is a mapping $\tilde{w} : S \rightarrow [0, 1]$ such that:

- (i) $\tilde{w}(\emptyset) = 0$, where $\emptyset$ is the empty set.
- (ii) $\tilde{w}(E) = 1$, where E is the universal event.
- (iii) If $E_i \subseteq E_j$, then $\tilde{w}(E_i) \leq \tilde{w}(E_j)$.

Definition 4.72 (*Binary rank dependent utility*): The utility representation of the prospect $(E_1, y; E_2, x)$ under rank dependent utility is given by

$$RDU(E_1, y; E_2, x) = [1 - \tilde{w}(E_2)] u(y) + \tilde{w}(E_2)u(x). \quad (4.23)$$

We now wish to define the sense in which two events are perceived to be equally likely.

Definition 4.73 (*Exchangeable events*):

- (i) Two disjoint events E_1 and E_2 are exchangeable if permuting their respective prizes has no effect on preferences, i.e.,

$$(E_1, x_1; E_2, x_2; \dots; E_n, x_n) \sim (E_1, x_2; E_2, x_1; \dots; E_n, x_n).$$

- (ii) An entire partition $(E_1, E_2, \dots, E_n)$ of the universal event is exchangeable if all pairs of events in it are exchangeable.

Definition 4.74 (*Source*; Abdellaoui, Baillon et al., 2011, p. 699): A source, S is an algebra. It contains the universal event (certain to happen), the vacuous event (certain not to happen), the complement of each element in the set, and the union of each pair of elements in the set.²⁵

We distinguish between the various sources of uncertainty (such as the single urn and the two urns in the Ellsberg paradox) by giving the following definition of a uniform source.

Definition 4.75 (*Uniform sources*): A source S is said to be uniform if for any partition of events in S , $(E_1, E_2, \dots, E_n)$, probabilistic sophistication (Definition 1.13) holds. In other words, choices among prospects of the form $(E_1, x_1; E_2, x_2; \dots; E_n, x_n)$ can equivalently be expressed as choices over prospects of the form $(x_1, P(E_1); x_2, P(E_2); \dots; x_n, P(E_n))$ where $P(E_i)$ is the subjective probability of the event E_i . The decision maker is indifferent between two event-contingent prospects “from the same source” that lead to the same probability-contingent prospect. This property need not hold if we were to change the source.

²⁵ Thus sources also contain every finite union and intersection of their elements.

If any finite partition of a source is exchangeable (Definition 4.73), then the source is a uniform source.

Example 4.31 (Source Preference; Wakker, 2010, p. 318) Suppose that A and B are two sources and we have

$$A \succeq B \text{ and } A^c \succ B^c \text{ for all } A \in \mathcal{A} \text{ and } B \in \mathcal{B}$$

but it is never the case that $B \succeq A$ and $B^c \succ A^c$, then we say that the decision maker prefers the source A to B .

Definition 4.76 (Source functions): Since probabilistic sophistication holds in any uniform source, S , so for any $E_i \subseteq S$ we have

$$\tilde{w}(E_i) = w_s(P(E_i)),$$

where w_s is known as a source function. In this case we can write (4.23) as

$$RDU(E_1, y; E_2, x) = [1 - w_s(P(E_2))] u(y) + w_s(P(E_2)) u(x).$$

Example 4.32 Consider the prospect $(E_1, x_1; E_2, x_2; \dots; E_n, x_n)$ in which the probabilities of all events are “objective probabilities” and $\cup_{i=1}^n E_i = S$. Then S is a uniform source. In this case we have the standard situation of choice under risk in which the source function w_s is written as a standard probability weighting function w without a subscript.

To check if the behavior of decision makers differs when they receive information from non-uniform sources, Abdellaoui, Baillon et al. (2011) propose the following modification of the Ellsberg experiments. They consider urns K and U as in the Ellsberg paradox. Urn K is known to contain 8 balls of different colors, while urn U is also known to have 8 balls; the color composition in urn U is unknown, but it contains no new colors relative to urn K . So urn U may contain one ball each of the 8 colors, or all 8 balls of the same color, or any combinations of the 8 colors that are present in urn K .

In order to test for uniformity, events $E_2, E'_2, E''_2, \dots$ are specified that have the same number of balls (3 balls in the experiments), for each of the two urns. The decision maker is then asked to state certainty equivalents for the prospects $(E_1, 0; E_2, 25)$, $(E_1, 0; E'_2, 25)$, $(E_1, 0; E''_2, 25)$, $\dots$ from each of the urns. Since each urn is hypothesized to be a uniform source, one would expect the events in each urn to be exchangeable, hence, the certainty equivalents for each prospect in each urn should be identical. However, if the K and U urns are different sources, then a comparison of the certainty equivalents for a pair of prospects across the two urns should reveal a difference.

Utility elicitation was carried out by using the method of Abdellaoui et al. (2008) (see Section 2.5). Certainty equivalents, CE , were elicited for prospects of the form $(E_1, 0; E_2, x)$, where x varied from 0 euros to 25 euros, and the event E_2 specified balls of 4 colors, red, blue, yellow, cyan, $E_2 = \{R_s, B_s, Y_s, C_s\}$; the sources being $s = K, U$. Since the event E_2 specifies 4 out of 8 colors, so we expect the subjective probability of the event to be 0.5 for each urn, i.e., $P(E_2) = 0.5$. A power form of utility was assumed, so $u(x) = \left(\frac{x}{25}\right)^{\rho_s}$, where $\rho_s > 0$ is a parameter. Using the definition of certainty equivalent, this implies that $\left(\frac{CE_s}{25}\right)^{\rho_s} = w_s(0.5) \left(\frac{x}{25}\right)^{\rho_s}$, where CE_s is the certainty equivalent when $s = K, U$. Non-linear least squares is then used to estimate the utility function and the source function at the probability 0.5.

For probabilities different from 0.5, we obtain the source function by varying the number of colors j in the event E_2 , $j = 1, 2, 3, 5, 6, 7, 8$. Once we obtain the 8 values of the source function

$(w_s(\frac{1}{8}), w_s(\frac{2}{8}), \dots, w_s(\frac{8}{8}))$, a two-parameter Prelec function, $w(p) = e^{-\beta(-\ln p)^\alpha}$ (Definition 2.22), is fitted through them.

The results are as follows.

1. Uniformity is not rejected for each of the two urns separately. This result holds at the aggregate and the individual-level data.
2. The estimates of ρ_s , $s = K, U$ are indistinguishable. Hence, potential explanations for the Ellsberg paradox should not rely on the differences in the utility functions across the two sources.
3. The most telling differences between the two urns come from the fitted source functions, w_s , $s = K, U$. The Prelec parameters for urn K are $\alpha = 0.85$, $\beta = 0.93$, and for urn U these are $\alpha = 0.64$, $\beta = 1.03$; Figure 4.1 plots the two source functions. The diagonal line corresponds to EU, the dotted curve to the source function for urn K and the heavy curve for urn U . Both parameter estimates for the source functions are significantly different from 1, hence, EU cannot explain the data (recall that for EU, $\alpha = \beta = 1$). A plausible interpretation is that each urn is viewed as a different source of uncertainty by the decision maker. The difference between the source functions for the two urns may be taken as a measure of the *ambiguity attitudes* of the decision maker. A measure of pessimism, that is developed by the authors, is significantly higher for urn U relative to urn K .
4. There is significant heterogeneity among the decision makers, as shown by the source functions for three subjects in Figure 4.2. Subject 2 is most pessimistic; subject 44 is most likely to be insensitive (flattest middle segment of the source function for urn U); subject 66 is *ambiguity seeking* because the source function for urn K lies outside the source function for urn U . Thus, subjects are characterized by a rich range of behaviors in the domain of uncertainty.

We have noted earlier that PT can be applied to risk, uncertainty, and ambiguity. An important empirical test of PT in this regard is provided by Kothiyal et al. (2014). These authors offer a more satisfactory treatment of PT relative to that reported in the tests of Hey et al. (2010). These tests involve a combination of two major advances: the source method employed in Abdellaoui,

Figure 4.1 Source-dependent probability weighting functions. Plots of the diagonal line (solid thin line) and the source functions for urn K (dashed curve) and urn U (solid line).

Source: Abdellaoui et al. (2008).

Figure 4.2 Subject heterogeneity for three subjects expressed in terms of their source functions.

Source: Abdellaoui, Baillon et al. (2011).

Baillon et al. (2011) and the experimental implementation of the method for testing multiple prior models in Hey et al. (2010).

The device of a three-color (pink, blue, and yellow) bingo blower (see discussion above in Section 4.3.6) is used to ensure that the *ambiguous urn* does not turn into a *suspicious urn*. The total number of balls was varied to be 10, 20, and 40. Three-event prospects of the form $(E_1, 100; E_2, 10; E_3, -10)$ are presented. An example is: $E_1 = \{\text{pink}\}$, $E_2 = \{\text{yellow, blue}\}$ and $E_3 = \emptyset$ (an impossible event that never occurs). In most alternatives to EU, the decision maker maximizes an objective function of the form

$$V = \pi_1 u(100) + \pi_2 u(10) + \pi_3 u(-10),$$

where π_i is the decision weight associated with event E_i , $i = 1, 2, 3$ and u is a utility function. Under SEU, the decision maker evaluates utility as shown in (4.22). *Subjective expected value* (EV) is similar except that $u(x) = x$. Under *Choquet expected utility* (CEU) described in Section 4.3.1, the weighting function, $\hat{w}$, has the properties: (i) $\hat{w}(\emptyset) = 0$, where $\emptyset$ is the empty set; (ii) if $E_i \subseteq E_j$, then $\hat{w}(E_i) \leq \hat{w}(E_j)$; (iii) $\hat{w}(\cup_i E_i) = 1$. The decision weights in this case are given as in cumulative transformations of probabilities under PT, i.e.,

$$\pi_1 = \hat{w}(E_1), \pi_2 = \hat{w}(E_1 \cup E_2) - \hat{w}(E_1), \pi_3 = 1 - \hat{w}(E_1 \cup E_2).$$

The decision weights under PT are similar except that we allow for different weighting functions in the domains of gains and losses; in this example, only event E_3 pushes the decision maker into the domain of losses. Thus, in PT, unlike CEU, the decision weights need not add up to 1. For estimation purposes, the parameters of the models need to be reduced. We leave the reader to pursue the details on this issue from the original paper.²⁶

A tournament is then run among 11 competing models (as in Hey et al. 2010); this list does not include models with second order beliefs. On most yardsticks, PT beats every other theory.

²⁶ For instance, the weighting functions for gains and losses under PT are treated to be identical, and the Prelec weighting function is used. The authors also examine the implications of relaxing some of these assumptions.

These yardsticks include log likelihoods and the number of subjects conforming to the theory. Among the other rank dependent theories, α -MEU with $\alpha = 1$ does best. The authors conclude (p. 16): “This facilitates the study of ambiguity (the difference between uncertainty and risk), where prospect theory, unlike most other ambiguity theories today, need not commit to the descriptively failing expected utility for risk.”

Exercises for Part 1

1. Using the reduction axiom, show that Proposition 1.1 holds for the case of any finite number of outcomes.¹
2. Using Definition 1.5, show that risk neutrality, risk aversion, risk seeking are equivalent, respectively, to a linear, concave, convex utility function.
3. (St. Petersburg paradox) Suppose that a decision maker were to accept the following gamble. A fair coin is tossed repeatedly in independent trials until a head comes up. If a head comes up on the n th toss, then the payoff from this gamble is 2^n . Show that the expected value of this gamble is infinite. People are typically willing to pay only about \$20 for this gamble. How much would a decision maker who followed the expected value criterion (EV) pay for this lottery? Show that a sufficient condition to reconcile the EV criterion with the empirical findings is to have a sufficiently concave utility function, $u(x)$, where x is an outcome.
4. (Affine transformations) Let $F : \mathcal{L} \rightarrow \mathbb{R}$ and $G : \mathcal{L} \rightarrow \mathbb{R}$, where $\mathcal{L}$ is the set of all simple lotteries. We say that G is a positive affine transformation of F if, and only if, there are real numbers, α, β , with $\beta > 0$, such that $G = \alpha + \beta F$. Show that $G : \mathcal{L} \rightarrow \mathbb{R}$ is a positive affine transformation of $F : \mathcal{L} \rightarrow \mathbb{R}$ if, and only if, F is a positive affine transformation of G .
5. Given two functions, $F : \mathcal{L} \rightarrow \mathbb{R}$ and $G : \mathcal{L} \rightarrow \mathbb{R}$, let the respective induced preferences on $\mathcal{L}$, be denoted by $\preceq_F$ and $\preceq_G$. Let the two functions, $F : \mathcal{L} \rightarrow \mathbb{R}$ and $G : \mathcal{L} \rightarrow \mathbb{R}$, satisfy, for all $L_1, L_2, L \in \mathcal{L}$, and all $p \in [0, 1]$,
 - (i) $F(x_1) \leq F(L) \leq F(x_n)$ and $F(x_1) < F(x_n)$,
 - (ii) $G(x_1) \leq G(L) \leq G(x_n)$ and $G(x_1) < G(x_n)$.
 - (iii) $F(L_1, p; L_2, 1-p) = pF(L_1) + (1-p)F(L_2)$,
 - (iv) $G(L_1, p; L_2, 1-p) = pG(L_1) + (1-p)G(L_2)$.
 Show that the induced orders, $\preceq_F$ and $\preceq_G$, are identical if, and only if, G is a positive affine transformation of F .
6. Show that Example 1.3 can be recast as a common consequence violation, as defined in Definition 1.15.
7. Prove Propositions 1.6 and 1.7.
8. Draw a probability triangle to explain the common consequence violation corresponding to Example 1.3 and show that the indifference curves in the triangle must *fan out* for consistency with the evidence.
9. (Probabilistic insurance; Wakker et al., 1997) Suppose that a decision maker has wealth, $W > 0$. With some probability $0 < p < 1$, the decision maker incurs a monetary loss, $L < 0$. In effect, the decision maker faces the lottery $(W - L, p; W, 1 - p)$. The utility function of the risk averse decision maker is given by $u(z)$, which is increasing and concave. Since utility is measured on an ordinal scale, we can, for pedagogical simplicity, choose the following normalization $u(W) = 1, u(W - L) = 0$.
 Suppose that the decision maker is offered a hypothetical insurance contract that charges a premium, $P > 0$, so that he just prefers to buy the insurance contract. The insurance contract offers the following lottery, $(W - P, p; W - P, 1 - p) \equiv (W - P, 1)$. Now, suppose that the decision maker is offered *probabilistic insurance*. Under this form of insurance contract, the decision maker will pay a premium of θP , $0 \leq \theta \leq 1$. Should a loss occur, then (1) with probability $1 - \theta$, the loss will not be covered, and the premium θP will be

¹ I am grateful to Ali al-Nowaihi for contributing several problems in this part.

returned, and (2) with probability θ , the loss will be fully covered, but the decision maker will have to pay an extra premium of $(1 - \theta)P$ (so in effect, a total premium of P in that state). All this is summarized in the following lottery under probabilistic insurance.

$$(W - L, (1 - \theta)p; W - P, \theta p; W - \theta P, 1 - p). \quad (4.24)$$

Show that conditional on just accepting the insurance contract at a premium P , an EU decision maker will prefer probabilistic insurance.

10. Prove Proposition 2.8.
11. Prove Proposition 2.9.
12. Consider the probability weighting function $w(p) = p^\gamma$, where $\gamma > 1$. Is this probability weighting function subproportional? Can it capture the certainty effect?
13. Check that the weighting functions in (2.5), (2.6), and (2.7) satisfy the conditions of a probability weighting function. Also check the conditions under which these functions are subproportional.
14. (al-Nowaihi and Dhami, 2011): Let $w(p)$ be the Prelec function. Suppose $\alpha \neq 1$. Then prove the following:
 - (a) $w''(\tilde{p}) = 0$ for some $\tilde{p} \in (0, 1)$ and, for any such $\tilde{p}$:
 - (i) For $\alpha < 1$: $p < \tilde{p} \Rightarrow w''(p) < 0$, $p > \tilde{p} \Rightarrow w''(p) > 0$.
 - (ii) For $\alpha > 1$: $p < \tilde{p} \Rightarrow w''(p) > 0$, $p > \tilde{p} \Rightarrow w''(p) < 0$
 - (b) The Prelec function has a unique inflexion point, $\tilde{p} \in (0, 1)$, and is characterized by $\alpha\beta(-\ln \tilde{p})^\alpha + \ln \tilde{p} + 1 - \alpha = 0$.
 - (c) $\beta = 1 \Rightarrow \tilde{p} = e^{-1}$.
 - (d) $\frac{\partial \tilde{p}}{\partial \beta} = \frac{\alpha \tilde{p}(-\ln \tilde{p})^{1+\alpha}}{(\alpha-1)(\alpha-\ln \tilde{p})}$.
 - (e) $\frac{\partial [w(\tilde{p}) - \tilde{p}]}{\partial \beta} = \frac{\tilde{p}(-\ln \tilde{p})^{1+\alpha}}{(\alpha-1)(\alpha-\ln \tilde{p})} \left(e^{\frac{1-\alpha}{\alpha}} (\tilde{p})^{\frac{1-\alpha}{\alpha}} - \alpha \right)$.
 - (f) $\tilde{p} \leq w(\tilde{p}) \Leftrightarrow \beta \leq 1$.
15. Prove Propositions 2.10, 2.11 and Corollary 2.1.
16. Prove Proposition 2.12.
17. Prove Proposition 2.13.
18. Consider the lottery $L = (15, 0.8; 0, 0.2)$ that captures the risky returns associated with a financial decision. The utility function of the decision maker satisfies $u(0) = 0$. The individual uses RDU to evaluate lotteries and has the probability weighting function $w(p) = p^2$. Relative to a decision maker who follows expected utility (EU), is this decision maker optimistic or pessimistic?
19. Consider the lottery $L = (9, \frac{1}{3}; 16, \frac{1}{3}; 25, \frac{1}{3})$ that captures the discounted risky returns associated with the purchase of a financial security. The utility function of the decision maker is $u(x) = \sqrt{x}$. [Restrict calculations to four decimal places.]
 - (a) Suppose that the decision maker follows EU. Compute the expected utility of the lottery. Is the decision maker risk averse, risk neutral, or risk loving?
 - (b) Suppose that the decision maker uses RDU to evaluate lotteries and has the probability weighting function $w(p) = \sqrt{p}$. Is this decision maker risk averse, risk neutral, or risk loving?
 - (c) If there is a difference in the risk attitudes found in parts (a) and (b), what accounts for the difference?
20. (RDU can explain the Allais paradox) Suppose that the utility function is $u(x) = x^{0.6} - x_0^{0.6}$, where x is the (final) level of wealth and x_0 is the initial level of wealth. The constant

$-x_0^{0.6}$ is added, so that $u(x_0) = 0$ (as was assumed in Example 1.2). Take the Prelec (1998) probability weighting function with $\alpha = 0.15$, $\beta = 0.5$. Show that RDU is able to predict the “common ratio violation” in Example 1.2.

21. Let a decision maker have initial wealth, x_0 , and utility function, u . Now consider problems 1 and 2 from Kahneman and Tversky (1979) that were given to 72 subjects. All lotteries are in units of Israeli pounds.

Problem 1: (72 subjects) Choose between

$$L_1 = (x_0, 0; x_0 + 2400, 1) \text{ and } L_2 = (x_0, 0.01; x_0 + 2400, 0.66; x_0 + 2500, 0.33).$$

Problem 2: (72 subjects) Choose between

$$L_3 = (x_0, 0.66; x_0 + 2400, 0.34) \text{ and } L_4 = (x_0, 0.67; x_0 + 2500, 0.33).$$

The data shows that 82% of the subjects chose L_1 in problem 1 and 83% of subjects chose L_4 in problem 2. Each of these preferences was significant at the 1% level.

- (a) Is the choice data of the majority of subjects consistent with expected utility?
 (b) Assume that $u(x_0) = 0$, and the weighting function is very steep in the neighborhood of $p = 1$, and flat in the middle, which, for instance, is the case with the Prelec function. Is the choice data of the majority of subjects consistent with rank dependent utility?
22. Prove Proposition 2.14.
23. Construct an example, analogous to Example 2.12 to illustrate Remark 2.6.
24. (Huber et al., 1982; Ok et al., 2015) Consider three alternatives, x, y, z . Each alternative has two dimensions (say, price and quality). Alternative x dominates y in one dimension and is dominated in the other. Alternative z (i) is dominated by x in both dimensions, and (ii) dominates y in one dimension, while being dominated in the other dimension. When given a choice from the set $\{x, y\}$ the decision maker chooses y and when given a choice from the set $\{x, y, z\}$ he chooses x . This is known as the *asymmetric dominance effect* or the *attraction effect*.
 (a) Within the neoclassical framework, does such an individual have a well-defined utility function?
 (b) How can you explain this effect using prospect theory?
25. Suppose that a decision maker who uses prospect theory faces the following lottery with two outcomes 0, x such that $x < 0$.

$$L = (0, 1 - p; x, p) \text{ where } x < 0.$$

Suppose that the utility function for losses is given by $u(x) = -2.5\sqrt{-x}$ and we treat the reference point r as zero wealth (so $u(0) = 0$). Let us use the Prelec weighting function, $w(p) = e^{-\beta(-\ln p)^\alpha}$ with $\alpha = 0.5$, $\beta = 1$. Show that depending on the value of p , such a decision maker can be both risk loving and risk averse. In particular, show that there is a cutoff point $p^* = 0.0183$ such that $w(p^*)^2 = p^*$, and (i) for $p^* < 0.0183$, the decision maker is risk averse, while (ii) for $p^* > 0.0183$, the decision maker is risk loving.

26. (Loomes et al., 1992) This exercise highlights various features of regret theory.
 (a) (Violation of transitivity under regret theory) Suppose that we have three states of the world, s_1, s_2 , and s_3 ; each occurs with probability $\frac{1}{3}$. There are three actions, A_1, A_2 , and A_3 ;

outcomes corresponding to these actions in the various states ($x_1 < x_2 < x_3$) are given in the following table.

	$s_1(1/3)$	$s_2(1/3)$	$s_3(1/3)$
A_1	x_1	x_2	x_3
A_2	x_3	x_1	x_2
A_3	x_2	x_3	x_1

Actions A_1, A_2, A_3 are said to be *stochastically equivalent* because the three states are equiprobable. Suppose that $A_1 \prec A_2, A_2 \prec A_3$ and $A_3 \prec A_1$, which violates transitivity. Can regret theory account for this pattern of intransitivity?

(b) (Violation of monotonicity): Suppose that we have only two actions, A_1, A_2 . The outcomes are shown in the following table:

	$s_1(\frac{1}{3})$	$s_2(\frac{1}{3})$	$s_3(\frac{1}{3})$
A_1	x_1	$x_2 + \epsilon$	x_3
A_2	x_3	x_1	x_2

where $\epsilon > 0$ is a sufficiently small number, so that $x_2 + \epsilon < x_3$ and

$$\frac{1}{3}R(x_3, x_1) + \frac{1}{3}R(x_1, x_2 + \epsilon) + \frac{1}{3}R(x_2, x_3) > 0. \quad (4.25)$$

Show that $A_1 \prec A_2$ but A_1 first order stochastically dominates A_2 .

27. (al-Nowaihi and Dhami, 2010a,b) Suppose that a decision maker can suffer the loss, $L > 0$, with probability $p \in (0, 1)$. He/She can buy coverage, $C \in [0, L]$, at the cost rC , where $r \in (0, 1)$ is the *premium rate* (which is *actuarially fair* if $r = p$). Hence, with probability, $1 - p$, the decision maker's wealth is $W - rC$, and with probability p , her wealth is $W - rC - L + C \leq W - rC$. Suppose that the reference point of the individual is the status quo, i.e., $y_0 = W$, the utility function is the power form in Equation (2.20) with $\gamma^+ \simeq \gamma^- = \gamma$, and the objective function is given in Definition 2.34. Assume that we have actuarially fair premium, $r = p$.
 - (a) Show that the optimal purchase is either zero or full coverage, i.e., $C^* = 0$ or $C^* = L$.
 - (b) What is the predicted insurance purchase under PT?
 - (c) What is the predicted insurance purchase under composite prospect theory (CPT)?
 - (d) Two kinds of insurance behavior are observed for low probability losses. Kunreuther et al. (1978) report little or no take-up of insurance for many individuals. However, Sydnor (2010) reports over-insurance for modest risks for many individuals. Can CPT account for these conflicting findings?
28. (al-Nowaihi and Dhami, 2010a) Consider the same setup as in Problem 27:
 - (a) Suppose that a decision maker faces a loss, L , with probability $p = 0.001$. Recall the formal definition of CPT in Section 2.11.3. Motivated by the insurance data from Kunreuther et al. (1978), suppose that the CPF is given by

$$w(p) = \begin{cases} e^{-0.61266(-\ln p)^2}, & \text{i.e., } \alpha = 2, \beta = 0.61266, & \text{if } 0 \leq p < 0.25, \\ e^{-(-\ln p)^{\frac{1}{2}}}, & \text{i.e., } \alpha = 0.5, \beta = 1, & \text{if } 0.25 \leq p \leq 0.75, \\ e^{-6.4808(-\ln p)^2}, & \text{i.e., } \alpha = 2, \beta = 6.4808, & \text{if } 0.75 < p \leq 1. \end{cases} \quad (4.26)$$

In this case (i.e., $p = 0.001$) the findings of Kunreuther et al. (1978) show that only 20% of the decision makers insure. Suppose that the utility function of the decision maker is given in (2.20) with $\gamma^+ \simeq \gamma^- = \gamma = 0.88$.

(a1) For decision makers who use PT, the probability weighting function is the standard Prelec function with $\beta = 1$ and $\alpha = 0.50$, i.e., $w(p) = e^{-(\ln p)^{0.50}}$. Show that such a decision maker will fully insure.

(a2) Consider decision makers who use CPT. Decision makers who belong to the fraction $1 - \mu$ use PT and so, as in (a), will fully insure. Now consider those who belong to the fraction μ . They use the composite Prelec function given in (4.26). Show that these individuals will not insure.

(b) Let the probability of the loss be $p = 0.25$ (instead of $p = 0.001$). Kunreuther's (1978) data shows that 80% of subjects in experiments took up insurance in this case. Show that the predictions of both PT and CPT are in close (but not perfect) conformity with the evidence.

(c) What do we learn from comparing the (correct) answers to parts (a) and (b)?

29. (Dhami and al-Nowaihi, 2013) Suppose that income from legal activity is $y_0 \geq 0$ and income from an illegal activity is $y_1 \geq y_0$. Hence, the benefit, b , from the illegal activity is $b = y_1 - y_0 \geq 0$. If engaged in the illegal activity, the individual is caught with some probability p , $0 \leq p \leq 1$. If caught, the individual is asked to pay a fine F . Assume that we have the *hyperbolic punishment function* $F = \varphi(p) = b/p$.²

(a) Consider a decision maker with continuously differentiable and strictly increasing utility of income, u . Show that under EU, if the decision maker is risk neutral, or risk averse, then the hyperbolic punishment function $\varphi(p) = \frac{b}{p}$ will deter crime. It follows that given any probability of detection and conviction, $p > 0$, no matter how small, crime can be deterred by a sufficiently large punishment. This is the *Becker proposition* alluded to in the text (see Proposition 22).

(b) Now suppose that the decision maker uses PT or CPT and that the reference incomes from the two activities, crime and no-crime, are, respectively, y_R and y_r . If a decision maker commits a crime, and is caught, then assume that the outcome ($y_1 - F$) is in the domain of losses (i.e., $y_1 - F - y_R < 0$). If he commits a crime and is not caught, then assume that the outcome, y_1 , is in the domain of gains (i.e., $y_1 - y_R > 0$). The recent literature has sometimes made the case for the reference point to be the rational expectation of income and also the state-dependent reference point.³ In the spirit of these suggestions, suppose that the expected income from each activity is the reference point. Thus, $y_r = y_0$ and $y_R = y_1 - p\varphi(p)$. Assume the power form of utility in (2.20) with $\gamma^+ = \gamma^- = \gamma$.

(b-1) Show that as the probability of detection approaches zero, a decision maker using PT does not engage in the criminal activity.

(b-2) Show that as the probability of detection approaches zero, under CPT, the fraction μ of individuals is not deterred from the criminal activity (which is consistent with the empirical evidence reviewed in the text). Why does CPT give a better account of criminal behavior?

² al-Nowaihi and Dhami (2012) show that the hyperbolic punishment function is optimal for a wide class of cost of deterrence and damage from crime functions. Furthermore, it provides an upper bound on punishments for a large and sensible class of cost and damage functions. Thus, if the hyperbolic punishment function cannot deter crime, then neither can the optimal punishment function, if different from the hyperbolic.

³ See, for instance, Koszegi and Rabin (2006, 2009). The act dependence of the reference point that we use is also consistent with the third generation prospect theory of Schmidt et al. (2008).

30. (al-Nowaihi and Dhami, 2010a) Rieger and Wang (2006) show that the St. Petersburg paradox re-emerges under PT. How can the St. Petersburg paradox be resolved under CPT?
31. Prove Proposition 3.33.
32. (Loss aversion as an explanation of the St. Petersburg paradox; Camerer, 2005) Consider the gamble set out in the St. Petersburg paradox in Exercise 3. Bernoulli explained this paradox by using a concave utility function with EU.⁴ Camerer (2005) showed that the paradox could also be explained by using loss aversion and OPT/PT. Suppose that a casino, which offers the gamble has a budget of $\$b$, which is the maximum possible payout. Let m be the number of trials such that if a head first came out on the m th trial, the maximum possible payout would be just about exhausted. Suppose that $b = \$1\text{billion}$ (check this implies $m = 30$). Thus, if a head came up on any trial beyond the 30th, then the casino will not be able to honor the terms of the gamble. Suppose that the gamble is purchased for a price equal to P and the decision maker has the piecewise linear utility function,

$$u(x) = \begin{cases} (2^j - P) & \text{if } 2^j \geq P \\ \lambda(2^j - P) & \text{if } 2^j < P \end{cases} \quad (4.27)$$

For some n , let $2^n < P < 2^{n+1}$ and use the identity weighting function $w(p) = p$.

Show that the imposition of a concave utility function is not a necessary condition for resolving the St. Petersburg paradox. Loss aversion also provides a sufficient condition for the resolution of the paradox.

33. (Birnbbaum, 2008) Consider the Birnbbaum critique of PT in Section 2.9.1. Suppose that decision makers obeyed the three principles—transitivity, coalescing, restricted branch independence (RBI). Then show that there can be no Allais paradox.
34. Prove Proposition 2.16(b).
35. Prove Proposition 3.35.
36. Prove Proposition 3.37.
37. Consider the Bayesian approach to uncertainty (SEU). In SEU, beliefs are required to be updated using Bayes' rule. However, Bayesian analysis is agnostic as to the source of beliefs. Evaluate the implications for SEU of the following two scenarios.
- (a) Consider two alternative ways of forming subjective beliefs, $\mu(E_i)$. In one case, the decision maker uses an actual accurate historical record to construct $\mu(E_i)$. In another, the decision maker is ignorant of any data and merely uses a hunch to construct $\mu(E_i)$. For instance, the decision maker can use the *principle of insufficient reason* and simply assign each of the n outcomes a subjective probability equal to $1/n$.⁵ Schmeidler (1989) argued that the two probabilities feel very different.
- (b) Beliefs can sometimes be updated without any apparently new information being available as, for instance, in the *fact-free learning theory* of Aragonés et al. (2005).

⁴ Bernoulli used the logarithmic function.

⁵ The principle of insufficient reason may be more reasonable to apply in problems where the alternatives appear to be relatively more symmetric.

PART 2

Other-Regarding Preferences

INTRODUCTION TO PART 2

Neoclassical economic theory typically relies on the assumption of *self-regarding* behavior, i.e., that individuals derive utility solely from their own pecuniary or non-pecuniary payoffs. We may term such preferences as *self-regarding preferences* and an individual with these preferences as a *self-regarding individual*.¹ This view of human behavior is often at odds with the evidence, particularly when interaction in small groups is considered but also, often in large-group interactions.

The evidence indicates that humans often exhibit direct or indirect concern about others for several reasons. As Gintis (2009, p. 49) puts it “We conclude from behavioral game theory that one must treat individuals’ objectives as a matter of *fact*, not *logic*.” Individuals may care for others on moral grounds, or they may directly care about the pecuniary and non-pecuniary payoffs of others, or they may derive a *warm glow* from helping those who are less unfortunate, or they may wish to punish others in the group whose treatment of them or of others in the group does not conform to expectations, or they may wish to signal desirable human qualities such as altruism or kindness to themselves and to others. In all these cases, humans exhibit *other-regarding preferences* (sometimes referred to as *social preferences*).

Part 2 of the book studies the behavior of individuals with other-regarding preferences.

The model with purely self-regarding preferences is unable to explain a range of phenomena from many diverse areas such as social dilemma situations, collective action, contract theory, the structure of incentives, political economy, and the results of several experimental games. By contrast, many of these phenomena can be explained by a model, which recognizes that individuals have other-regarding preferences. On the other hand, many phenomena such as the behavior of competitive experimental market subjects seem to be in conformity with the model of self-regarding preferences (Roth et al., 1991).² However, in richer competitive environments, one still recovers a role for other-regarding preferences (Fehr et al., 1998). One challenge for theoretical research is to describe why the same individual exhibits other-regarding preferences in small groups, or in bilateral interactions but self-regarding preferences in anonymous, large-group, market situations; see Fehr and Schmidt (1999) for a successful example of such a behavioral model.

Most experiments reveal a mixture of self-regarding and other-regarding preferences, but the relative fractions of players who exhibit the two types of preferences vary. For instance, Fischbacher et al. (2001) show that 30–40% may have self-regarding preferences while the remaining may have other-regarding preferences. An important and interesting issue for theoretical and empirical research is to examine the implications of such heterogeneity in preferences. We shall

¹ The literature sometimes uses the term *selfish preferences* for *self-regarding preferences*. For most of the models that we consider, individuals try to maximize their objective functions, whether they have self-regarding or *social preferences*. For this reason, we find the term self-regarding to be more appropriate.

² Interestingly, in the Roth et al. (1991) experiments, bilateral behavior of subjects is consistent with models of social preferences. This dichotomy of behavior in multilateral and bilateral settings is not simply a figment of experimental data. Bolton and Ockenfels (2014) confirm these experimental findings from a field study based on eBay transactions. This also adds to a growing number of field studies that increasingly establish the external validity of lab experiments, a theme that we consider in more detail in Section 5.5.

show that the introduction of even a small fraction of individuals with other-regarding preferences in a model with self-regarding preferences can substantially alter the results and vice-versa.

Evidence for other-regarding preferences comes from many sources. Consider the following examples; the reader is invited to ponder if the model with purely self-regarding preferences could account for these results.³

1. Wages are usually not lowered in a recession as firms fear that this action may be construed by the workers to be *unfair* and have a negative effect on worker's *morale* (Bewley, 1999, 2005). The experimental findings of Fehr et al. (1993) and Fehr and Falk (1999) demonstrate that downward wage rigidity is caused by the belief on the part of employers that workers will reciprocate lower wages with lower levels of effort. For instance, in a double auction experiment, Fehr and Falk (1999) showed that employers accepted high wage offers in excess of the competitive level when the effort was endogenous. However, when the workers' effort was exogenously fixed, firms accepted the lowest wage offers. Thus, firms did not accept high wage offers purely for fairness considerations but rather because they expected effort reciprocity on the part of workers. In actual practice, firms may prefer to hire workers who have other-regarding preferences because they may be expected to reciprocate positive actions by the firms and other co-workers in the team.
2. Consider a two-stage public goods game, where individuals make voluntary contributions to a public good, followed by the possibility of non-contributors being punished by the contributors. The model with purely self-regarding preferences predicts *free-riding*, i.e., zero contributions and no punishment of non-contributors by the contributors because bygones are bygones. In contrast, the experimental results show that individuals contribute more when others contribute more in previous rounds (Fischbacher et al., 2001). In experiments in many Western societies, we also observe the punishment of non-cooperators by cooperators and close to the first best level of contributions (Fehr and Gächter, 2000).
3. In one-shot interactions, in a range of experimental games considered below, such as the ultimatum game, the dictator game, and the trust game, people pass on far higher monetary amounts to others than are predicted by models of self-regarding preferences.
4. Kahneman et al. (1986) asked people if they would view a hardware store's action to increase the price of shovels following a snowstorm as fair? Most people thought that such a price increase was unfair. However, they did not perceive an increase in price following an increase in the cost of inputs as unfair. In actual practice, many firms may go to great lengths to establish their credentials for fair behavior.
5. Bargaining often stalls (*bargaining impasse*) in a range of situations, such as civil litigation, labor unrest, domestic strife, and clashes among religious and ethnic groups. An important psychological cause of bargaining impasse is that typically, individuals confuse between what serves their self interest and what is fair (Babcock and Loewenstein, 1997).⁴

³ It is possible that self-regarding preferences in conjunction with other auxiliary assumptions may explain these examples. However, if these assumptions are empirically rejected, then such explanations are ad hoc.

⁴ We do not specially focus on bargaining issues in Part 2; these are considered in more detail in Part 4. Some of the reasons for bargaining impasse are as follows. First, confusion between self-interest and what is fair, reduces the set of feasible agreements. Second, if each party believes that its (misplaced) notion of fairness is shared by the other party, then even potentially kind intentions by the other party could be perceived as being unkind. Third, psychological evidence indicates that parties in a bargaining situation are unwilling to settle below what they (mistakenly) perceive to be a fair entitlement. The reader might also wish to read a nice discussion of bargaining issues related to the issue of norms and social preferences in Crawford (1997, Section 5.3).

6. Individuals make donations to charity, donate blood at Red Cross blood drives, and often volunteer time and money for prosocial actions. Such prosocial actions are often carried out for the benefit of non-kin members at a personal cost. The provision of monetary incentives for prosocial behavior may even be counterproductive (Titmuss, 1971; Bénabou and Tirole, 2003, 2006).
7. In one-shot interactions, such as in the trust game, pre-game *promises* and *threats* are predicted to be ineffective in altering behavior. Yet, such promises and threats are effective in generating more prosocial behavior (Ellingsen and Johannesson, 2004). Indeed, humans seem to value virtuous behavior such as honesty, fairness, and justice for its own sake; in neoclassical economics such behavior is instrumental *but not intrinsic*.
8. In one-shot interactions, when firms have a choice between a bonus contract and an incentive contract, the model with self-regarding preferences predicts the choice of an incentive contract. Bonus contracts should be ineffective in eliciting any effort from workers. Yet, we observe the predominant choice of bonus contracts in such a situation and much higher effort levels as well as profitability relative to incentive contracts (Fehr et al. 2007).
9. Military training programs typically focus on creating a separate identity—the identity of a soldier, in contrast to a civilian identity. A soldier's identity is associated with norms of behavior in particular situations that can be different from civilian norms of behavior in similar situations. These include the norms of *service before self*, courage, sacrifice, and fortitude under adversity. Similarly, firms try very hard to alter the identity of workers into *insiders* from *outsiders*. Insiders typically buy into the culture of the firm and subscribe to its objectives.

There has been a traditional aversion in economics to altering preferences/tastes in order to explain economic phenomena. This aversion may have been historically well-placed because the alternative could have been a proliferation of ad-hoc models with preferences tailored to explain every possible situation. However, research in behavioral economics has provided a solid foundation, based on extensive experimental evidence, to propose models of other-regarding preferences. This is not ad hoc, and has enormously increased the ability of economic models to explain economic phenomena. Conversely, one may argue that in the face of overwhelming evidence that many humans exhibit some form of other-regarding preferences, it is ad hoc to focus exclusive attention on self-regarding preferences. As Gintis (2009, p. 49) puts it: “Self-regarding agents are in common parlance called sociopaths.”

The argument that neoclassical economics does not rule out the role of other-regarding preferences is correct. Indeed, an older generation of economic models considered ideas such as *keeping up with the Joneses*, and *snob consumption* (Veblen, 1899; Duesenberry, 1949). However, while plausible, these models were not empirically well-founded and would not be able to explain the results from modern experimental games on fairness and reciprocity. In contrast, the current approach in behavioral economics offers empirically well-founded and parsimonious models of other-regarding preferences.

Let us consider some terminology that is used in models of other-regarding preferences. This terminology is by no means standard, partly because its origin straddles several disciplines such as economics, biology, anthropology, and sociology. Hence, we simply clarify the sense in which various terms are used in this book, without claiming that such usage is unique or the best possible.

Preferences are *altruistic* (respectively, *spiteful*) if one's utility is increasing (respectively, decreasing) in the consumption or well-being of others. Altruism is *unconditional kindness*, while spite is *unconditional unkindness*, irrespective of the behavior of other players. In practice, however,

pure altruism is unable to explain a wide range of behaviors. For instance, it does not explain why many individuals are *conditional cooperators*, i.e., they cooperate only when others cooperate (as in successive rounds of a public goods game).⁵ An *inequity averse* individual not only derives utility from own material consumption but also derives disutility from differences in own material consumption relative to the consumption of others. Such an individual dislikes relatively greater consumption (altruism) or relatively lower consumption (envy).

Reciprocal behavior can also be shown to arise in traditional economic analysis with self-regarding preferences. In classical game theory, in infinitely repeated games (or finitely repeated games with some uncertainty), cooperative behavior can be sustained in equilibrium. Such behavior is said to be *instrumentally reciprocal* because it is motivated purely by the prospect of a trade-off between short-run and long-run material gains.⁶ By contrast, in a finitely repeated game, say, in a principal–agent relation, under self-regarding preferences, the outcome is that the worker shirks and output is low. However, under other-regarding preferences, theory and empirics support superior cooperative outcomes (Brown et al., 2004, 2012). Thus, the evidence violates instrumental reciprocity here, and in many other classes of games.

Reciprocity that takes the form of responding to kindness and unkindness of others with like behavior, even in the absence of long-term gains and under complete certainty, may be termed as *intrinsic reciprocity*. People who exhibit such behavior are often described as *conditional cooperators*. Many important behavioral explanations on human sociality rely on *intrinsic reciprocity*.

Altruism among kin members in humans is well documented (Daly and Wilson, 1988). However, among humans, one observes cooperation among non-kin group members and impressive division of labour at a level that is unprecedented in the animal kingdom. Cooperation is much lower in primate societies with whom we share a common ancestor. Cooperation is well documented among ants, bees, and wild dogs, but this seems limited to genetic relations. Furthermore, humans are possibly unique among all animals to consider the fairness implications of their actions for kin and non-kin members.

An important component of human sociality is that group members often engage in costly punishment (respectively, costly rewards) of actions by third parties that are inimical (respectively, favorable) to some social goal or group norm. The punishers may not be directly affected by the actions of the third parties, yet they chose to punish/reward. Such costly punishment also takes place in finitely repeated games with no uncertainty, and no kin relation among group members. This form of reciprocity may be termed as *indirect reciprocity* and plays an important role in upholding group norms and social goals.

Strong reciprocity is a more encompassing concept that includes conditional cooperation and indirect reciprocity. Bowles and Gintis (2003) provide a working definition of strong reciprocity:

A strong reciprocator comes to a new social situation with a predisposition to cooperate, is predisposed to respond to cooperative behavior on the part of others by maintaining or increasing his level

⁵ Axelrod and Hamilton (1981) conducted the classic experiments in reciprocity in the context of a sequence of repeated prisoner's dilemma games where there is some probability of the continuation of the game to the next period; see, also Axelrod (1984). They found evidence for the superiority of the tit-for-tat strategy when subjects are randomly matched in each round of the game. In this strategy, subjects initially start by cooperating and then reciprocate in subsequent rounds, i.e., based on their experience in previous rounds, play defect in response to defect and play cooperate in response to cooperate. Such a strategy did best among the ones that were considered.

⁶ A related concept from biology is that of *reciprocal altruism*. This involves a tendency to reward or punish others in response to their kind or unkind behavior, when such net rewards are in the long-term interests of the animal/individual. See, for instance, Axelrod and Hamilton (1981) and Trivers (1971).

of cooperation, and responds to free-riding behavior on the part of others by retaliating against the offenders, even at a cost to himself, and even when he cannot reasonably expect future personal gains from such retaliation. The strong reciprocator is thus both a conditionally altruistic cooperator and a conditionally altruistic punisher whose actions benefit other group members at a personal cost.

In what follows, when there is no confusion, we shall mostly use the generic term reciprocity to denote various forms of reciprocity. How can we distinguish among various reciprocity concepts such as instrumental reciprocity, intrinsic reciprocity, and strong reciprocity? The solution is provided by carefully constructed experiments that are able to conduct sharp tests of the competing hypotheses and disentangle the various confounding factors. We shall review a range of such experimental studies below.

There are four chapters in Part 2. We give a very brief introduction here; a more detailed introduction follows in each chapter.

Chapter 5 considers the empirical evidence on other-regarding preferences using a range of experimental games. These games include the *ultimatum* and *dictator games*, the *trust* and *gift exchange games*, and the *public goods game* with and without punishments. In this chapter, we also consider the external validity of lab experiments and the issue of the student subject pool (see also the introduction to the book). We show that lab evidence is representative of real-world human behavior, and if anything, the student subject pool delivers results in favor of the self-regarding model.

Chapter 6 considers models of *social preferences*, *type-based reciprocity*, *intentions-based reciprocity*, and other *hybrid models*.⁷ We not only consider the leading theoretical models but also use empirical evidence to evaluate the relative success of the models. We show how these models can be used to explain the empirical evidence in Chapter 5. We give applications to behavioral political economy, and develop appropriate stochastic dominance concepts in the presence of other-regarding preferences. We also draw the implications of other-regarding preferences for a Walrasian competitive equilibrium as well as for the fundamental welfare theorems. A wide range of further applications is given in each of the successive chapters.

Chapter 7 considers two new topics, *human morality* and *social identity*, both of which are not traditionally considered in courses in neoclassical economics, which is amoral. We first give the evidence on human morality, such as the aversion to lying, aversion to breaking promises, and wishing to uphold one's integrity. This is followed by an application to the hold-up problem in industrial organization. We then consider the evidence on social identity and explore applications on incentives in organizations.

Chapter 8 is the longest chapter in Part 2. It considers issues of moral hazard and asymmetric information in the presence of other-regarding preferences, and the literature on complete and incomplete short- and long-term contracts. Unlike many treatments of contract theory, we also closely consider the evidence on alternative contractual forms as well as the theoretical models and the relevant empirical evidence on *extrinsic* and *intrinsic motivation*.

⁷ The formal development of intentions-based reciprocity requires the use of *psychological game theory*, so it is postponed to Part 4 of the book.

CHAPTER 5

The Evidence on Human Sociality

5.1 Introduction

In this chapter, we review the evidence from several kinds of experimental games. These include the *ultimatum game*, the *dictator game*, the *gift exchange game*, and *public goods games* with and without punishments. In small group interaction, particularly in bilateral interaction, these experiments reject the notion that humans have purely self-regarding preferences. The behavior of a majority of people is consistent with other-regarding preferences and conditional reciprocity, although a significant minority exhibits purely self-regarding preferences. An important finding, from these experiments, is that the introduction of a small fraction of individuals with other-regarding preferences in a population of self-regarding individuals can result in a large change in the outcomes (Fischbacher et al., 2001; Fehr and Fischbacher, 2005; Fischbacher and Gächter, 2010).

Section 5.2.1 considers the ultimatum game, one of the most widely replicated experimental games in economics. In this two-player game, originally introduced by Güth et al. (1982), a *proposer* proposes to share a part of his endowment with a *responder*. The only action of the responder is to accept or reject. If accepted, the split proposed by the proposer is implemented, but if rejected, both get nothing. The prediction under self-regarding preferences is that the responder will be offered the smallest indivisible part of the endowment by the proposer. By contrast, the results are consistent with other-regarding preferences. Mean offers are 30–40% of the endowment and the median offers are 40–50% of the endowment.

These results continue to hold when the stakes are raised, say, up to an equivalent of about 62 hours of work (Slonim and Roth, 1998). But, for extremely large stakes, equivalent to 1600 hours of work, the responders' rejection rates fall but the median offer by the proposer is still about 20% of the endowment (Andersen et al., 2011). However, these stakes are too large relative to those that are commonly observed in real life among individuals. The evidence also indicates that there is some interaction between experience and the choices made in the ultimatum game but the self-regarding outcome is still not achieved. It would seem, therefore, that for most people other-regarding preferences are very hard to switch-off and most of us may be intrinsically disposed to exhibit at least some altruism and reciprocity, even when the stakes are reasonably high. We postpone a formal definition of *reciprocity* to Chapter 13, where we introduce the machinery of psychological game theory. For the moment, humans exhibit reciprocity if they respond to the kind actions of others with kindness, and unkind actions with unkindness.

It has been alleged by some critics that subjects play prosocially in ultimatum games because they mistakenly apply repeated game heuristics to an essentially static but multi-stage game (Binmore, 1998). However, the evidence from ultimatum games does not support this view (Fehr and Fischbacher, 2002). There is wide variation in the offers made by proposers and in the rejection rates of responders in different societies (Henrich et al., 2001). This cautions us against generalizing results too much from one culture to another. Interestingly, contrary to what students of economics may have been led to believe, offers and rejection rates are higher in societies where market exchange is more prevalent, although the direction of causality is difficult to establish with the available evidence. Indeed, market exchange requires a high degree of interpersonal trust especially because contracts may often be verbal and informal.

In Section 5.2.2, we consider the dictator game, which is a variant of the ultimatum game in which the responder has no actions, so the proposer's proposed split is always implemented. Nevertheless, proposers still make a mean offer of about 15–20% of the endowment in this case (Forsythe et al., 1994). This establishes two results. (i) Since the mean offer is lower relative to the ultimatum game, high offers in the ultimatum game arise partly for strategic reasons, i.e., to ensure acceptance of the offer by conditionally cooperative responders. (ii) Since the mean offers are strictly positive in the dictator game, proposers exhibit altruism.

Recent scholarship gives a more nuanced view of the results from dictator games. A distinction has been drawn between *genuine altruists* and *reluctant altruists* (Dana et al., 2006). A reluctant altruist is someone who, for instance, may give money to a beggar should he unexpectedly run into one, but prefers to be on the other side of the road if he spots a beggar from the distance. There are many reasons why people seem to behave more altruistically in dictator games when they perceive they are being watched (Haley and Fessler, 2005). For instance, people may have beliefs about the expectations of others about their actions, and they may dislike falling short of these expectations (*guilt*). Emotions such as guilt may directly enter one's utility function. Formal modeling of these issues requires the machinery of *psychological game theory* that is considered in Part 4 (Geanakoplos et al., 1989; Battigalli and Dufwenberg, 2009). Another potential explanation is that *identity* and *self-esteem* may be important determinants of the desire to appear fair to oneself and to others (Bénabou and Tirole, 2011).

In Section 5.2.3, we consider dictator game experiments that allow us to draw inferences about the rationality of subjects (Andreoni and Miller, 2002). Subjects in these experiments reveal that they have other-regarding preferences because there are strictly positive offers in the dictator game, yet the same subjects satisfy the *generalized axiom of revealed preference* (GARP). Hence, there is nothing irrational about other-regarding preferences.

Section 5.3 considers two related games, the *gift exchange game* and the *trust game*. We first consider the gift exchange game (Fehr et al., 1993; Fehr et al., 1997) in Section 5.3.1. A firm (player 1) makes a contract offer (w_b, e_n) to a worker (player 2) that specifies a binding wage level, w_b , and a non-binding effort level, e_n . The contract may offer *positive rents* to the worker, i.e., a wage (net of effort costs) that is greater than the outside option. If the contract is accepted, the worker chooses an actual effort level, e_a . Since the wage is binding, if workers have self-regarding preferences, they should shirk, i.e., $e_a = 0$. Anticipating this, firms should offer $w_b = 0$, so the rents of workers should be zero. By contrast, the experimental findings are that (i) workers are offered positive rents, and (ii) the rents and actual effort levels of workers are highly positively correlated. These results provide important confirmatory evidence for other-regarding preferences. In experiments that allow firms to punish shirking workers when $e_a < e_n$, results show that shirking is significantly reduced. If the firm were self-regarding, punishments should be ineffective because bygones are bygones in classical game theory.

The results of experiments in the gift exchange game have been extended in several directions. The effects of a wage decrease may have a more pronounced effect on effort as compared to wage increases (Kube et al., 2006). Although the sample sizes are small, this result is consistent with the findings of Bewley (1999) that firms are reluctant to cut wages in a recession. As in the ultimatum game, there are cultural differences in the degree of sociality in the gift exchange game (Charness et al., 2004). Fehr et al. (1998) embed a gift exchange game within competitive markets where quality is endogenous. They find substantial departures from the competitive equilibrium outcome. Thus, current competitive equilibrium experiments (see Part 4 of the book) that justify the equilibrium outcome may not be rich enough to deal with all the relevant aspects. The idea that sociality may survive and affect outcomes in competitive markets is one of the most important results in Part 2 of the book.

When the gift exchange game is played with a firm and two or more workers, then additional insights emerge, depending on the relative pay and effort levels of the workers. It turns out that the degree of sociality in gift exchange games is influenced by the degree of *social comparisons* in the workplace (Gächter et al., 2012; Abeler et al., 2010; Cohn et al., 2011). The degree of sociality also depends on whether the workers' rent is monetary or non-monetary (Kube et al., 2012). Recent work explores the *duration effects* of the gift exchange relation. Gneezy and List (2006) conclude that the effects are short-lived. However, Bellemare and Shearer (2007) find that the short-lived effects only apply to workers who are hired on the spot market. By contrast, workers with longer tenure exhibit stronger reciprocity and long-lived effects of gift exchange. The predictions of the gift exchange game are confirmed by survey evidence (Dohmen et al., 2009).

In the gift exchange game, the total surplus is controlled by player 2, the worker, who exerts mutually beneficial effort. In Section 5.3.2, we consider the *trust game* in which player 1 determines the surplus in the relation (Berg et al., 1995). Both players are given an identical initial endowment, $e > 0$, by the experimenter. Player 1, the *trustor*, chooses an investment, $i : 0 \leq i \leq e$. The experimenter then multiplies this investment by a number $m \geq 1$ and passes it on to player 2, the *trustee*. The trustee voluntarily returns an amount of money $r : 0 \leq r \leq mi + e$ to the trustor. The numbers i (investment) and r (return) are, respectively, taken as measures of *trust* and *trustworthiness*. If players are self-regarding, then the subgame perfect outcome of the trust game is $i = r = 0$. By contrast, the meta-study of Johnson and Mislin (2011) shows that, pooling across all regions, trustors invest 50.2% of their endowment and trustees return 37.2% of the feasible amount. But there is significant regional heterogeneity (e.g., North Americans send back significantly more than Africans), older people are more trusting, students are less trusting, stakes do not appreciably affect the results, and the results depend on the value m . Overall, these results confirm the presence of other-regarding preferences and intrinsic reciprocity.

When subjects have an opportunity to examine the history of the other player in trust games, most players choose to do so. Interestingly, subjects may use the past levels of "trust" exhibited by other players to also infer their "trustworthiness," suggesting that these two human virtues may be correlated (Charness et al., 2011). In an interesting experiment, Eckel and Petrie (2011) offer subjects a chance to view a photograph of their opponent at a price. They find that there is a stable demand curve for these photographs. Conditional on having observed the opponent's picture, players behave more prosocially. White trustors discriminate between white and black trustees, investing more if the trustee is white. Black trustors do not discriminate. There are hardly any gender differences in prosocial behavior. On the whole, there appears to be an information value in a face.

Section 5.4 considers *public goods games*. Section 5.4.1 considers the basic model *without punishment* and Section 5.4.2 *with punishments*. In these games, a group of individuals simultaneously

choose their level of contributions to a public good that is non-rival in consumption and non-excludable. For each extra unit of contributions to the public good, an individual receives some private per unit benefit from the public good that is less than the private marginal cost of the contribution. If all contributors have self-regarding preferences, then the unique prediction of the model is that all players will *free-ride*, i.e., each player will contribute zero. In the model with punishments, there is a second stage in which, once the contributions are revealed, players can engage in costly punishments of other players. However, under self-regarding preferences, in the second stage, bygones are bygones, so players should not punish others. Without the threat of punishments, the predicted results with and without punishments are identical, i.e., everyone free-rides.

The evidence from public goods games, in Section 5.4.3, rejects the predictions of the self-regarding model, irrespective of whether punishments are available or not (Fehr and Gächter, 2000). In the absence of punishments, contributions typically start off from a high level and then gradually decay over successive rounds of the experiment. Self-regarding preferences cannot explain the pattern of decay, nor the reason why contributions start off from a high level, once the game is restarted. When punishments are allowed, then the outcome is close to the first best. Contributors punish non-contributors when the game is played in most Western countries where the *rule of law* and the *norm of civic cooperation* are high (Herrmann et al., 2008).

The evidence on various aspects of the public goods game is rich and extensive. The negative net effects of punishments that are sometimes found when the experiment is repeated over a few rounds, typically 10, are reversed when the experiment is repeated a large number of times, say, 50 rounds (Gächter et al., 2008). This informs our view of why punishments may have evolved; they are efficiency enhancing in enforcing social norms, provided the game is played over sufficiently many rounds. A combination of rewards and punishments elicits even greater cooperation as compared to the use of these instruments on their own (Sefton et al., 2007). Non-monetary punishments such as ostracization may also be effective in securing cooperation (Masclét et al., 2003; Cinyabuguma et al., 2005). Endogenous group formation in which players or the experimenter choose group members based on their past contributions influences contributions (Chaudhuri and Paichayontvijit, 2006; Gächter and Thöni, 2005; Page et al., 2005). Face to face communication enhances cooperation, but it is predicted to be ineffective under self-regarding preferences (Bochet et al., 2006). Publicly given, intergenerational, advice achieves nearly 90% of the socially optimal contributions (Chaudhuri et al., 2006).

In Section 5.4.4, we consider an explanation of the pattern of contributions in public goods games based on heterogeneous other-regarding preferences (Fischbacher et al., 2001; Fehr and Fischbacher, 2005; Fischbacher and Gächter, 2010). This model highlights two fundamental features of many social dilemma situations. (i) There is a mix of people with self-regarding and other-regarding preferences. (ii) There are profound implications of having even a small fraction of subjects with one type of preferences in the presence of the other type. Suppose that in a public goods game, a majority of the subjects have other-regarding preferences and we begin with initially high levels of cooperation. Then the presence of a minority of subjects with self-regarding preferences may drive contributions to low levels. The reason is that over successive rounds of the game, as contributors discover that some of the other players are free-riders, negative reciprocity kicks in, and they respond with successively lower contributions. Thus, we cannot conclude, by observing a lack of cooperation, that most players have self-regarding preferences.

In Section 5.4.5, we consider games in which two rival groups expend costly resources to win a contest and the prize is shared equally among the members of the winning group (Abbink et al., 2010). Thus, the prize has the nature of a public good. Examples include countries going to war,

trade union strikes, and firms lobbying for a government contract. The winning probability, for any group, depends on the relative resources expended. If both groups increase their expenditures in the same proportion, their payoffs fall, but winning probabilities are unaltered. Thus, if the groups can coordinate, they can simultaneously, and proportionally, reduce their expenditures without altering winning probabilities, but increasing their payoffs; this is the sense in which the expenditures are unproductive. Each group, by incurring such expenditures, reduces the winning probability of the other group, a negative externality that it does not take into account. Empirical evidence shows that the unproductive expenditures are much higher than the Nash predictions.

Section 5.4.7 considers cultural differences in the nature of punishments in public goods games (Herrmann et al., 2008). In societies where the *rule of law* and the *norm of civic cooperation* is strong, one observes *prosocial punishments*, i.e., cooperators punish non-cooperators and this enhances prosociality. However, in other societies where one observes a weaker rule of law and a lower norm of civic cooperation, one observes *antisocial punishments*, i.e., non-cooperators may punish the cooperators in revenge for having been punished in the past. This has adverse effects on the level of contributions in public goods games. One reason for the net negative effect on outcomes in the presence of antisocial punishments is that experiments may overstate the extent of punishment opportunities that we observe in society. For instance, societies typically engage in collective punishments through a legal code. It is quite likely that private punishments may be harsher relative to those prescribed by the legal code, however, experiments typically do not distinguish between the two. When one allows for credible punishments over a reasonably high number of rounds, then the net effect of punishments is positive (Gächter et al., 2008).

Section 5.4.7 gives some observations on the evolutionary sources of reciprocity. Part 5 of the book considers this material in far greater detail.

Section 5.5 considers the issue of the *external validity* of lab experiments as well as other possible *biases* in such experiments. The introduction to the book also gives a detailed consideration of these issues, so the treatment here minimizes the degree of overlap between the two. Several concerns have been raised about the validity of lab experiments (Levitt and List, 2007). Section 5.5.1 considers the criticism that the typical experiment is conducted with students, and more prosocial students may have been self-selected into the experiments. Being watched by the experimenter may bias the behavior of subjects in experiments (*experimental scrutiny effects*). Furthermore, students may deliberately appear more prosocial, anticipating that this is what the experimenter desires (*experimenter demand effects*). An increasingly robust finding in the emerging experimental literature is that the student population is less prosocial as compared to the general population (Falk et al., 2013; Carpenter and Seki, 2011; Fréchette, 2015). If anything, this biases the results in favor of the textbook self-regarding model. More prosocial students do not self-select themselves into experiments (Cleave et al., 2012). Experimental scrutiny does not necessarily lead to more prosocial behavior (Barmettler et al., 2012).

In any case, even if experimental scrutiny were important, as is suggested in several experimental papers, then it too makes a powerful case for the importance of other-regarding preferences. If the presence of a stranger (the experimenter) in the room switches on other-regarding preferences, then it is quite plausible that most human activity, which is carried out in the direct presence or indirect presence¹ of others is similarly affected. It would appear that the negative implications of experimental scrutiny may have been exaggerated, even if such scrutiny were important.

¹ For instance, the party that is unfairly treated can disseminate information about an unfair person to others, including legal institutions if the behavior is illegal.

A rapidly expanding body of empirical literature, that we consider in Section 5.5.2, supports the external validity of lab experiments (Camerer, 2015). Japanese fishermen who operate in a collective manner in the field (sharing of costs and the fish catch) are also more prosocial when they play the public goods game in the lab (Carpenter and Seki, 2011). The conditional reciprocity of fishermen estimated in the lab is a significant predictor of their field productivity. Subjects who reveal more self-regarding preferences in the lab are also less likely to increase their effort in the real world, following a wage increase (Cohn et al., 2012).

Shrimpers and fishermen in northeastern Brazil who behave more selfishly in public goods games also behave more opportunistically in the field (Fehr and Leibbrandt, 2011). More prosocial behavior in the lab is correlated with better market performance (Leibbrandt, 2012). In Ethiopia, subjects who cooperate more in the public goods game also behave in a less opportunistic manner in their real-world activity that involves forest management (Rustagi et al., 2010). A greater degree of trustworthiness in trust games predicts a greater likelihood of repaying loans in a microcredit program in Peru (Karlan, 2005). Chicago MBA students who exhibit more trustworthiness in the lab are also more likely to make charitable donations (Baran et al., 2010). Similar results are true for Swiss students (Benz and Meier, 2008).

In a game played between two players, if a third party who has no material stakes in the game, is willing to engage in costly punishments and rewards, then it exhibits *indirect reciprocity* (Gintis, 2009). In the final part of the chapter, in Section 5.6, we consider the extensive evidence in favor of indirect reciprocity (Seinen and Schram, 2001; Engelmann and Fischbacher, 2009; Fehr and Fischbacher, 2004).

5.2 Ultimatum and dictator games

5.2.1 *The ultimatum game*

The *ultimatum game*, introduced by Güth et al. (1982), is played between two players, a *proposer* and a *responder*. The *proposer*, is given an integer amount $\$x$ by the experimenter. Suppose that the smallest indivisible amount of money is one cent. The proposer offers a share $s \in \{0, 0.01, 0.02, \dots, x.00\}$ to the *responder*. If the responder accepts the offer, then the proposer's initial offer is implemented and the payoffs of the proposer and the responder are, respectively, $y_P = x - s$, and $y_R = s$. If the responder rejects the offer, the respective dollar payoffs are $y_P = 0$, and $y_R = 0$.

If both players have self-regarding preferences, then in the subgame perfect outcome the dollar amount of payoffs are $y_P^* = x - 0.01$, $y_R^* = 0.01$. If the amount $\$x$ was infinitely divisible, then the subgame perfect outcome is $y_P^* = x$, $y_R^* = 0$.² The experimental results do not support this prediction. The results have been summarized in several places.³ The gist of the experimental results is as follows. (1) The mean offer is $s = 0.3x$ to $0.4x$. (2) The median offer is $s = 0.4x$ to $0.5x$. (3) There are rarely any unfair offers ($s = 0$ or $0.1x$) or over-fair offers ($s > 0.5x$). (4) Low offers are often rejected.

² If the amount $\$x$ were infinitely divisible with α being the smallest equal part, then the subgame perfect outcome is $y_P^* = \lim_{\alpha \rightarrow 0} (x - \alpha) = x$, $y_R^* = \lim_{\alpha \rightarrow 0} \alpha = 0$.

³ See for instance, Camerer (2003), Camerer and Thaler (1995), Thaler (1988), Güth and Tietz (1990), Roth et al. (1991).

These results continue to hold in several studies conducted in high stakes games. For instance, Cameron (1999) conducted high stakes experiments in Indonesia in which x ranged from 5,000 to 200,000 rupiahs (about three months' wages). The mean offer was $s = 0.4x$ to $0.45x$. Respondents were more likely to accept offers when stakes were high while the behavior of the proposers hardly changed.⁴

Slonim and Roth (1998) consider varying experiments with varying stakes in the Slovak Republic in which x equals 2.5, 12.5, and 62.5 hours of wages respectively. The rejection rates in the low and the high stakes conditions are similar in the first round and fall slightly in the high stakes condition by round 10, the last round of the experiment. This indicates that there is some interaction of experience and stakes in the rejection rates of offers. However, the mean and median offers are very similar in the low and the high stakes conditions. Exit interviews show that the main motive for the rejection of low but positive offers is that responders find them to be *unfair*.

Carpenter et al. (2005) find that for moderately high stakes, a given proportional increase in stakes leads to a much less proportionate fall in the offers made by the proposer.⁵ For instance, a ten-fold increase in stakes from \$10 to \$100 leads to a halving of the median offer from 40% to 20%, and to an even lower proportionate fall in the average offer from 33% to 25%. Andersen et al. (2011) raise the stakes beyond the levels of most previous studies. Their study, carried out in a northeastern Indian village, allowed stakes to vary between 20 rupees to 20,000 rupees (1.6 hours of work to 1600 hours of work).⁶ They find that although the median offer by the proposer is to give 20% of the share to the respondent, the rejection rate falls with the increase in the stake.⁷ As the authors correctly point out, these results do not invalidate the practical applicability of earlier results because one does not typically encounter real-life situations with such high stakes and the bulk of market transactions are low stake transactions.

The ultimatum game has been mostly played with university students. In an interesting study, Henrich et al. (2001) explore cross-cultural variations in the ultimatum game. In this study, evidence was gathered from 15 small-scale societies across 4 continents and 12 countries. The predictions of the ultimatum game with self-regarding preferences are typically not borne out in any of these societies. The mean offers were quite variable (26–58%) relative to experiments done previously with university students where the mean offers are 43–48%. In some societies, even low offers were rarely rejected, while in others, even extremely generous offers were rejected because in such societies, the rejection of a gift is considered tantamount to the rejection of subordination.

The two main factors that enhanced sociality in the results of Henrich et al. were the following. (1) *Market integration* in the community, i.e., the predominance of buying/selling and working for a wage. (2) *Cooperation in production*, i.e., whether production is carried out on an individual basis or it is cooperative, e.g., in a team environment. These two factors enhanced sociality in the sense of higher offers by proposers and accounted for 66% of the variation in the outcomes in the ultimatum game. On average, people from the least market-integrated communities offered about one-quarter of the stake. By contrast, those from the most integrated communities, such as rural Missouri, offered roughly half. Thus, *markets may foster sociality*, an idea that might seem surprising to some students of mainstream economics because this is hardly ever highlighted.

⁴ Similar findings are reported in Fehr et al. (2014) and Hoffman et al. (1996).

⁵ See also, List and Cherry (2008).

⁶ By way of comparison, in the study by Slonim and Roth (1998), the highest stake level is 62.5 hours of wages.

⁷ In one condition, they find that at the highest level of the stake the rejection rate falls to 0%.

The results of the ultimatum game are sensitive to how much proposers feel that they are entitled to their endowments—a sort of *entitlement norm*. A feeling of entitlement may be created by simply announcing an entitlement (Hoffman and Spitzer, 1982; Cherry et al., 2002), or by having a contest to choose proposers to play a high stakes ultimatum game (List and Cherry, 2000), or by having the proposer earn the endowment (Parrett, 2006). The greater is the entitlement offered to the proposers, the lower is their offer to the responder. Harrison and McCabe (1996) find that the outcomes in an ultimatum game depend on the history of offers and rejections in previous rounds of the game, which might serve to establish a *fairness norm*.

Binmore et al. (1995) and Roth and Erev (1995) have used learning models to explain the results of the ultimatum game in terms of purely self-regarding preferences. The basic argument is that there is an asymmetry between the learning propensities of proposers and responders when the proposers make low offers. The payoff loss to a responder from rejecting a low offer is very low but for a proposer it is very high. Hence, proposers quickly learn not to make very low offers and responders learn very slowly not to reject very low offers. Over time, which can involve thousands of iterations, the behavior with self-regarding preferences can be shown to converge close to the subgame perfect outcome ($y_P^* = x$, $y_R^* = 0$). There are two problems with this approach. First, there is no guarantee that convergence takes place in any sensible amount of time. Second, the structure of the ultimatum game is incredibly simple and it seems simply implausible that subjects are making systematic mistakes of this sort.

Binmore (1998) explains the results of the ultimatum game in terms of social norms. The idea is that in the real world, subjects in experiments may be used to playing repeated games. Hence, in the laboratory, they may mistakenly apply repeated game heuristics to the static ultimatum game and cooperate even when the subgame perfect outcome requires them not to cooperate. It is likely that individuals, in their role as subjects in experiments, bring with them real-world norms into the lab (see, for instance, the variation in offers in different cultures in the study by Henrich et al., 2001). However, whether subjects mistake a static context (the ultimatum game) for a repeated game is an empirical question. And the empirical evidence rejects this view. The same subjects in experiments behave very differently in the lab when they play static games and when they play repeated games where reputation building is important.⁸ Furthermore, neuroeconomic evidence does not support the view that subjects make mistakes in these simple games.⁹

Fehr and Fischbacher (2003) conducted experiments with the ultimatum game in which 10 proposers and 10 responders met each other over successive rounds. No players are paired more than once. In the *reputation condition*, the past behavior of the responders is made public, while in the *no-reputation condition* it is private information to the responder. In the reputation condition, responders have an opportunity to develop a reputation for being tough by rejecting low offers, which is costly in the short run. The gain from such an action is the possibility that future proposers may make high offers to them. The average acceptance thresholds were significantly higher in the reputation condition relative to the no-reputation condition.

Some related issues in ultimatum games are also considered in the section on bargaining games in Chapter 12.

⁸ See, for instance, Andreoni and Miller (1993), Engelmann and Fischbacher (2009), Fehr and Fischbacher (2003), and Gächter and Falk (2002).

⁹ A region of the brain, the dorsal striatum, associated with the reward circuits of the brain is activated when subjects punish behavior that is perceived to be unfair; see, for instance, de Quervain et al. (2004). Knoch et al. (2006) show that an impairment of the prefrontal cortex that is associated with rational thinking reduces the ability of subjects to reject unfair offers.

5.2.2 The dictator game

It is useful to compare the predictions of the ultimatum game with the *dictator game* for additional insights. The dictator game is similar to the ultimatum game except that the responder (sometimes referred to as the *receiver*) is passive and has no actions. Thus, the dictator's offer is always implemented. If all individuals had purely self-regarding preferences, then the prediction is that the dictator will keep all the money and offer none to the responder. On the other hand, a strictly positive, but relatively lower, offer in the dictator game would indicate the following. (1) Proposers are inequity averse, or altruistic.¹⁰ (2) Higher offers in the ultimatum game are made partly for strategic concerns such as fear of rejection because responders may have inequity averse preferences.

Forsythe et al. (1994) find that proposers' offers are higher in ultimatum games relative to dictator games. They find that the average offers made by the proposers in dictator games are between 10–25%. While these offers are lower, on average, relative to those found in ultimatum games, the offers are still significantly higher than zero. The results of this study have been replicated many times. The interested reader can consult Camerer (2003) for a useful table of results (see p. 57). The mean transfer, across studies, made by the proposer in dictator games is roughly 15–20% of the endowment.

List (2007) broadens the action set of the proposer in dictator games to allow for both positive and negative transfers. This is achieved by first giving an endowment to the proposer and the respondent. Negative transfers mean that the proposer is allowed to take money from the respondent's endowment. The main finding is that this reduces the average and median offers made by the proposer, yet the equilibrium outcome under self-regarding preferences (i.e., the proposer makes a offer of zero) does not arise. Levitt and List (2007) explain these findings in terms of the attempts by subjects in experiments to find *contextual clues* in the game in order to apply appropriate norms. For instance, the expansion of the action set of the proposer in dictator games to negative transfers, reduces the scope of what might be construed as a self-regarding offer.

Haley and Fessler (2005) find that when dictators make their proposal where they perceive that they are being watched, say, merely by having pictures of eyes in the room, then they tended to make more generous offers. Similar results are found in a related context, where a picture of eyes elicited greater voluntary contributions for a drink, relative to a picture of flowers (Bateson et al., 2006). However, in games with minimal strategic elements, such as in the trust game, these result do not survive. No effect of the eyes cue was found for either prosocial individuals or self-regarding individuals in the experiments of Fehr and Schneider (2010).

In general, there is wide variation in the offers made in dictator games that are quite sensitive to simple framing effects. These results point to the high degree of sensitivity of the results under dictator games to framing effects and experimental protocol relative to those of, say, the ultimatum games. Despite its popularity, the dictator game might not be a particularly good game to test alternative theories that require even a modicum of strategic interaction (Fehr and Schmidt, 2006).

Dana et al. (2006) consider a variant of the dictator game in which dictators were given an initial amount of \$10. In the first experiment, once the dictators had made their choices, but before these choices were communicated to receivers, dictators were given the option of exiting the game

¹⁰ Selten and Ockenfels (1998) consider a modified dictator game, called the *solidarity game*. In this game, players had a ex-ante chance to be proposers and responders and outcomes were risky. They find it difficult to explain the behavior of a set of their subjects (36% of the total) using altruism alone.

with \$9. If dictators wished to exit the game in this manner, responders were not informed of the dictator's offer, or the game they were playing. Despite the fact that dictators could get a higher payoff by playing the dictator game than exiting in this manner, a significant percentage, 28%, choose the exit option.

In a second experiment, in the private condition, receivers did not know if the money offered to them came from the dictator or the experimenter, thus, the dictator's intentions are not revealed. In this case, 1 out of 24 dictators exited. However, when the first experiment was replicated, 9 out of 24 dictators exited. These results show that at least for a significant minority of the dictator subjects, the offers of proposers may reflect their desire not to appear self-regarding to the receivers.

Dana et al. (2007) introduce a degree of opacity in a variant of the usual dictator game. In the *baseline treatment* with the usual and fully transparent dictator game, the dictator can choose one of two actions, A or B with respective payoffs (6,1) and (5,5) (the first payoff is the dictator's and the second is the responder's). Thus, by accepting a small reduction in his own payoff by a unit, the dictator can enhance the payoff of the responder by four units. In the *hidden payoff treatment*, the payoff of the responder is uncertain, so the respective payoffs from the actions A and B are shown to be (6,?) and (5,?). All subjects were told that the payoffs from A and B are equally likely to be either (i) (6,1) and (5,5), or (ii) (6,5) and (5,1). In each case, the proposer can, costlessly and voluntarily, choose to reveal the payoffs by clicking a button on a computer screen but this information could not be seen by the responder. Clearly, the dictator is more comfortable with his altruism by choosing B in case (i) and A in case (ii).¹¹

If inequity aversion is the dominant motive, then the proportion of dictators who "give" in the baseline treatment, i.e., choose B, should be the same as the proportion of dictators who click to reveal the payoffs in the hidden payoff treatment. A high proportion, 74% (14 out of 19), of the dictators in the baseline treatment chose the more generous option, B. This could be either because they are inequity averse or that they did not wish to appear non-altruistic. However, in the hidden payoff treatment, 56% of the proposers did not choose to click the button to reveal the payoffs. The difference in the proportion of dictators who choose to ensure a generous offer in the two treatments is statistically different. Thus, the authors conclude that the desire to appear fair to others and possibly to oneself is an important determinant in dictator games, which cannot be accommodated by current models of inequity aversion. These results resonate with the observation of why one might cross to the other side of the street to avoid a beggar. In conjunction these findings suggest that in dictator games, many dictators may be *reluctant altruists*. One way in which these findings and those on antisocial punishments in public goods games (see below) can be explained is by a more explicit theoretical model of the microfoundations of human identity and morality. For progress in this direction, see Bénabou and Tirole (2011).

However, it has proved hard to replicate results on moral wiggle room in games where some strategic interaction is involved. For instance, van der Weele et al. (2014) show that moral wiggle room in the trust and the moonlighting games does not reduce reciprocity. This is another instance of why results in the dictator game are quite special and non-robust with respect to other domains.

Ockenfels and Werner (2012) conduct Internet experiments with a large, diverse, subject pool, using the dictator game. The size of the cake that the dictator shares can be small or large. In the Noinfo treatment, the responder never discovers the size of the cake; he only observes the

¹¹ Some may argue that this substantially alters the dictator game, the essence of which is that the respondent's payoff equals the proposer's endowment minus the amount the proposer wishes to keep for himself.

dictator's offer. In the Info treatment, after the dictator has made his offer, the responder is informed about the size of the cake. In the Noinfo condition, when the cake is *large*, the dictator typically offers a share to the responder that is less than one half of the *small cake*. Hence, the dictator hides behind the "small cake effect." By contrast, when the cake is small there is very little difference between the results in the two treatments. These results suggest that giving in dictator games is influenced by second order beliefs, i.e., what the dictator believes the responder believes he will get. It may be the case that the dictator is overcome by guilt if the dictator believes that the responder believes that he will get more than the dictator actually gives (Battigalli and Dufwenberg, 2007). In other contexts, several papers have demonstrated an *audience effect* on giving.¹² These are all cases in which second order beliefs influence one's action. The appropriate framework to rigorously analyze these concerns is psychological game theory (see Part 4).

Andreoni and Bernheim (2009) consider the norm of sharing 50–50 in dictator games. About 20–30% of the dictators offer a 50–50 split to the responder. This can be explained by the dictator's desire to appear fair to the responder, particularly if there are shared social norms about equitable splits. It is important to consider the influence of social norms of sharing in many of the experimental games on other-regarding preferences, an area that is likely to gather more steam in the future.

Lotz et al. (2013) ask if there is a fraction of *genuine altruists* as distinct from *reluctant altruists*, and if we can predict the nature of altruism? They invoke an underlying measure of altruism known as justice sensitivity (JS) that has been used by several psychologists to explain individual-level differences in behavior (Schmitt et al., 1995; Schmitt et al., 2010). Subjects are asked 40 questions and asked to rate each on a scale of 0 (strongly disagree) to 5 (strongly agree). Examples of questions include the following: I cannot easily bear it when people profit unilaterally from me; It bothers me when someone gets something they don't deserve; I have a bad conscience when I receive a reward that someone else has earned. These responses are used to derive measures of sensitivity to becoming a victim of injustice (JS_{victim}), sensitivity of a neutral observer ($JS_{observer}$), sensitivity of an actual perpetrator ($JS_{perpetrator}$), and sensitivity of a passive beneficiary ($JS_{beneficiary}$). The last three measures are combined into a single measure- JS_{others} . The main findings are as follows. At the aggregate level, the authors replicate the result that dictators wish to avoid appearing unfair. However, at the individual level, those with a high JS_{others} score are genuine altruists with stable other-regarding preferences and those with a low JS_{others} score are reluctant altruists. This appears to be an important advance in the literature; it not only suggests a more nuanced view of the dictator game but could also help reconcile conflicting results in this game.

In Part 6 of the book, in the chapter on emotions, we make the distinction between *deliberative choices* and *automatic choices*. Deliberative choices involve the cognitive part of the brain, the prefrontal cortex (system II), that takes account of the long-run consequences, the costs and benefits, and the morality of one's action. By contrast, automatic choices are associated with the more primitive part of the brain, the limbic system (system I); these are quick, instinctive, reactive, pre-programmed choices that may respond to a range of emotions such as fear, anger, and anxiety. Are the choices of players in ultimatum and dictator games deliberative or automatic? One branch of the literature argues that preferences for fairness are deliberative choices. In support, this literature cites evidence that kindergarten children make more self-regarding choices (an automatic response), while adults are more likely to make other-regarding choices. Hence,

¹² See, for instance, Soeteven (2005) in the context of charitable giving in churches and Rege and Telle (2004) in the context of public goods games.

fairness preferences are acquired. A second literature, that is neurobiological and behavioral, suggests that fairness preferences are an automatic response in adulthood.

Neither of the two systems, system I or system II, has primacy over the other. However, system II can use a scarce, but easily depleted, resource, *willpower*, in order to control system I. Hence, willpower-depleted choices are more likely to be in greater conformity with system I. In Halali et al. (2013), subjects first participate in 20 incongruent trials of a *Stroop task*. For instance, they may be shown a red colored ink that is named blue. Subjects then have to suppress their automatic response of saying “red” by saying “blue” instead. This is presumed to deplete their willpower (particularly if the questions are posed rapidly). The evidence suggests that their automatic responses can then be elicited.

In the ultimatum game, following depletion of willpower, proposers make relatively fairer offers. Furthermore, the difference in the choices made under systems I and II (corresponding to relative depletion of willpower) is statistically significant. There are two possibilities. (P1) The automatic response is fear of rejection by the responder, so the offers are higher. (P2) The automatic response is more fair as compared to a deliberative response that is more self-regarding. But if P2 is the correct explanation, then we should also observe more fair offers in the dictator game. By contrast, the automatic response in dictator games is to make more self-regarding offers. This implies that P1 is the more likely explanation, i.e., the automatic response is strategic—fear of rejection. The authors also confirm similar findings for responders in other work.

5.2.3 *Rationality of other-regarding preferences in dictator games*

The rationality of other-regarding preferences hinges on whether they are complete and transitive. An obvious test is to observe the relevant restrictions on actual demand curves, such as the Slutsky restrictions on the cross partial derivatives of Hicksian demands. If this test is satisfied, then the demand curves are the outcome of a utility maximization exercise. But in actual practice, it is hard to observe demand curves.

An alternative approach, using *revealed preference*, is to directly observe the market prices $(p_1, p_2, \dots, p_n)$ and the associated levels of demands $(x_1^*, x_2^*, \dots, x_n^*)$.¹³ Thus, our observations are a sequence of price–quantity pairs $(p_i, x_i^*)_{i=1}^n$. A utility function, u , *rationalizes* these observations if for any $i = 1, \dots, n$ we have $u(x_i^*) \geq u(x_i)$ for all x_i such that $p_i x_i^* \geq p_i x_i$. Thus, x_i^* is revealed to be preferred to all other consumption bundles, x_i , that the consumer is able to afford at the price p_i . In this case, we can infer that the data was generated by a utility maximization process. Hence, the underlying preferences are rational, i.e., complete and transitive.

A sufficient condition to guarantee rationality and, hence, the existence of a utility function that rationalizes the data is the *generalized axiom of revealed preference* (GARP). Suppose that choices are generated by utility maximization. Suppose also that we observe that at price p_i , consumption bundle x_i^* was chosen when another bundle $\bar{x}$ was available and affordable, i.e., $p_i x_i^* \geq p_i \bar{x}$. In this case, x_i^* is *directly revealed preferred* to $\bar{x}$; we write this as $x_i^* D \bar{x}$. If choices were generated by utility maximization, then we must have $u(x_i^*) \geq u(\bar{x})$.

We may also, in our data, observe a series of binary choices of the following form: $x_i^* D x_j$, $x_j D x_k$, $\dots$, $x_n D \bar{x}$. In this case, we say that x_i^* is *revealed preferred* to $\bar{x}$; we write this as $x_i^* R \bar{x}$. If choices were indeed generated by utility maximization, then we may again conclude that $u(x_i^*) \geq u(\bar{x})$.

¹³ Each x_i^* may be a vector, in which case the corresponding price, p_i , is also a vector.

Suppose that we impose the restriction of non-satiation on the utility function, i.e., $u(x) < u(x + \varepsilon)$, $\varepsilon > 0$. In this case, if data are generated by utility maximization, the observation $p_i x_i^* > p_i \bar{x}$ would imply that $u(x_i^*) > u(\bar{x})$. In particular, it cannot be that $u(x_i^*) = u(\bar{x})$. For if it were, then, given $p_i x_i^* > p_i \bar{x}$, we can find some x in the neighborhood of $\bar{x}$ that is affordable, $p_i x_i^* \geq p_i x$, yet, it gives higher utility, $u(x_i^*) = u(\bar{x}) < u(x)$, on account of non-satiation. But this contradicts that x_i^* was chosen at a price p_i .

Now suppose that we observe that at price p_i , consumption bundle x_i^* was chosen when another bundle $\bar{x}$ was strictly cheaper, i.e., $p_i x_i^* > p_i \bar{x}$. In this case, we say that x_i^* is *strictly directly revealed preferred* to $\bar{x}$; we write this as $x_i^* SD \bar{x}$.

Definition 5.1 (*Generalized axiom of revealed preference, GARP*): Suppose that x_i^* is chosen at a price p_i when $\bar{x}$ is available and affordable. If $x_i^* R \bar{x}$, then it cannot be the case that $\bar{x} SD x_i^*$.

Andreoni and Miller (2002) test for GARP in the dictator game, using the following method. Suppose that a dictator is given an income y and he wishes to propose the split (y_P, y_R) . For every unit of income that the dictator wishes to give to the responder, he needs to give py_R units to the experimenter, where $p > 0$. The experimenter then credibly gives y_R units to the responder. The variable p may be thought of as the price of giving. If the dictator has other-regarding preferences, then he solves a standard utility maximization problem in which he maximizes $u(y_P, y_R)$, subject to the budget constraint $y_P + py_R = y$. The levels of income used were $y = 40, 60, 75, 80, 100$, and the prices used were $p = 0.25, 0.33, 0.5, 1, 2, 3, 4$.

Andreoni and Miller (2002) use Afriat's *critical cost-efficiency index* (CCEI) to measure whether a violation of GARP is severe or not. The CCEI gives an indication of how much of the budget must be shrunk in order to rationalize the data. The closer the index is to 1, the less severe are the violations. Out of 176 subjects, there were 18 violations of GARP, i.e., the choices of 18 subjects cannot be rationalized by utility maximization. Based on the CCEI index, there were only 4 violations. Random choice, on the other hand, would have led more than three-quarters of the subjects to violate GARP. With the exception of 3 subjects, the observed data can be rationalized by a quasiconcave utility function. This evidence suggests that the subjects are rational and one can find a utility function that rationalizes the choices that they have made.

At a price of $p = 1$, the dictator gave away, on average, about 23% of the endowment, which is similar to the results in Forsythe et al. (1994). There is heterogeneity among the subjects and only a small minority are unconditional altruists. A little less than a quarter of the subjects behaved as if they had self-regarding preferences, 14.2% of the subjects tried to equalize their payoffs with the other player (Leontief preferences) and 6.2% of the subjects had preferences of the perfect substitutes form.

Results along similar lines, i.e., consistency with GARP and heterogeneity at the individual-level, when CES utility functions are fitted to individual-level data in dictator games, are also reported by Fisman et al. (2007). In a more recent study, Iriberri and Rey-Biel (2013) also implement a similar framework to that in Andreoni and Miller (2002) and Fisman et al. (2007) in dictator games. They find that self-regarding preferences are the most common (47%), followed by inequity averse preferences (21%), social welfare maximizers (19%), and competitive preferences (13%).

Volk et al. (2012) elicit contribution rates of subjects in public goods games (see Section 5.4) at three different dates: in the base period, and 2.5 months and 5 months from the base period. They classify subjects into three categories: conditional cooperators, free-riders, and others. At the aggregate level, the distribution of the level of cooperation is unchanged at the three dates.

This is important because most inferences in public goods games are drawn at the aggregate level (see Section 5.4 below). There is variation in intertemporal stability of preferences at the individual level. While two-thirds of the subjects stay in their category at all three dates, a third switch categories.¹⁴ Personality traits, in particular, the trait of being *agreeable* is a significant predictor of temporal stability of preferences at the level of the individual.

In conclusion, there is nothing irrational about other-regarding preferences.

5.3 Gift exchange and trust games

5.3.1 *The gift exchange game*

The *gift exchange game* was introduced by Fehr et al. (1993). Its objective was to test for the presence of *intrinsic reciprocity*, using a labour market setting. It drew on the insights of Akerlof (1982) and Akerlof and Yellen (1990), who had already explored departures from competitive market outcomes in macroeconomic models by using notions of fairness and reciprocity in labour markets. In exploring the effects of wage rates greater than the market clearing wage rates, as in models of efficiency wages, Akerlof (1982, p. 544) writes: “On the worker’s side, the ‘gift’ given is work in excess of the minimum work standard; and on the firm’s side the ‘gift’ given is wages in excess of what these workers could receive if they left their current jobs.” These critical insights pervade the literature that followed.

Consider the gift exchange game used in the experiments conducted by Fehr et al. (1997). Subjects in experiments were assigned to one of two roles: a principal or an agent. The identities of trading partners were not revealed to any experimental subject, ruling out repeated game effects and any attempts to build a reputation for cooperative behavior. Principals offer a contract (w_b, e_n) to agents that specifies a *binding* wage level, w_b , and a *non-binding* effort level, e_n . Since a binding effort level cannot be specified, there is contractual incompleteness in the model. The wage level can be chosen from the set $\{0, 1, 2, \dots, 100\}$, while the effort level can be chosen from the set $\{0.1, 0.2, \dots, 1\}$. Let e_a be the *actual* effort level chosen by the agent. The payoff of the principal is $100e_a - w_b$. The payoff of the agent is $w_b - c(e_a)$, where $c(e_a)$ is an increasing and convex function of effort with the endpoints given by $c(0.1) = 0$ and $c(1) = 18$. The outside option of the agent is zero.

If all agents possess self-regarding preferences, then the outcome is very simple. Because the effort level is non-contractible, each self-regarding agent chooses the lowest effort level, $e_a = 0.1$. The rational, forward-looking, principal correctly anticipates this, so he offers a wage $w_b = 0$, which ensures that the individual rationality constraint of the agent binds, i.e., $w_b = c(0.1) = 0$.

Suppose that the agent has *other-regarding preferences* or *intrinsic reciprocity*, and that this is known to the principal. In this case, the principal anticipates that the intrinsic reciprocity of the agent would induce him to reciprocate higher wage offers with higher actual effort levels. If the cost of eliciting higher effort is not too high, then it may be optimal to offer $w_b > 0$ and, on account of gift exchange, one would expect to observe $e_a > 0.1$.

The experimental results are depicted in Figure 5.1, where the vertical axis measures the actual effort, e_a , and the non-binding contractual effort level, e_n . The horizontal axis measures the level of rents, $w_b - c(e_n)$, embodied in a contract. The following conclusions arise.

¹⁴ These estimates on stability are higher than some of the other estimates; see, for instance, Muller et al. (2008).

Figure 5.1 The relation between effort and rent in the gift exchange game.

Source: Reprinted from *European Economic Review*, 46: 687–724. Fehr, E. and Falk, A. "Psychological foundations of incentives." Copyright © 2002, with permission from Elsevier.

1. There is a direct relation between e_a and $w_b - c(e_n)$. Hence, workers respond to higher rents by actually working harder. These results are consistent with at least some fraction of the workers having a preference for intrinsic reciprocity but are consistent with principals having either self-regarding or other-regarding preferences. (a) Even principals with self-regarding preferences who are aware that the agents have intrinsic reciprocity will wish to tap into such reciprocity by offering higher wages that elicit higher effort, provided that eliciting effort is not too costly. (b) So long as a high enough fraction of workers has intrinsic reciprocity, the principal will have an incentive to offer rents, i.e., wages greater than the market clearing level even if other workers have purely self-regarding preferences.
2. Conditional on any given level of rents, there is some shirking, i.e., $e_a < e_n$.
3. There is a significant fraction of self-regarding agents who put in the minimum effort level, $e_a = 0.1$. Fehr and Falk (2002) summarize the weight of the evidence from several studies and suggest an indicative figure for the fraction of self-regarding subjects that lies between 40% and 60% percent. The remaining fraction is accounted for by subjects who have other-regarding preferences.¹⁵

Suppose now that, ex-post, the principals can punish workers who work less than the contracted level, $e_a < e_n$, and reward those who work more than the contracted level, $e_a \geq e_n$. If all principals had purely self-regarding preferences, then introducing such an option should have no effect. This is because at the end of the game, bygones are bygones and punishments do not directly increase the material utility of individuals. However, if principals are believed to have other-regarding preferences or intrinsic reciprocity, then agents rationally believe that they could

¹⁵ For an estimation of the relative proportions of self-regarding and other-regarding economic agents, see also Berg et al. (1995), Fehr and Falk (1999), McCabe et al. (1998), Abbink et al. (2000).

be punished for underperforming.¹⁶ Hence, we may expect an increase in actual effort, e_a . The main results in Fehr et al. (1997) are as follows.

1. If $e_a < e_n$, then principals punish in 68% of the cases.
2. If $e_a \geq e_n$, then principals reward in 41% of the cases.
3. Workers seem to anticipate the principal's reciprocity. When $e_a < e_n$, workers anticipate being punished in 54% of the cases. When $e_a > e_n$, workers expect to be rewarded in 98% of the cases.
4. The presence of rewards and punishments decreases shirking from 83% of the cases to only 26% and increases the average level of effort from 0.37 to 0.65.

The gift exchange game has been replicated a large number of times. The general finding of a positive relation between mean effort level and the rent offered by the principal is quite robust.¹⁷ Many studies, some reviewed below, indicate that the positive relation between effort and wages is less strong than originally thought but that there is a much stronger reduction in effort following a wage decrease. Thus, wage decreases appear to be much more costly relative to the gains to firms from equivalent increases in wage. For instance, the elasticity of effort with respect to a wage increase is 0.15 in Gneezy and List (2006) and 0.30 in Kube et al. (2006). However, the elasticity is 0.82 for a wage decrease in Kube et al. (2006).

Fehr et al. (2009) conjecture two reasons for the finding of a weak positive effect of rents on effort in the empirical literature. First, the sample sizes are quite small. Second, the base wage over which rents are offered is already too high. Evidence indicates that workers are more likely to make a greater increase in effort if the base wage is perceived as unfair.

Falk (2007) ran the following field experiment with a non-student population. A Swiss charity made two different kinds of gifts in solicitation letters sent out to 10,000 potential donors. In the baseline case of the *no gift condition*, no gift was included. In the *small gift condition*, the request for donations was accompanied by a single card from a child in Bangladesh. In the *large gift condition*, four such cards were included. The relative frequency of donations in the no gift condition, small gift condition, and the large gift condition was respectively 12%, 14%, and 21%. These differences were statistically significant, which confirms the insights of the gift exchange game. Further, there was insignificant intertemporal substitution in the sense that larger donations in the current period did not crowd out future donations.

Indirect evidence of gift exchange is also found in situations where strikes or other labour relation disruptions in companies lead to a perception of unfairness on the workers' part. If workers perceive that they are unfairly treated, they then tend to reduce effort. Such indirect evidence has been found by Mas (2006) at the New Jersey police department, Mas (2008) at Caterpillar, Krueger and Mas (2004) at Bridgestone/Firestone tires, and Lee and Rupp (2007) for airline wage settlements.

Do the results of the gift exchange experiments survive with an increase in stakes? Fehr et al. (2002) conducted experiments in Russia where subjects earned, on average, the monetary equivalent of 1 week's worth of wages in one condition, and 10 week's worth of wages in another condition. No significant differences were found in the results between the two conditions. These stakes are high enough to cover a very large fraction of real-world economic transactions.

¹⁶ Principals may well have such preferences. Fehr and List (2004) use the trust game in Fehr and Rockenbach (2003), which was performed on students, to examine the behaviour of CEOs in Costa Rica. They find that CEOs are actually more trusting and trustworthy relative to students.

¹⁷ See, for instance, Charness (2000), Fehr et al. (1993, 1998), Fehr et al. (2007), Fehr and Falk (1999), Gächter and Falk (2002), and Hannan et al. (2002).

The gift exchange experiments of Charness et al. (2004) show that there are possibly cultural differences between European and US subjects in experiments. The US subjects engage in lower levels of gift exchange. They also find negative effects on the magnitude of gift exchange when payoff tables are provided. However, it is not clear why the provision of these tables should matter, e.g., does it clarify the structure of the problem or induce particular framing effects?

GIFT EXCHANGE AND COMPETITIVE EQUILIBRIUM

The results of Fehr et al. (1998) speak to the class of results that find support for the predictions of competitive market equilibria in experimental markets (Smith, 1962; Davis and Holt, 1993).¹⁸ Fehr et al. (1998) embed a gift exchange game within competitive markets by allowing sellers to choose a variable quality for a good (see the introductory chapter for more details). If buyers pay a higher price, then sellers can choose to supply them with a higher quality. Under self-regarding preferences, the sellers should supply the lowest quality, and anticipating this, buyers should offer low prices. By contrast, the experimental evidence shows that buyers offer a higher price in anticipation of reciprocal behavior on the part of sellers, who reciprocate by supplying higher quality. The outcome of the experiments departs significantly from the competitive market equilibrium predictions, due to fairness and reciprocity considerations. Furthermore, such reciprocal behavior has a positive effect on the profits of buyers. In conjunction with the results from ultimatum games that reveal more prosocial behavior in the presence of greater market integration, these results challenge the conventional view that the market necessarily produces self-regarding outcomes.

GIFT EXCHANGE AND SOCIAL COMPARISONS

The standard gift exchange experiments assume a bilateral employment relation, i.e., there is one principal and one agent. This feature is relaxed in several experiments. Maximiano et al. (2007) extend the standard framework to allow for four workers working for the same principal and find that the effort levels of the workers in the bilateral and multilateral conditions are very similar.

Social comparisons seem to be an important determinant of reciprocity. Gächter et al. (2012) modify the gift exchange game by considering one employer and two employees. The employer announces a publicly observed wage. The employees then choose their effort levels sequentially. Employee 1 chooses his effort level first, which is observed by employee 2, who then chooses his effort level. When the wage level is high enough, then a higher effort level by employee 1 is followed by a higher effort level by employee 2. This effect is over and above the normal effort levels in the gift exchange game. Cohn et al. (2011) consider randomized field experiments in which teams of two agents are paired with a principal. They consider two separate treatments. In the first, the wages of both agents are cut by 25%, while in the second, the wage of only one of the two agents is cut by 25%. The effort level of the agent whose wage is cut in the second treatment decreases twice as much (by 34%) relative to that in the first treatment (by 15%). This demonstrates that social comparisons play an important role in gift exchange experiments.

In an interesting set of experiments, Abeler et al. (2010) consider repeated interaction between a principal and two agents. Neither effort nor wages are contractible. In one treatment, the equal wage treatment (EWT), both workers are paid equal wages, so there is no horizontal inequity. In

¹⁸ The results of experimental competitive markets are discussed in more detail in Part 4 of the book.

Figure 5.2 The effect of the equity norm on effort levels.

Source: "Gift exchange and workers' fairness concerns: When equality is unfair," Abeler, J., Altmann, S., Kube, S., and Wibrall, M., *Journal of the European Economic Association*, 8(6): 1229–1324. Copyright © 2010 European Economic Association.

a second treatment, the individual wage treatment (IWT), unequal wages are allowed. EWT may be viewed as fair if both workers put in identical levels of effort. However, in the case of unequal efforts, an EWT may be perceived as unfair and, hence, may prove detrimental to effort. The experimental results support these findings; see Figure 5.2 for the average effort level across 12 rounds. In the EWT treatment, the worker who initially puts in a higher level of effort responds to equal wages by putting in a lower effort level in the next round. Effort, in this treatment, moves downwards over successive rounds. By contrast, in the IWT, the worker who puts in a lower effort level in one round, receives a lower wage from the principal and responds by putting in a higher effort level in the next round. In this case, effort increases over successive rounds. Average wage is positively correlated with the effort levels as in gift exchange games.

Kube et al. (2012) find that gift exchange is more effective when the firm offers a non-monetary reward to the worker as compared to a monetary reward. Students are hired for a data entry task and earnings of 36 euros for a three-hour task are announced. In the *monetary gift treatment*, subjects discover that their wage has been unexpectedly raised to 43 euros. In the *material gift treatment*, workers unexpectedly receive a material gift worth 7 euros. Workers respond by entering 6% more data in the first treatment but 30% more data in the second treatment. Interestingly, in a binary choice comparison, workers preferred to receive 7 euros in preference to the gift. This suggests that the gift is not perceived to be more valuable, however, the gift seems to have a signaling value, which elicits greater effort.

GIFT EXCHANGE AND DURATION EFFECTS

Gneezy and List (2006) make two extensions to the standard gift exchange game. First, they look at field experiments rather than lab experiments. Second, they focus on studying the effort provision of workers over an extended period of time. In one of their tasks, the library task, workers were recruited with an offer of an hourly wage of \$12 for six hours of work. They were not told that they were participating in an experiment. In the no-gift treatment, workers were paid a flat wage

Figure 5.3 Behavior of workers' effort levels in the library task.

Source: Gneezy and List (2006) with permission of the Econometric Society.

of \$12/hour as promised. In the gift treatment, they were unexpectedly paid an increased, but flat, wage of \$20/hour. Effort was initially higher in the second treatment, possibly on account of the gift exchange motive. However, gradually, over six hours, the effort levels in the two treatments converged, as shown in Figure 5.3.

These results beg two questions. First, what are the reasons for the downward movement in effort in the gift treatment? The authors' preferred explanation is that workers in the second treatment have not had a chance to figure out the game with a cool head (the so-called *hot state*, *cold state* comparison). However, an alternative explanation, based on the adjustment of the reference points, also appears plausible. The reference point of workers whose wage has gone up, may adjust upwards, so that the unexpected increase in wage no longer seems like a gift after the adjustment has been made. Second, if real-world firms are rational, then firms should eventually learn that the effects of gift exchange do not last long. So instead of offering a flat unexpected increase in wage to \$20/hour, it might well be optimal to offer a gradual increase in the wage rate in small increments to elicit a positive incremental effort level over time. In this sense, the Gneezy and List (2006) results enrich the insights from the gift exchange game by offering insights about duration effects.

Bellemare and Shearer (2007) point out that the Gneezy and List (2006) results rely on observations taken from spot markets but do not speak to the issue of the long-term relations between workers and firms. They examine the effect of a one-off surprise bonus of \$80 in a tree planting firm in British Columbia where the average daily earnings were \$200. There are workers of varying tenure length within the firm. The results are shown in Figure 5.4 for two typical profiles of workers who begin their employment at the age of 20 and 28, respectively. The effort levels of workers, measured in terms of the number of trees planted daily, are observed over six weeks. Significant long-term effects on the effort levels are found in workers with longer tenure, after controlling for planter-fixed effect, weather, and day-of-week effect (to control for fatigue). Such effects are insignificant for workers with very short tenures (as in the spot markets of Gneezy and List, 2006). In general, there is a positive relation between reciprocity and tenure. This complements nicely the Gneezy–List results suggesting that the gift exchange relationship survives over the long term, provided there are long-term relations between the firm and the workers. Indeed this might even provide a new rationale for long-term relations in firms.

Figure 5.4 The relation between reciprocity and tenure.

REFERENCE DEPENDENCE AND GIFT EXCHANGE

The evidence shows that other-regarding preferences can be reference dependent (Fehr et al., 2009). This may interact with gift exchange issues that future research can examine. Thus, labour market policy interventions such as minimum wage laws could alter the perception of workers about a fair wage and they may respond in the effort decisions, accordingly. Hence, after the introduction of minimum wage laws, firms may find that they must pay higher wages or be perceived unfair. The experiments of Brandts and Charness (2004) show that market competition and minimum wage laws do not have a significant effect on the results of gift exchange experiments, although effort is somewhat lower in the presence of minimum wages. In contrast to these results, Owens and Kagel (2010) find that in gift exchange experiments, the effect of a minimum wage is to increase effort levels. Falk et al. (2006) explore the relation between minimum wages and fairness and find that the minimum wage raises the reservation wage of workers. It is interesting that if minimum wage laws are repealed, then workers do not reduce their notion of a fair wage by as much as the drop in the minimum wage, giving rise to a sort of *ratchet effect*. Hence, firms may find it difficult to reduce wages sufficiently, giving rise to downward rigidity in wages.

Kube et al. (2013) use a field study to examine the contention by Bewley (1999) that firms are reluctant to cut wages for fear of reducing morale and effort. The authors allow for an exogenous variation in the wage in a one-shot interaction between a firm and its workers. Student-workers are hired to undertake a data entry task and informed that the projected wage is EUR 15/hour for six hours. This was intended to serve as a reference point for the wage that workers could expect. In the baseline treatment, students were actually paid EUR 15/hour. In the PayCut treatment, they were paid EUR 10/hour, and in the PayRise treatment they were paid EUR 20/hour. These variations in the wage levels were not related to the past level of wages, a problem that often arises in actual firm-level data.

Figure 5.5 Productivity of workers in different wage conditions.

Source: "Do wage cuts damage work Morale? Evidence from a natural field experiment," Kube, S., Maréchal, M. A., and Puppe, C., *Journal of the European Economic Association*, 11(4): 853–70. Copyright © 2013 by the European Economic Association.

The results are shown in Figure 5.5. In the left panel, each quarter on the horizontal axis represents a 90 minute period. The average number of books marked was significantly lower in the PayCut treatment as compared to the Baseline treatment, and this difference is stable over time. On average, the number of books marked was 21% lower in the PayCut treatment, relative to the Baseline treatment. By contrast, the difference between the PayRaise and the Baseline treatments was not statistically different. Thus, the evidence is not consistent with positively reciprocal behavior but it is consistent with negatively reciprocal behavior and with Bewley's findings. In the right panel of Figure 5.5, we plot the cumulative distribution functions of the number of book entries. The PayCut distribution is first order stochastically dominated by the distributions in the other two treatments.

These results can be explained by models of inequity aversion if one assumes that all players consider only the incomes earned during the field experiment and ignore outside incomes (narrow bracketing). The results can also be explained by models of reciprocity. The authors show that the model by Cox et al. (2007) can explain their findings.

SURVEY EVIDENCE FOR GIFT EXCHANGE

Most of the results on the gift exchange game have been based on experimental findings. In a novel study, Dohmen et al. (2009) use panel survey data from the German Socio-Economic Panel Study (SOEP) from the 2005 wave. Many economists have aversion to survey evidence on a-priori grounds,¹⁹ but a-priori grounds can also be used to defend survey evidence, particularly if people respond to survey questions, using their intrinsic motivation, and have some aversion to lying

¹⁹ The standard arguments are that survey evidence is typically not as tightly controlled as lab experiments, there is no guarantee that the responses are incentive compatible, and face to face interaction while collecting the evidence may bias choices.

Figure 5.6 Average responses for the positive reciprocity questions (left panel) and negative reciprocity questions (right panel).

Source: "Homo reciprocans: Survey evidence on behavioral outcomes," Dohmen, T., Falk, A., Huffman, D., and Sunde, U., *The Economic Journal*, 119(536): 592–612. Copyright © The Authors. Journal compilation © Royal Economic Society 2009.

(see Chapters 7 and 8). Indeed, survey evidence is routinely used by government agencies and firms as the basis of important decisions. Six interesting questions on reciprocity were asked in the 2005 wave. These were as follows.

- (1) If someone does me a favor, I am prepared to return it.
- (2) If I suffer a serious wrong, I will take revenge as soon as possible, no matter what the cost.
- (3) If somebody puts me in a difficult position, I will do the same to him/her.
- (4) I go out of my way to help somebody who has been kind to me before.
- (5) If somebody offends me, I will offend him/her back.
- (6) I am ready to undergo personal costs to help somebody who helped me before.

Questions 1, 4, and 6 elicit positive reciprocity and 2, 3, and 5, negative reciprocity of the responders. Responders had to rank their response on a scale of 1 (does not apply) to 7 (applies perfectly).

The results are shown in Figure 5.6, averaged across the positive reciprocity questions (1,4,6) and the negative reciprocity questions (2,3,5); the vertical scales in the left and the right panels are different. For the three positive reciprocity questions, less than 5% of the responders answer 1 (does not apply) and the modal response is 6 or 7. For the three negative reciprocity questions, the modal response is a 1 or 2 and 10% choose a 6 or 7. There is heterogeneity in responses in both cases but there is significantly greater heterogeneity in the negative reciprocity questions. Positive reciprocity weakens as the costs of reciprocal behavior increases. The response 7 (fully agree) is chosen by 60% when there is no cost (Q1), by 35% when responders need to go out of their way (Q4) and by 22% when there is a personal cost (Q6). While modal responses are low for negative reciprocity, these responses do not appear to be sensitive to the costs of reciprocity. An important finding in this study is that the correlation between positive and negative reciprocity is quite low, 0.021. Hence, the extent of negative reciprocity in a responder does not allow one to predict very well the extent of positive reciprocity.

Suppose that we interpret overtime work as a measure of reciprocity and assign to it a binary variable (1 if overtime, 0 if no overtime).²⁰ A probit regression shows that individuals who score high on the positive reciprocity questions are also more likely to do overtime work and

²⁰ Obviously, overtime work could be entirely supply side driven, and reflect responder circumstances unrelated to reciprocity.

individuals who score highly on the negative reciprocity questions less likely to do so. Not only does the effect of reciprocity, measured in 2005, show up in overtime work in the current year 2005 but also in future years, 2006, 2007. Positive reciprocity has an even stronger effect on the probability of overtime work, when responders perceive that they are paid a fair wage. A similar effect of reciprocity on absenteeism is found.

Mincer-type equations are traditionally used in economics to explain earnings as a function of several explanatory variables such as individual characteristics and educational attainment. The authors get all the classical effects²¹ but, in addition, positive reciprocity enhances earnings in current and future years. However, there is no significant effect of negative reciprocity. Furthermore, individuals who are positively reciprocal are less likely to be unemployed, more likely to have a larger number of close friends, and more likely to report greater satisfaction with life.

5.3.2 The trust game, trust, and trustworthiness

The trust game was introduced by Berg et al. (1995), which in turn is a simplified version of a game in Camerer and Weigelt (1988). Consider a static game, played between an *investor* and a *responder*, sometimes known, respectively, as the *trustor* and the *trustee*. Each player is endowed with some fixed level of endowment, say, 10 MUs (an MU is a unit of money in the experiments). The investor must decide to send, or invest, an amount $i \in \{0, 1, 2, \dots, 10\}$ to the responder, via the experimenter. The experimenter multiplies the amount by a number $m > 1$, known as the *multiplier*, which captures the market return and passes it on to the responder; $m = 3$ in many experiments. The responder then returns an amount $r \in \{0, 1, 2, \dots, mi\}$ back to the investor. The respective payoffs of the investor and the responder at the end of the game are $10 - i + r$ and $10 + mi - r$.

Definition 5.2 (*Trust and trustworthiness*): The numbers i and r are, respectively, measures of trust and trustworthiness.

RELATION BETWEEN THE GIFT EXCHANGE GAME AND THE TRUST GAME

The reader may have noted the similarity in the structure of the trust game with the gift exchange game. The surplus in the trust game, found by adding the payoffs of the two players is $20 + (m-1)i$, which is increasing in the investment made by the investor. By contrast, the surplus in the gift exchange game is $\theta e_a - c(e_a)$, where $\theta > 0$ is the marginal product of effort; for instance, $\theta = 100$ in the Fehr et al. (1997) experiments described above. If θ exceeds the marginal cost of effort (which is the case in all experiments), then the surplus is increasing in the effort level. From these observations, the main difference between the two games is that in the trust game, the first mover (investor) can increase the surplus through his actions (investment). By contrast, in the gift exchange game, it is the second mover (the worker) who can increase the surplus through his action (effort level).

If subjects in experiments have self-regarding preferences and are rational, then the responder will never send any money back to the investor ($r = 0$). The rational investor correctly anticipates the responder's behavior, and sends an amount, $i = 0$. Thus, the unique subgame perfect outcome is $i = r = 0$.

²¹ For instance, men are paid more than women, experience has an increasing and concave effect on earnings, and education has a positive effect on earnings.

Figure 5.7 Measures of trust and trustworthiness in a meta study.

Source: Reprinted from *Journal of Economic Psychology*, 32(5): 865–89. Johnson, M. D. and Mislin, A., "Trust games: a meta-analysis." Copyright © 2011, with permission of Elsevier.

By contrast, if subjects in experiments have other-regarding preferences (or intrinsic reciprocity), then responders are likely to reciprocate higher levels of i with higher levels of r . One would then expect $i > 0$ and $r > 0$. This prediction is borne out by the evidence. Responders typically return back the investment that they have received from the investor. The investor finds that his investment is, at least, mildly, profitable, so he sends a strictly positive amount. However, small upward jumps in i are typically ineffective in eliciting greater r , relative to larger jumps in i .

A large number of replications of the trust game have been conducted. The interested reader may consult the meta-study by Johnson and Mislin (2011) that draws on 161 replications of the trust game with a total of 23,000 respondents. They measure trust by a variable pSent, and trustworthiness by a variable pReturn, defined respectively as $i/10$ and $r/(10 + mi)$, i.e., the fraction of total amounts available that are sent by each of the players. These measures are shown in Figure 5.7.

Across all studies, the mean amount sent by the investor, pSent, is .502 (so investors send about half their wealth), while the mean amount sent by the responder, pReceive, is .372 (so responders send about 37.2% of their wealth). For instance, if initial endowments are 10 each, $m = 3$, and $i = 5$, then $r = 9.3$. The meta-study reveals many other interesting features. The amounts sent are larger when interacting with a human, as compared to a non-human, subject such as a computer; older people send larger amounts; significantly lesser amounts are sent in Africa as compared to North America; students send a significantly lower amount as compared to the non-student population; reducing the multiplier from 3 to 2 reduces the amount returned by the respondent. An important finding from the meta-study is that stakes do not have any affect on the results.

The experimental results in Charness et al. (2011) show that providing a history of the behavior of respondents alters the amounts transferred by the investors. When given a choice of exploring past data on the history of the responders, 70% of the investors choose to check the relevant history. Past behavior that is more trusting and trustworthy gives rise to greater trust. However, subjects also use past data on trust to infer greater trustworthiness, suggesting that these two measures may be correlated. Does it pay to trust based on past data? The answer is yes, in both treatments, although in only one treatment is it statistically significant.

Eckel and Petrie (2011) consider a trust game in which investors and responders can, at a price, look up a photograph of the other player.²² They explore if the amount of trust and trustworthiness changes as a result of looking at a photograph of the other player. The motivation for this paper is earlier work that discovered a link between economic decisions and human characteristics such as beauty, ethnicity, and gender.²³ In their trust game experiments, both parties are endowed with 10 tokens each (each token is equivalent to \$1.5). In various sessions, the subjects face different prices for buying photographs of the other player. Not all subjects decide to purchase the photographs. At the lowest price of \$0.20, 50% of the subjects buy the photographs, but they respond to an increase in price by reducing their demand for photographs. Hence, there appears to be a downward sloping demand curve for photographs.

The difference between the demands for photographs of investors and responders is not statistically significant. However, investors are willing to pay more for the photographs, relative to responders, because their decision in a trust game is relatively more strategic. There is no gender difference in the demand for photographs, but there is an ethnic difference. White investors are 40% more likely to wish to buy photographs as compared to subjects of any other ethnicity. Conditional on buying a photograph, white investors discriminate in their investment, i , based on the ethnicity of the responder. On average, they send 3.6 tokens to a black responder and 5.5 to a white responder; the difference is statistically significant. Black investors send significantly fewer tokens than whites, but they do not discriminate in their investment choices based on ethnicity.²⁴ There is no difference in the number of tokens sent based on the relative genders of the investor and the responder.

For responders, the response, r , to the amount sent by the investor, i , is upward sloping. The highest slope of the response function is for white responders. In general, conditional on observing a photograph, responders send more tokens to the investor, relative to the case where they do not see a photograph. In their roles as responders, both blacks and whites send more tokens back to an investor of the same ethnicity. The authors conclude that the “informational value of a face is non-zero.” However, the informational value differs for different ethnic groups.

We have used the term *trust* in an informal manner, without a formal definition. This is clearly unsatisfactory. In applied economic work, various proxies for trust are used. This literature indicates that measures of trust are correlated with GDP, growth, inflation, volume of trade, and the propensity to invest in the stock market. What sort of trust does the trust game capture? There have been attempts to answer this question in terms of altruism and *betrayal aversion*. For a fuller discussion of these very interesting issues and the formal definitions of the relevant terms, see the excellent survey by Fehr (2009).

The trust game is not the only context in which *trust* and *trustworthiness* have been measured. Bolton et al. (2004) consider these concepts in the context of feedback systems in online electronic purchases such as those on Amazon and Ebay.²⁵ In these experiments, a buyer first chooses to buy or not. If the buyer chooses to buy, he needs to pay the money upfront. The seller then chooses to

²² In related research, dictators give only a third as much to an anonymous responder relative to the case where they are told that the responder is the Red Cross; see, for instance, Eckel and Grossman (1996).

²³ See Croson and Gneezy (2009) for a survey of the link between decisions and gender. For the link between beauty and decisions, see, for instance, Hamermesh and Biddle (1994), Mobius and Rosenblat (2006), and Andreoni and Petrie (2008).

²⁴ The authors conjecture that whites are in a majority, so they are more likely to be “teachers in school or bosses in workplace” hence, they are less likely to be discriminated against.

²⁵ See also the follow-up paper by Bolton et al. (2013) that speaks to the limitations of field studies in online auctions in engineering changes that might promote more trust through various feedback systems.

dispatch the good or not. The seller's action is subject to moral hazard because he might choose to run with the money and not dispatch the good. This setting characterizes many forms of online purchases. Three markets are considered. In the *strangers market*, buyers and sellers meet only once and do not have access to each other's transactions history. In the *feedback market*, an online system tracks the previous shipping decisions of the seller and reveals them to the buyer at the time of the buying decision. However, buyers and sellers are randomly paired in each round. Finally, in the *partners market*, feedback is as in the feedback market, but the buyer and seller pairings are unaltered over the experiment.

In this online experimental market, we may define *efficiency* by the percentage of potential transactions completed. *Trust* is measured by the percentage of buyer orders and *trustworthiness* by the percentage of seller dispatches, once the buyer has decided to buy. On all these indicators, the partners market does the best, followed by the feedback market, while the strangers market performs the worst. The reason for the difference is that each of these markets has different incentives for building reputations, and there are differences in the quality and interpretation of feedback. For instance, we may use information on the last item shipped, or not shipped, by the seller as a predictor of trust in each market. Such information has no effect on trust in the strangers market (because such information is not available). However, conditional on the last item being shipped, in the feedback market, the probability of trust doubles from 33% to 65%. The effect on trust in the partners market is even stronger. The quality of feedback in the partners market is superior because current feedback improves one's own future buying decisions. By contrast, in the feedback market, the benefit accrues to others. Thus, one market form is superior, relative to the others, in the internalization of information externalities arising on account of the feedback.

The experimental results of the ultimatum game show that market integration and cooperation in production are associated with greater sociality. Huck et al. (2012) consider whether increased competition can enhance sociality and efficiency in trust games.²⁶ They consider the game in Figure 5.8, originally due to Bohnet et al. (2005). The trustor (player 1) has two strategies: Trust (T) or not trust (N). The trustee (player 2) also has two strategies: Honor trust (h) or exploit trust (e). The game has a unique subgame perfect Nash equilibrium (N,e). The *trust rate* is defined as the percentage of times the trustor plays T and the *honor rate* is the percentage of times the

Figure 5.8 The trust game in Huck et al. (2012).

Source: Reprinted from *Games and Economic Behavior*, 76(1): 195–209. Huck, Steffen, Lünses, Gabriele, and Tyran, Jean-Robert, "Competition fosters trust." Copyright © 2012, with permission from Elsevier.

²⁶ Trust can also be influenced negatively by the degree of inequality in outcomes in a game; see for instance, Hargreaves Heap et al. (2013).

trustee plays h . The efficiency rate is defined as the percentage of times one observes the outcome (T, h) .

In the *control treatment*, the stage game is played repeatedly over 30 rounds with randomly matched players. In the original experiments by Bohnet et al. (2005), in the control treatment, the efficient outcome (T, h) is played only 5% of the time and, as expected, the trust and honor rates are very low. Huck et al. (2012) introduce additional treatments to isolate the effect of competition. Over the 30 rounds, subjects are assigned either to the role of trustors or trustees over the entire duration of the experiment. A “market” has four players in each role. In the private information treatment (pi), each subject is informed of only their own past interactions (their actions and the actions of the opponent) in the game. In the full information treatment (fi), all trustors have access to the histories of all the trustees. There is a second dimension to these treatments. In the random matching treatment each trustor is randomly assigned to a trustee in each round. In the endogenous matching treatment, the trustors choose which trustees they would like to be matched with. Since trustees compete for trustors, this is known as the *treatment with competition*.²⁷

The results are as follows. In the control treatment, the results are similar to those in Bohnet et al. (2005). The efficiency rate is only 8% and the trust rate and the honor rates are identical at 28%. In the case of random matching, private information (pi) and full information (fi) give similar results but with vastly improved rates of sociality relative to the control treatment—the trust rate almost doubles to 50%, the honor rate doubles to 69%, and the efficiency rate quadruples to 36%.²⁸ However, the most dramatic effect arises in the treatment with competition, irrespective of whether information was private or full. For instance, in the full information treatment with competition, the trust rate, honor rate, and the efficiency rates are respectively 0.90, 0.94, and 0.85, roughly triple those in the control treatment.²⁹

Burnham et al. (2000) postulate that humans have a friend or foe (FOF) mental mechanism. Depending on whether humans perceive their opponent to be a friend or a foe, they make different choices. The authors test for such a mechanism by priming subjects in two-player trust games. For instance, if the other player is termed as a “partner” he might be perceived as a friend and if he is termed as an “opponent” he might be perceived as a foe. They find that partners trust more than opponents. They also find twice the level of trustworthiness among partners relative to opponents.

5.4 Public goods games

In this section, we separately consider the public goods game with and without punishments, followed by an examination of the evidence on such games.

²⁷ If a trustee is matched with more than one trustor in any round, the trustee can choose only one action. His total payoff for that round is the sum of his payoff across all matchings.

²⁸ These findings are in line with those in Bolton et al. (2004) who also find that giving feedback to players about past play improves sociality.

²⁹ In other contexts, with similar endogenous matching of participants, Page et al. (2005) show that contributions in public goods games improve and Bohnet and Kübler (2005) show that cooperation improves in social dilemma games.

5.4.1 Public goods game without punishments

There are $i \in N = \{1, 2, \dots, n\}$, $n \geq 2$, risk-neutral individuals and each has an initial endowment $y > 0$, expressed in some monetary units. They simultaneously decide on their respective contributions, $g_i \geq 0$, to a public good. The total monetary contribution towards the public good is given by $G = \sum_{i=1}^n g_i$. The monetary payoff, m_i , of individual $i \in N$ is given by

$$m_i = y - g_i + rG; \quad \frac{1}{n} < r < 1, \quad (5.1)$$

where r is the monetary equivalent of the return, or benefit, to an individual, arising from one unit of the public good, G .

Definition 5.3 *The variable r in (5.1) is called the marginal per capita return (MPCR).*

The Nash equilibrium outcome of this game when individuals have self-regarding preferences involves *free-riding*; it is derived in the next proposition.

Proposition 5.1 *(i) In the unique Nash equilibrium, all self-regarding individuals make zero contributions, i.e., $g_i^* = 0$ for any $i \in N$. (ii) By contrast, the social optimum is characterized by $g_i^* = y$ for all i .*

Proof: (i) Recall that all individuals are risk-neutral. To check that in a Nash equilibrium $g_i^* = 0$ for any $i \in N$, let the vector of contributions of others $\mathbf{g}_{-i}^* = \mathbf{0}$. Using (5.1),

$$\frac{dm_i}{dg_i} = r - 1 < 0; \quad \because r < 1,$$

hence, $g_i^* = 0$, which proves the result.

(ii) The social objective function is $W = \sum_i m_i = ny - G + rnG$. To find the social optimum, note that

$$\frac{dW}{dg_i} = rn - 1 > 0; \quad \because \frac{1}{n} < r,$$

hence, in the social optimum, $g_i^* = y$ for all $i \in N$. ■

5.4.2 Public goods game with punishments

In the public goods game with punishments, there are two stages. In the first stage one plays the public goods game without punishments. In the second stage, once the individual contributions, $g_1, g_2, \dots, g_n$, are public information, each player simultaneously chooses a punishment vector $\mathbf{p}_i = (p_{i1}, \dots, p_{in})$ where p_{ij} is the punishment inflicted by player i on player j at a cost of c per unit and $0 < c < 1$. In this game, the utility function of a risk-neutral individual i with self-regarding preferences is given by

$$m_i = y - g_i + rG - c \sum_j p_{ij} - \sum_j p_{ji}. \quad (5.2)$$

The first three terms in (5.1), (5.2) are identical. The fourth and fifth terms, respectively, in (5.2) capture the cost of punishing others and the cost of being punished by others.

Definition 5.4 (*Efficiency of punishment*) : Equation (5.2) assumes a linear punishment technology. For any player i , it costs c units (in some appropriate units, such as experimental tokens) to punish player j , $j \neq i$, by 1 unit. The efficiency of punishment is defined by $1/c$. So, a lower cost of punishment/unit corresponds to a higher efficiency of punishment.

Proposition 5.2 When all players have self-regarding preferences, the Nash equilibrium of the public goods game with punishments and without punishments is identical, i.e., in equilibrium the contribution of any player is $g_i^* = 0$ for all $i \in N$.

Proof: Conditional on any vector of first stage contributions $(g_1, g_2, \dots, g_n)$ consider the subgame that begins with the decision by players to engage in punishment. Conditional on the punishment vectors of others, $\mathbf{p}_{-i}$, the choice of $\mathbf{p}_i = \mathbf{0}$, maximizes m_i . Hence, it is a dominant strategy, for each player, to not engage in any punishment in the subgame. Given that the second stage outcome is $\mathbf{p}_i = \mathbf{0}$ for all $i \in N$, the first stage payoffs in (5.1), (5.2) are identical. Hence, using Proposition 5.1, $g_i^* = 0$ for all i . ■

Proposition 5.2 shows that in this multi-stage game, punishments are never optimal for players with self-regarding preferences because bygones are bygones. Hence, any threats to engage in punishment are not credible, thus, punishments carry no bite.

5.4.3 Empirical evidence on public goods games

How do the results in Propositions 5.1, 5.2 compare with the empirical evidence? Experiments on public goods games without punishments typically proceed as follows. There are a fixed number of rounds, say, 10, and a certain number of subjects in experiments, say, $n = 6$. At the start of the experiment, subjects are given some endowment (tokens or points), say, $y = 20$, that can be redeemed at the end of the experiment for money. In each period, subjects are asked to contribute to a common pool or a public account, which captures the idea of a public good. After the contributions have been made, the experimenter places some percentage, say 30% (so $r = 0.3$), of the total amount in the public account into the private account of each individual. This captures some level of uniform benefits from the provision of the public good.

At the end of each period, all subjects are able to observe the total amount in the common pool as well as the individual contributions of others. In public goods games with punishments, a second stage is added to the first in which contributors can punish non-contributors at some personal cost. Typically, for each token surrendered by a punisher to the experimenter, the recipient of the punishment has to surrender more than one token depending on the efficiency of punishment (see Definition 5.4). The same sequence of play then takes place in the subsequent rounds.

The socially efficient outcome is for each individual to put all the endowment into the common pool (Proposition 5.1(ii)). In the socially efficient outcome, each subject parts with the 20 units of endowment but receives $0.3(20 \times 6) = 36$ from the experimenter, for a net gain of 16. However, the essence of the privately optimal solution is that conditional on others contributing, any individual can do better by not contributing, i.e., free-riding. For instance, if the first 5 players contribute, then by not contributing, the 6th player's payoff is $20 + 0.3(20 \times 5) = 50 > 36$. Thus, in a Nash equilibrium, nobody contributes (see Proposition 5.1(i)).

Experimental evidence in public goods games without punishments typically shows that subjects begin by contributing about half of their endowments to the common pool. The contributions then begin to drop in subsequent rounds and towards the last round, the contributions for most subjects are nearly zero, as predicted by the model with self-regarding preferences.³⁰ This evidence from the later rounds is sometimes taken as supportive of the predictions of the model with self-regarding preferences (Proposition 5.1). However, on the whole, this pattern of contributions is not consistent with self-regarding preferences because it does not explain (i) why contributions are initially high, and (ii) why if the game is restarted, the contributions typically jump up to a higher level (Fehr and Fischbacher, 2003).

The results of the public goods game with punishments under self-regarding preferences (see Proposition 5.2) are rejected by the evidence. For instance, Fehr and Schmidt (1999) report that, on average, across various studies considered by them, 73% of the subjects choose $g_i = 0$ in the public goods game without punishments. By contrast, on average, 80% cooperated fully in the public goods game with punishments.

The experimental results of Fehr and Gächter (2000) reject the predictions in Proposition 5.2. First, cooperators in public goods games are willing to engage in costly punishment of the free-riders, although such punishments do not give them any material benefits. Second, the extent of punishment inflicted on the free-riders depends on the magnitude of free-riding. Third, in the presence of punishment, there is less free-riding. Thus, potential free-riders seem to realize that they are likely to be punished if they free-ride.

More fully, Fehr and Gächter (2000) used ten rounds and four subjects in each group. They consider the following three treatments. In the *partner treatment*, the same four subjects remained in the group for the ten periods. In the *stranger treatment*, subjects were randomly reassigned at the end of each period, not ruling out the possibility that some subjects may be matched with each other in more than one period. Finally, the *perfect stranger treatment* is similar to the stranger treatment except that it was ensured that no two subjects get matched in the same group in more than one period. The public goods game with punishments was played in the first ten rounds followed by the public goods game without punishments in the next ten rounds. The results are shown in Figure 5.9.³¹

In the first ten rounds, when costly punishment is allowed, cooperation as measured by average contributions is mostly increasing in all treatments. In the last ten rounds, when the punishment option is removed, we get the standard result that cooperation deteriorates over time. In the partner treatment, when punishment is permitted, one achieves close to full cooperation (i.e., the socially efficient outcome) by round 10. Furthermore, the cooperation level in the partner treatment is greater than any of the other two treatments. Once a group member is punished, it is likely that all subjects in a group believe that inadequate contributions will almost certainly invite credible punishment. The cooperation levels in the other treatments, while lower than the partner treatment, are still impressive and much higher than the prediction of zero cooperation under self-regarding preferences (see Proposition 5.2).

The punishment levels remain at high levels in the final rounds when there is little or no future to worry about. Thus, these punishments are not carried out for instrumental reasons, such as preventing future levels of shirking. Rather, these punishments appear to reflect the innate desire to discipline violators of the norm of cooperation, and/or to derive hedonic utility from punishing

³⁰ See, for instance, Andreoni (1988), Isaac et al. (1985). The results from a wide range of studies on this issue are surveyed in Dawes and Thaler (1988) and Ledyard (1995).

³¹ The gaps in the curve representing the perfect stranger treatment arose because of the finiteness of the number of participants in the experiment.

Figure 5.9 Evolution of average contributions in three different treatments in the presence and in the absence of punishments.

Source: Fehr and Gächter (1999).

non-cooperators. In Part 9 we show that the neuroeconomic evidence supports this view (de Quervain et al., 2004).

We now give a brief and selective overview of some further results on public goods games. By varying the MPCR (see Definition 5.3), Brandts and Schram (2001) find that conditional cooperation is not caused by errors on the part of subjects in experiments. Kurzban and Houser (2004) find that the fraction of subjects who exhibit a preference for conditional cooperation is stable across various public goods games; about 65% of subjects appear to be conditional cooperators. Thus, the results of the public goods game are not simply errors, they indicate stability of reciprocal preferences.

As in the other experimental games on human sociality, there are cultural variations in prosocial behavior for the public goods game. Kocher et al. (2008) find variation in the fraction of subjects who are conditional cooperators in a sample from the US, Austria, and Japan. The highest percentage of conditional cooperators are in the US, at 80.6%; the respective figures for Austria and Japan are 44.4% and 41.7%. Brandts et al. (2004), however, find little variation in the fraction of conditional cooperators in the US, Spain, Japan, and the Netherlands. Herrmann and Thöni (2009) find fairly stable fractions of conditional cooperators (about 56%) that do not depend on rural/urban regions, or on several socioeconomic variables.

Gächter et al. (2008) consider the effects on the degree of cooperation by varying the number of replications of the public goods game (10 and 50 rounds respectively) with two treatments, punishment, P, and no punishment, N. This gives four sets of experiments: 10P, 50P and 10N, 50N. They wish to test if the costly consequences of punishments on payoffs in 10P experiments, relative to the benefits of increased cooperation, are eliminated or reversed in 50P experiments. They find that the highest levels of cooperation and the maximum payoffs among the four cases arise in the 50P game; in particular, these exceed the observed levels for the 10P case. Towards the final rounds of the 50P game, the contribution levels stabilize and one observes very little punishment.

Thus, an observation of little punishment does not mean that punishments are ineffective. Rather very little punishment may be required if individuals make high contributions to the public good; see also Gintis and Fehr (2012).

Sefton et al. (2007) consider the possibility of both positive punishment (sanctions) and negative punishment (rewards) in public goods games. They find that a combination of rewards and punishments elicits greater cooperation relative to punishments or rewards alone. However, in their setup, the efficiency of punishment (see Definition 5.4) is only 1. Nikiforakis and Normann (2008) consider the effect of the degree of efficiency of punishment on the extent of cooperation. They consider four levels of efficiency, $1/c$, namely, 1, 2, 3, and 4. They find that the contributions to the public good are increasing in the efficiency of punishment. For very efficient punishments ($\frac{1}{c} = 3, 4$) they achieve contributions that are close to the socially optimal solution. Using data on Dutch subjects in experiments, Egas and Riedl (2008) also find that the level of contributions are at the socially optimal level for $\frac{1}{c} = 3$, and older subjects are more likely to punish non-contributors.

There are two opposing effects on cooperation as group size increases under the assumption that the cooperation of group members can only be elicited through costly monitoring. In a larger group, there could be a greater incentive to free-ride because the probability one may be monitored by any single player is smaller. However, a countervailing force in a larger group is that there are more monitors. The net effect on the probability of detection of non-cooperation, and, hence, the incentive to free-ride is not clear. Carpenter (2007) considers simulated automata and finds that larger groups are more efficacious in making higher contributions, and they exhibit a lower level of free-riding.

In the typical public goods experiments, punishments are monetary. In traditional societies, however, punishments often take a non-monetary form, such as ostracization and other social sanctions. Masclet et al. (2003) consider a public goods game in which, in addition to monetary punishments, subjects can assign between 1 and 10 “disapproval points” to non-contributors that do not affect their monetary payoffs. They find that both monetary and non-monetary punishments produce greater cooperation as compared to the case of no punishments. However, while in the initial rounds of the experiment, non-monetary punishment is initially quite effective, subsequently, monetary punishment is more effective.

Cinyabuguma et al. (2005) consider another form of non-monetary punishment, namely, expulsion of free-riders by a majority vote. Expelled members can play subsequent rounds of the public goods game but their endowments are halved. Individuals who are expelled, or if a vote is taken on their expulsion, respond by contributing more in subsequent periods. Not many expulsions take place to ensure high contributions, possibly because the threat of expulsion is a sufficient deterrent. The expelled members are typically those who contribute the least, so punishments are not antisocial. There is a fairly rich and varied literature on the differential responses of individuals to democratically and non-democratically chosen policies. For instance, Dal Bó et al. (2010) show that players cooperate more in prisoner’s dilemma games when a policy, say, punish if others do not cooperate, is chosen democratically rather than randomly by a computer.

In a public goods game, Chaudhuri and Paichayontvijit (2006) find that 62% of the subjects are conditional cooperators. If information is given to subjects about the conditional cooperation of other subjects, then conditionally cooperative subjects are found to increase their contributions. Page et al. (2005) allow for the endogenous formation of groups in the sense that subjects can express a preference for who they would like to be paired with after being provided with information about the contributions of others. This also facilitates high levels of contributions to public goods, even in the absence of punishment.

Several other papers study the implications of matching *like-minded players*, in the sense of similarity in contributions in a public goods game, into separate groups. It is found that the contributions in the initial rounds of the public goods game are a useful measure of cooperative disposition (Gunnthorsdottir et al., 2007). Gächter and Thöni (2005) conduct an initial round of a public goods experiment and based on the contributions, they group the top three contributors in the first group, the next three in the second group and so on. Each group then plays a public goods experiment over ten rounds with an MPCR (Definition 5.3) chosen to be 0.6. Even in the absence of any punishment, the average contributions in the first group are nearly socially optimal.³²

Monetary and non-monetary punishments are not the only mechanisms to elicit greater contributions. Bochet et al. (2006) allow for several kinds of communication devices such as *face to face* (direct communication for five minutes prior to the game), *chat-room* (communication via a computer monitor), and *numerical cheap talk* (each person types in a number indicating his/her intended contribution to the public good that is seen by others but no further communication is allowed). Face to face communication is the most effective form and achieves total contributions that are about 96% of the socially optimal solution.

Chaudhuri et al. (2006) explore the implications of several forms of intergenerational advice given by one generation of players playing the public goods game to the next generation. They allow for several treatments that are differentiated on the basis of whether the advice is given to one member of the next generation, or to all members, and if this advice is publicly announced or not. Publicly announced advice is most effective in eliciting the greatest level of contributions, that is 90% of the socially optimal level.

Iturbe-Ormaetxe et al. (2011) consider *threshold public goods games* in which the public good materializes only when total contributions exceed a certain threshold level. In one treatment, the public goods provision game (PGP), subjects simultaneously contribute towards a public good and if the total contributions exceed a threshold, the public good is provided to all participants. In a second treatment, the public goods deterioration (PGD) treatment, subjects are initially endowed with a public good. But they are told that the good will completely deteriorate in the future, unless a threshold amount of voluntary contributions are raised to prevent the deterioration. In standard theory, one should not expect any difference in the results in the PGP and PGD treatments. By contrast, the authors find that the contributions are significantly higher in the PGD treatment. They explain their results using prospect theory. The presence of an initial entitlement to the public good in the PGD treatment creates a higher reference point. Since losses bite more than equivalent gains in prospect theory (loss aversion), subjects are willing to pay relatively more to avoid degradation of the public good. This result is analogous to the explanation of the endowment effect (see Part 1 of the book).

5.4.4 *Heterogenous preferences and the pattern of contributions*

In public goods games, the *expectations of the contributions of others* is a critical factor in determining one's own contributions. Subjects in experiments initially contribute about 40–60% of

³² The level of contributions in the other groups are quite high as well. While the contributions in the second group are also high, the average contributions among the lowest group from round 4 onwards are about half the social optimum. The authors conjecture that the results for the lowest group arise on account of strategic considerations while those among the higher groups arise on account of conditional reciprocity.

their endowment.³³ In the absence of punishments, why does the level of cooperation drop off in successive rounds of the public goods game? One possible explanation is that subjects gain experience and, hence, learn how to maximize their self-regarding payoffs. But this does not explain why these subjects start with high cooperation rates if they are asked to play a repeated public goods contribution game once again (Andreoni, 1988).

The leading candidate for the explanation of these stylized facts is a theory that recognizes the role of reciprocity and the heterogeneity of players. The evidence is consistent with the view that a fraction of the subjects are conditional cooperators, while the remaining have self-regarding preferences. In repeated public goods games, the evidence in Fischbacher et al. (2001) indicates that 10% of the subjects always match the expected average contribution of others, 14% fully match the expected contributions of others until they spend half their endowments, 40% match the expected contributions of others to a lesser extent, 30% are free-riders, and the remaining 6% have no well-defined behavioral pattern.³⁴

For the moment, let us ignore the last group which has no well-defined pattern, and find the rational expectations equilibrium of the model. Denote the expected average contribution of others by $\bar{y}^e$. Suppose that subjects have spent less than half their endowments. Then the behavior of the first two groups, constituting 24% of the population, is given by $y_1 = a_1 + \bar{y}^e$ and that of the third group, constituting 40% of the population, is given by $y_2 = a_2 + b_2\bar{y}^e$, where $0 < b_2 < 1$ and $a_1, a_2 \geq 0$ are constants that are independent of $\bar{y}^e$. For the 30% who are free-riders, the contributions are $y_3 = 0$. Hence, conditional on $\bar{y}^e$, total contributions $y = 0.24y_1 + 0.40y_2 + 0.30y_3$ can be written as

$$y = f(\bar{y}^e) = a + b\bar{y}^e, \quad (5.3)$$

where $a = 0.24a_1 + 0.4a_2 \geq 0$ and $b = 0.24 + 0.4b_2 < 1$.

A rational expectations equilibrium requires us to find the fixed point of $y = f(\bar{y}^e)$. For one parameterization of the model, $y = f(\bar{y}^e)$ is depicted in Figure 5.10 by the line labeled “average conditional contribution.” Crucially, this line is flatter than the 45° line, which is also shown. Suppose that we begin at an initial level of cooperation of 80% and subjects best respond to the observed contributions in the previous period. There is then a gradual temporal decay in cooperation until an equilibrium is achieved with an aggregate contribution of about 10%. The following important lessons emerge from this analysis.

1. Despite the fact that the self-regarding individuals are in a minority (30%), they drive down the level of cooperation of the conditionally cooperative players, who in this case are in a majority (64%), from a high level (80%) to a very low level (10%).
2. One cannot infer the incidence of reciprocity/altruism in a population, just by observing the final outcome. In this case, the aggregate equilibrium contribution of 10% hides the fact that more than half the players are conditional cooperators.
3. Upholding the belief that others will cooperate is very important for a cooperation norm to develop. If the possibility of punishment of non-cooperators is introduced, and the

³³ See, for instance, Dawes (1980) and Fischbacher et al. (2001). For an extensive survey of the results till about 1995 see Ledyard (1995).

³⁴ For an early use of the term “conditional cooperation” in the context of public good experiments, see Sonnemans et al. (1999). Keser and van Winden (2000) find that as many as 80% of the experimental subjects behave in a conditional manner. Fischbacher and Gächter (2010) find that 55% of their subjects are conditional cooperators and 23% are free-riders.

Figure 5.10 Explaining the pattern of contributions when there is heterogeneity in social preferences.

Source: Fehr and Fischbacher (2005).

punishment technology is effective enough, then cooperation can be sustained.³⁵ The credibility of punishment, which arises from intrinsic reciprocity, prevents the non-cooperators from free-riding, hence, strengthening the belief that others will cooperate.

Gürerk et al. (2006) conduct public goods experiments in which individuals self-select themselves into two possible “institutions” over 30 rounds. In any round, there are three stages. In stage 1, subjects choose among two institutions, a *sanctioning institution* (SI) and a *sanction-free institution* (SFI). Only in the SI can subjects engage in ex-post rewards and punishments. In stage 2, subjects are grouped by their chosen institution, given an endowment of 20 MUs, and play a simultaneous move public goods game. In stage 3, subjects may positively or negatively sanction other players in their group, if their institutional choice allows it. At the end of each round, subjects learn the payoffs of other players in each institution before playing the next round, where they get an opportunity to once again choose one of the two institutions.

The results are shown in Figure 5.11. In the first round, the results are as follows. The majority institutional choice is to shun sanctions; 36.9% choose SI to SFI. Of those who chose SI, almost half contribute at least 15 MUs (high contributors) and nearly three-quarters engage in punishment of low contributors. The neoclassical prediction with self-regarding preferences is that players should not engage in any ex-post punishments in this finitely repeated, full information game. High contributors in the SI comprise 13.1% of the total population of 84 subjects, and may be termed as strong reciprocators. This is in contrast to the outcome in the SFI, where 43.4% are free-riders and only 11.3% are high contributors. Only 2.4% of the subjects in SFI may be classified as strong reciprocators. Across both institutions, 15.5% are strong reciprocators in the first round.

³⁵ See Fehr and Schmidt (1999), Fehr and Gächter (2002), Ostrom et al. (1992), and Yamagishi (1986).

Figure 5.11 Choice of institutions and contributions.

Over time, subjects endogenously choose the SI, so that it becomes the predominant institution. Furthermore, average contributions in the SI reach almost first best levels of 20 MUs, while those in the SFI converge to near 0 MUs. In round 30, for instance, the average contribution in the SI is 19.4 MUs, while that in the SFI is 0 MUs.

What causes the switch in institutions to a more cooperative form? Suppose that individuals mimic the high payoff players. After round 5, the payoff of high contributors in the SI is higher than the payoff of high/low contributors in the SFI and also higher than the payoff of low contributors in the SI. This provides a powerful incentive for free-riders in the SI to switch to high contributions in subsequent rounds. Furthermore, 80.3% of subjects who switch institutions from the SFI to the SI, immediately increase their contributions as they gain membership of the SI. In a significant finding, 27.1% of subjects who make this institutional switch, convert from being free-riders (0 MUs) to full cooperators (20 MUs). Thus, subjects quickly internalize the norm of contributions and punishments when they switch to a cooperating group; this is reminiscent of conformist behavior in models of cultural selection. Conversely, those who switch in the opposite direction, SI to SFI, immediately reduce contributions in a similar manner.

5.4.5 Unproductive expenditures on public goods

In the standard public goods experiments, punishments enhance efficiency and improve individual payoffs. However, in another class of public goods games, punishments may deter efficiency. Consider wasteful expenditures that might be incurred by groups of players in rent-seeking

games to obtain a prize. The prize has the nature of a public good; it is non-rival and non-excludable for members of the winning group. For instance, two countries fighting a war over rights to a territory, a trade union striking for better wages, ethnic conflicts in countries, R&D competition among firms, several firms lobbying for a government contract, and two political parties fighting an election. These disputes could be between groups of people, or between individuals, or between individuals and groups. Abbink et al. (2010) consider this class of problems using Gordon Tullock's rent-seeking model.

Suppose that there are two competing groups, $j = A, B$. The number of group members are $n_j = 1, 2, 3$, or 4 players depending on the treatment; when $n_j = 1$, the group comprises a single individual. The composition of the groups stays the same over successive rounds of the experiment. Each player is given an initial endowment of $E = 1000$ points, which can either be used to buy contest tokens (one point can be exchanged for one token), or be added to one's points balance, which can be redeemed for money at the end of the experiment. The objective is to win a prize of 1000 tokens, which is given to each player in the winning group. The total prize received by a winning group of size $N \in \{n_A, n_B\}$ is $1000N$. Thus, the prize has the characteristic of a public good (non-rival in consumption and non-excludable).

Each team member, in each group, simultaneously chooses to buy a contest token. Denote the number of tokens purchased by player i in group $j = A, B$ by t_{ij} . Suppose that the total number of contest tokens purchased by groups A and B is $T_A = \sum_{i=1}^{n_A} t_{iA}$ and $T_B = \sum_{i=1}^{n_B} t_{iB}$. As in Tullock's model, the probability that any of the two groups, $j = A, B$, wins the prize equals $\frac{T_j}{T_A + T_B}$. The payoff of any risk-neutral player i in any of the groups $j = A, B$ in any round of the experiment is given by

$$\pi(t_{ij}, T_A, T_B) = E + \frac{T_j}{T_A + T_B} 1000 - t_{ij}. \quad (5.4)$$

There are 20 rounds of the experiment. In each round, each player from each group, selects the number of contest tokens to buy. Using (5.4), the first order conditions with respect to t_{ij} , $j = A, B$, for an interior solution, give rise to two equations: $(T_A + T_B)^2 = 100T_B$ and $(T_A + T_B)^2 = 100T_A$. It follows that, in a Nash equilibrium, $T_A = T_B$. Setting $T_A = T_B$ in any of the first order conditions, one gets the Nash prediction $T_A^* = T_B^* = 250$.³⁶ The Nash equilibrium does not impose any restrictions on the contest tokens purchased by individuals, so long as $\sum_{i=1}^{n_j} t_{ij} = 250$, $j = A, B$.

In a Nash equilibrium, both groups spend the same amounts on buying tokens, thus, the winning probability for each group is $\frac{1}{2}$. Since $\frac{T_j}{T_A + T_B}$ is not defined for $T_A = T_B = 0$, if both groups coordinated by mutually reducing their respective total expenditures to any smallest possible amount $\epsilon > 0$, then their winning probability is also $\frac{1}{2}$. However, since expenditure on tokens reduces utility (see (5.4)), the total expenditure on tokens across both groups $\sum_{j=1}^{n_j} \sum_{i=1}^{n_i} t_{ij}$ may be viewed as the extent of wasteful or unproductive expenditures.

We denote a generic treatment by $x : y$, where $x = n_A$ and $y = n_B$. The first three treatments are the following: 1:1, 1:4, and 4:4. In the fourth treatment, denoted by 4:4P, a punishment option is allowed and each group has four members. In treatment 4:4P, at the end of each round, after observing the contributions of other members of one's group, a group member can engage in costly punishment. Sacrificing a token reduces the number of tokens of the punished player by

³⁶ If one incorporates risk aversion in the payoff functions of individuals, then it can be shown that the equilibrium purchase of contest tokens is smaller.

three tokens. As in public goods games with self-regarding preferences and punishments, bygones are bygones, so we should not observe any punishments in equilibrium. Thus, the Nash equilibrium of the games 4:4 and 4:4P is predicted to be identical when individuals have self-regarding preferences.

We next define a measure of the total unproductive expenditures (tokens plus punishment expenditures) across both groups as a percentage of the total amount won, 1000N.

Definition 5.5 (*Rent dissipation*): The “rent dissipation not accounting for punishment costs” is given by $\sum_j \sum_i t_{ij}/1000N$, where N is the number of members in the group that wins the prize. Suppose that player i in group j inflicts a total punishment of p_{ij} tokens on other group members. Then “rent dissipation accounting for punishment costs” is given by $\sum_j \sum_i (t_{ij} + p_{ij})/1000N$.

In the fifth, and last, treatment denoted by 4:4/40, the treatment in which $n_A = n_B = 4$ is conducted over 40 rounds, instead of 20 rounds.

The results are as follows. Figure 5.12 considers treatments 1:1, 1:4, and 4:4P in which there is no punishment. It shows the average contest expenditures over the 20 rounds as well as the benchmark Nash equilibrium prediction of a contest expenditure of 250 tokens. When a single individual plays against a team of players (as in the treatment 1:4), then in the curve labeled (Teams), the sum of the expenditures of all team members is shown, while in the curve labeled (Individuals) only the individual expenditure of the singleton member is shown.³⁷

Figure 5.12 Contest expenditures in the treatments without punishment.

Source: Abbink et al. (2010) with permission from the American Economic Association.

³⁷ Thus, the curve labeled 1:4 (Individuals) shows the expenditure by the single team member of group A, while the curve labeled 1:4 (Teams) shows the expenditure by the combined team members of group B. The curve labeled 4:4 (Teams) shows the average across each of the two teams.

In each of the treatments, the difference between the Nash prediction and the actual expenditures is statistically significant.³⁸ On average, individuals spend about twice the Nash prediction and teams spend about four times the Nash prediction. The average contributions reduce in successive rounds in the direction of the Nash prediction. Yet in the last five rounds, when contributions are lowest, in treatments 1:4 and 4:4, they are still significantly higher relative to the Nash prediction in a statistical sense. Teams contribute significantly more towards conflict expenditures relative to individuals.

The downward trend in contributions over successive rounds makes one wonder if with sufficiently many rounds, the contributions would converge to the Nash prediction. However, when the 4:4/40 treatment is run, the contributions stabilize by round 30, so that there is no significant difference in contributions between rounds 31–35 and 36–40. The average contributions still remain significantly above the Nash prediction.

The effect of punishments is seen by comparing the two treatments, 4:4P, and 4:4. The punishment option significantly increases the level of conflict expenditures. Expenditures in treatment 4:4P are everywhere above the levels of the 4:4 treatment and higher in a statistically significant sense, even in the last five rounds. Indeed, if one adds the conflict expenditures across both teams of four players, they are nearly equal to the prize that the winner gets (4×1000). This dissipates almost the entire gains from the costly contest.

The punishment option is frequently used by the subjects in experiments in experimental games when it is available, as in public goods games. In classic public goods games experiments, due to free-riding, the actual contributions are lower than the socially optimum level, which is typically full contribution of the endowments (Fehr and Gächter, 2000). In this case, punishments nudge the contributions towards the social optimum and increase the payoffs of players. However, in the case of conflict expenditures, even though the prize has the features of a public good, the players contribute higher than the target (Nash equilibrium) and punishments drive the contributions further away from equilibrium and reduce the payoffs of players.

Figure 5.13 shows the extent of rent dissipation in the presence and the absence of punishment for each of the four treatments, for each quarter of the 20 rounds. For the 4:4P treatment we show, separately, rent dissipation, while accounting for and not accounting for punishment (Definition 5.5). Rent dissipation is very high for the 1:1 treatment.³⁹ Interestingly, rent dissipation in the 4:4P treatment is higher than the 4:4 treatment and even higher than the 1:1 treatment. Thus, unlike the public goods game, punishments lead to huge, non-productive, expenditures in this case.

5.4.6 *Antisocial punishments*

The efficiency enhancing role of punishments in public goods experiments has mainly been documented in experiments conducted in the US and in Western Europe. In these societies, the indices for the *norms of civic cooperation* and *rule of law* are high.⁴⁰ Norms of civic cooperation encompass attitudes to tax evasion and abuse of the welfare state, while rule of law reflects peoples' trust in law enforcement institutions. Herrmann et al. (2008) consider the role of punishment in

³⁸ This is not a new result; see Abbink et al. (2010) for the relevant references.

³⁹ Recall that in the definition of rent dissipation, the denominator is $1000N$, where N is the number of members in the group that wins the prize. Ceteris paribus, rent dissipation is highest when $N = 1$.

⁴⁰ These indices can be found, for instance, in the World Values Survey (see <http://www.worldvaluessurvey.org/>).

public goods games in 16 diverse societies (see Figure 5.14 for a list) with varying norms of civil cooperation and the rule of law.

The subject pool is undergraduate students who were similar in age and socio-demographic characteristics. The main finding is the presence of *antisocial punishments*, i.e., punishment of cooperators by non-cooperators, in public goods games that can reduce the level of cooperation. Groups of four players played the public goods game over ten rounds in the no punishment (N) and the punishment (P) treatments. Each subject had an initial endowment of 20 tokens, and for each token contributed to the public good, each player received a return of 0.4 tokens (in the terminology of Section 5.4.1, $r = 0.4$).

Figure 5.14 (left panel) shows the mean level of *prosocial punishments*, i.e., punished players contribute lower amounts, and *antisocial punishments*, i.e., punished players contribute higher amounts. Five categories of punishment are shown. The category labeled $[x, y]$, $x < y < 0$ shows the punishment of someone who contributed between x to y tokens less than the punisher (prosocial punishment). When $0 < x < y$, the category $[x, y]$ shows the punishment of players who contributed between x to y tokens more than the punisher (antisocial punishment). Prosocial punishment is widespread and the degree of variability is low. However, there is high variability in the level of antisocial punishment and differences in such punishments across groups are statistically significant.⁴¹ The right panel of Figure 5.14 shows a negative relation between the mean levels

⁴¹ In a follow-up study, Gächter and Herrmann (2009) find large cross-cultural differences in the antisocial punishment of prosocial cooperators in four cities in Russia and Switzerland.

of antisocial punishment and contributions to the public good (Spearman's correlation coefficient is -0.87). Thus antisocial punishments are associated with detrimental social outcomes.

One possible determinant of antisocial punishment is the human desire for revenge. Indeed, controlling for the level of contributions, the amount of punishment in period $t - 1$ is a significant determinant of the level of antisocial punishment in period t . This effect is highly significant in 7 groups, weakly significant in 2 groups and insignificant in the remaining groups. In all the groups, the level of cooperation stabilized over successive rounds in the P condition (LHS panel of Figure 5.15). However, unlike the earlier experimental results, punishments did not necessarily lead to high levels of contributions. By contrast, in the N condition (RHS panel of Figure 5.15), the level of contributions converged towards low levels in most groups, although there is still significant variability by round 10. In both treatments, history plays a powerful role. Groups that start off at higher levels of contributions continue at a higher level throughout the 10 rounds of the experiment. On the whole, the cooperation level was relatively higher in the P treatment, in a weakly significant sense, in 11 groups, while there was no significant difference in the other 5 groups.

Thus, a central message here is that when one allows for cultural variations and departures from Western subject pools, the efficacious effect of social sanctions cannot be taken for granted. A regression analysis shows that antisocial punishments are more likely to be carried out in groups where the norm of civic cooperation and the rule of law is weak. Both variables are statistically significant when antisocial punishments take place. However, with prosocial punishments, the rule of law is no longer significant in explaining the differences in contribution rates. In interpreting these results, Gintis (2009, p. 81) writes: "The success of democratic market societies may depend critically upon moral virtues as well as material interests, so the depiction of economic actors as 'homo economicus' is as incorrect in real life as it is in the laboratory."

Falk et al. (2005) explore the motivation for private sanctions in a three-player prisoner's dilemma game. After the strategy choices have been made, by giving up a unit of their payoffs, players who sanction can reduce the payoff of another player by an amount $\gamma \geq 1$. In the high sanctions treatment (high γ), they find that 68.5% of the cooperators punish defectors. Indeed, cooperators almost exclusively punish defectors. About 40% of defectors imposed sanctions on other defectors. However, 34% of defectors punished other cooperators—a form of antisocial punishment. At the individual level, cooperators punish more than defectors. In the low sanctions condition ($\gamma = 1$), sanctions cannot reduce payoff differences. Only 2.2% of the defectors punished others but nearly 60% of the cooperators punished other defectors; intentions based-theories (see Chapter 6) may provide one possible explanation.

5.4.7 Evolution and reciprocity

Why does reciprocity arise? One strand of the literature arising from theories of evolution argues in terms of a *selfish gene* where altruism reduces the fitness of a player (Dawkins, 1989). Reciprocity in this framework is a *maladaptation* (Ghiselin, 1974; Hamilton, 1964; Trivers, 1971; Williams, 1966). However, the propensity of individuals to cooperate with others and act in a prosocial manner, reviewed above, especially those who are not related by kin, suggests that self-interest is not the only motive. In other words, there is support for conditional reciprocity, which includes intrinsic reciprocity. Gintis (2000) shows that starting from a population of purely self-regarding individuals, mutants who have regard for others can successfully invade the population, i.e., purely self-regarding preferences is not an evolutionary stable strategy. In equilibrium, there is a polymorphic population that consists of both self-regarding and reciprocal types. The intuition is that during times of hardship, e.g., wars and famine, and in cooperative activities, such as hunting, the ability to cooperate is essential for survival. Purely self-regarding phenotypes will find it difficult to survive such periods. Hence, a certain critical number of prosocial types may become essential to tide over such times. Furthermore, in group conflict, altruism may result in an increase in the fitness of the group, which is a controversial idea in biology. These issues are

sufficiently vexed, and important at the same time, that they require a fuller treatment and the development of the relevant analytical machinery (Bowles and Gintis, 2013; Gintis et al., 2001; Gintis et al., 2003). We devote an entire chapter in Part 5 to these issues.

5.5 How representative is the lab evidence?

Can the experimental evidence provide a useful guide to the actions of individuals in the field? This is the issue of *external validity* of the experiments that is already considered in detail in the introductory chapter; the interested reader must read both treatments in conjunction because they often consider non-overlapping issues. Consider some possible objections to the external validity of the experimental evidence in the context of other-regarding preferences (Levitt and List, 2007). First, there may be adverse selection among students who volunteer for experiments. For instance, those with preferences for reciprocity may self-select themselves to participate in these experiments leading to an overestimation of reciprocity among humans. Second, subjects in experiments may simply be acting in a reciprocal manner because they believe that this is what the experimenter wishes to demonstrate (*experimenter demand effect*).⁴² Third, subjects in experiments interact anonymously with others in the experiment whereas most real-world data is generated by personal interaction among people. These are legitimate concerns. The aim of this section is to examine the empirical evidence for such concerns. Recent scholarship allays fears over many of these concerns.

5.5.1 The student subject pool and experimental scrutiny

Falk et al. (2013) examine the criticism that the experimental results derived from the student population may have biased the findings. From 2004 to 2009, 89% of the studies considered by them used the student population as subjects in experiments. This is a particularly valuable study because it elicits fairness concerns of the student and the non-student populations, using the same experimental protocol. A variant of the trust games is used to elicit fairness preferences.

The main findings are as follows. First, students with reciprocal preferences are not more likely to be self-selected into experiments. Second, the non-student subject pool exhibits more reciprocity in the sense that responders return significantly more money to the proposer in the trust game. So if anything, the student population may lead to downwardly biased inferences about the degree of reciprocity. A range of other evidence supports the assertion that the non-student population is relatively more prosocial; see, Fehr and List (2004), List (2004), Bellemare et al. (2008), Carpenter et al. (2008), Burks et al. (2009), and Baran et al. (2010). In a gift exchange game, Hannan et al. (2002) also find lower reciprocity among undergraduate students relative to MBAs under identical experimental conditions. Their explanation is that MBAs have greater experience in job environments where gift exchange is important.

Cleave et al. (2012) conduct experiments with 1,173 students that are recruited to play a trust game and a lottery choice task. The resulting data are assumed to be the preferences of the general student population. These 1,173 students are then invited to participate in a lab experiment. Those who turn up for the lab experiment exhibit preferences similar to those of the general student

⁴² For a thought provoking discussion of the issues involved in such *experimental demand effects*, and how they might be minimized, see Zizzo (2010).

population. Thus, the authors conclude, it is not necessarily the case that more prosocial students select themselves into lab experiments.

Could students simply be making more prosocial choices in the lab because they perceive that this is what the experimenter desires (experimenter demand effects and experimental scrutiny)? Or, perhaps, they may feel that self-regarding or greedy choices are likely to be frowned upon by other observers (*audience effect*), hence, they may, falsely, exhibit other-regarding preferences in the lab? These concerns are articulated in Levitt and List (2007). Bandiera et al. (2005) find that the monitoring of workers, relative to non-monitoring, induces more prosocial behavior. Recall also the discussion on Haley and Fessler (2005), above, in which simply showing subjects a pair of eyes in dictator games may induce them to give more, yet these results do not carry over to games with strategic concerns (Fehr and Schneider, 2010).

Barmettler et al. (2012) directly address the question of experimental scrutiny in a carefully controlled experiment using three experimental games—a dictator game, an ultimatum game—and a trust game. In the dictator and the ultimatum games, the first mover, respectively, the dictator and the proposer, was given CHF 20 to allocate between himself and the second mover (the responder). In the trust game, the trustor and the trustee were given an endowment of CHF 10 each. Each subject played each game only once in a between-subjects design.

The typical method of conducting these experimental games is through a computer interface. However, this requires the presence of an experimenter who may scrutinize the choices that students make. For this reason, the authors conduct their experiments with paper and pen in a classroom, and the students were seated sufficiently far apart to ensure anonymity of choices. The students were provided packages with colored envelopes and pens and a personal ID number that only they knew. They made their choices on paper and stuffed the choices back into the envelopes. The envelopes were collected by the experimenters, and the relevant payments based on the choices were put back into the envelopes.

In the single-anonymous treatment (S), at the end of the experiment, the subjects reported their id numbers to the experimenter who matched it to the envelopes and handed the envelopes to the subjects. In this case, the experimenter could have observed the choices of the students. In the double-anonymous treatment (D), the subjects collected their payments directly, and privately, from a table on which the envelopes with ID numbers were placed. In this case, the experimenter could not identify the choices made by the participants.

The results are shown in Figure 5.16. In none of the three games and for any player in any role (proposer or responder, trustor or trustee), is there any statistically significant difference in the choices of the players across treatments S and D. In the dictator game, in treatment S, the median amount transferred by dictators is CHF 3.9, while in treatment D it is 3.6; the difference is statistically insignificant. These results are consistent with the results in Hoffman et al. (1994) for dictator games who varied the degree of experimental anonymity but the results were not statistically different.

For the ultimatum game, the mean offer of the proposer is CHF 8.6 in treatment S and CHF 8.3 in treatment D. The difference is statistically insignificant and the median offers are identical. The behavior of responders in treatments S and D is not statistically different.⁴³ In the trust game, the

⁴³ Bolton and Zwick (1995) find significant effects of anonymity on the results for ultimatum games in some of the trials. But anonymity only explains a small percentage of the departures from equilibrium play in their experiments. Barmettler et al. (2012) also note procedural differences across the single- and double-anonymous treatments in Bolton and Zwick (1995).

median transfer by the trustor in treatment D is CHF 8, while in treatment S it is CHF 7. In this case as well, the differences are statistically insignificant and the average transfers are identical.

Critics of the effect of experimental scrutiny on other-regarding preferences have perhaps been too harsh. If experimental scrutiny turns out to be important, it would serve to illustrate the powerful role of other-regarding preferences. Some critics argue that simply by having an observer (an experimenter) in the room or having a picture of a pair of eyes of an anonymous individual in the room seems to switch-on other-regarding preferences. Many real-world interactions are either directly observed by third parties or allow for credible information transmission to third parties. Using the critics’ argument, institutions that wish to promote human sociality then appear to have an extremely low-cost method of switching-on other-regarding preferences in most cases. This is in line with anthropological findings of cooperation in small groups of individuals; see Gintis (2009).

5.5.2 The external validity of experiments on other-regarding preferences

Cohn et al. (2012) address issues of the external validity of lab experiments in the gift exchange game. Using a Swiss subject pool, where subjects distributed newspapers at train stations and other public places, working on a regular hourly pay of CHF 22, they implemented an increase in salary of CHF 5 to CHF 27. They found that only workers who felt that the original salary was

Figure 5.17 Workers' performance response to the wage increase (vertical axis), conditional on their fairness perceptions.

Source: Cohn et al. (2012). Reproduced with permission. Copyright, INFORMS, <http://www.informs.org>

unfair responded by putting in more effort. Those who felt that the original salary was fair, did not increase their effort in a statistically significant manner; Figure 5.17 shows the workers' average performance and the standard errors. In a lab experiment, conducted on the same subjects, they were able to elicit the other-regarding preferences of the subjects. Those subjects who behaved selfishly in the lab did not increase their effort in the field, following a wage increase, regardless of whether they considered the original salary (CHF 22) to be fair or unfair. Thus, the effect shown in Figure 5.17 is driven by workers who were prosocial in the lab. In this case, behavior in the lab appears to have a high degree of external validity.

Carpenter and Seki, (2011) study the behavior of two types of fishermen in Toyama Bay, Japan, who mainly fish for shiroebi (Japanese glass shrimp). The *poolers* who have been operating as such since the early 1960s, pool their incomes, expenditures, and the fish catch. This activity requires substantial coordination, cooperation, and concern among the individuals. The second group of fishermen, the *non-poolers*, who have been operating since 1992, work on an individual basis; they do not pool their resources, or the fish catch. The aim of the study is to see if there is a link between the other-regarding preferences of the two groups, as elicited by a *modified public goods game* (MPG game) and the choice of their real-life activity, poolers or non-poolers. Thus, the study directly addresses the issue of the external validity of lab experiments on other-regarding preferences.

In the MPG game, conducted in 2003, groups of four individuals are formed, and the experimenter gives each individual an initial endowment that is equivalent to about USD 4.30. The experiment lasted less than an hour and each participant earned USD 73.19, on average. The experiment is conducted separately with poolers, non-poolers, and students recruited from nearby universities.

In the first five rounds of the experiment, the participants play a standard public goods game without punishments. The experimenter doubles the total contributions of the group and then redistributes the resulting total among the four members. Since the return on a unit of contribution is 0.5 for each group member, it is optimal to free-ride if one has purely self-regarding preferences. The efficient outcome is for each individual to contribute their full endowment. In the remaining five rounds of the experiment, a *social disapproval protocol* is unexpectedly introduced at the end of each round. According to this protocol, the contributions of all group members are randomized and shown to the others. Conditional on having observed the contribution of others, group members can then buy, at a cost of 10 yen each, either a smiley face (to indicate approval) or a sad face (to indicate disapproval). These faces are then shown to the group at the beginning of the next round, so that group members can gauge the approval levels of others.

The MPG game allows the experimenter to identify several aspects of the other-regarding preferences of poolers, non-poolers, and students. For instance, when individual contributions in round t are regressed on total contributions in round $t - 1$, the intercept term recovers the degree of *unconditional cooperation*, while the slope term recovers the degree of *conditional cooperation*. Similarly, the propensity to send sad faces recovers *disapproval*, and the reaction in round t to the number of sad faces based on contributions in round $t - 1$, recovers *response to disapproval*.

One can now directly examine the productivity of fishing boats belonging to poolers and non-poolers and examine if productivity is affected by (1) conditional cooperation, (2) unconditional cooperation, (3) propensity to show disapproval, and (4) response to disapproval. A range of other control variables, e.g., the experience of the fishermen, is carefully introduced. Conditional cooperation, recovered from the lab evidence, is significantly positively correlated with actual productivity of the fishermen. This tendency is stronger for poolers as compared to the non-poolers. Conditional cooperation in the lab is the single most important variable in explaining the higher productivity of poolers relative to non-poolers.

The propensity to show disapproval is also a statistically significant factor in explaining higher productivity, although the response to disapproval is not positively related to productivity. Finally, poolers are found to exhibit greater unconditional cooperation in the lab, relative to non-poolers. It is eminently possible that many decades of being involved in team production has shaped the other-regarding preferences of poolers. As in Falk et al. (2013), the finding here is that the student population is less cooperative. The authors remark in their conclusion that: “This sort of result—students being less pro-social than field participants—has become a “stylized fact” of the field experimental literature.”

Fehr and Leibbrandt (2011) study the behavior of fishermen in rural fishing villages in north-eastern Brazil. There are two kinds of individuals. Those who catch shrimp (shrimpers) and those who catch fish (fishermen). The shrimpers and the fishermen operate on a lake that has common property rights with no legal limits on the amount of the catch and the costs of fishing are relatively small. The main focus is on the fishing instruments used. Shrimp traps with small holes or fishing nets with smaller holes increase the catch but create an immediate and future negative externality for others. Shrimpers and fisherman are aware of this channel of causality.

The size of the holes is taken as a measure of the cooperation of the shrimpers and the fishermen. The smaller the holes, the less cooperative is the observed behavior. Shrimpers and fishermen first play a public goods game (PG). Each participant is also asked to state, prior to making their contributions, the contributions that they expect of others. It is found that the expected contributions of others are the best predictor of one's contributions in the PG game, which suggests

Figure 5.18 Checking the external validity of lab data on social preferences.

Source: Reprinted from *Journal of Public Economics*, 95(9–10): 114–55. Fehr, E. and Leibbrandt, A., “A field study on cooperativeness and impatience in the Tragedy of the Commons.” Copyright © 2011, with permission from Elsevier.

the presence of conditional cooperation. In a separate experiment, the time preference parameters of the shrimpers and fishermen are also elicited because the negative externalities accrue now and in the future.

Figure 5.18 illustrates the main insights of the paper. The horizontal axis classifies the contributions in the PG game into three categories—low, medium, and high. The vertical axis measures the actual hole size used by shrimpers and fishermen. More cooperative behavior in the PG game is also associated with a larger hole size, which corresponds to greater cooperation in the field data. Fehr and Leibbrandt (2011, p. 1146) write: “We show that there is no insurmountable gap between the laboratory and the field, even though the context in our laboratory environment differs from the field context in important ways.” Impatience, as measured in the time preference experiments, is not related to contributions in the public goods game. Hence, while both cooperation and impatience are important in the degree of exploitation of common resource problems, they operate through separate channels.

The subject pool in Leibbrandt (2012) is shrimp fisherman in Brazil who sell their shrimp, individually, in open air markets. The fishermen participate in a public goods experiment (PGE) and a risk aversion experiment in which the identity of the opponents is kept anonymous. In the PGE, each player is given 10 MUs (monetary units). In the unique Nash equilibrium, each player should free-ride and in the socially optimal equilibrium, each player should contribute all 10 MUs. The number of MUs that are contributed is used to measure the *degree of prosociality*. This allows the segregation of all subjects into two pools.

Those that contribute less than 4 MUs (54.6%) are classified as *less prosocial* and those who contribute 4 MUs or more (45.4%) are classified as more prosocial. Following the collection of lab data, two kinds of real-life data are collected from the shrimp sellers. First, survey data on various aspects of their sociality. Second, actual data on prices and quantities sold. The results are as follows.

1. Less prosocial sellers are more likely to sell their shrimp catch at a relatively lower price. Except for a minimal range of prices, the distribution function of the price of shrimps sold

by more prosocial sellers first order stochastically dominates the distribution function of less prosocial sellers. Sellers who completely free-ride in the PGE, achieve the least shrimp price per unit. Controlling for several other factors (shrimp size, risk aversion, experience, gender, and color of shrimp) sociality, as observed in the lab, has a significantly positive effect on the prices of the individual shrimp sellers.

2. More prosocial sellers are less likely to lose important buyers and more likely to have trade relations of greater duration. For instance, 59.3% of the less prosocial sellers had trade relations less than or equal to 3 years, while the corresponding figure for more prosocial sellers is 37.7%. The average duration of the trade relationship for more prosocial sellers is 6 years, and the corresponding figure for less prosocial sellers is 4.5 years.
3. In the self-reported surveys, more prosocial sellers also report greater confidence in the extent to which they can signal their trustworthiness.

These results are intriguing. Future research can check for the robustness of these findings in other contexts and clarify the transmission mechanism between other-regarding preferences and the relevant economic variables. However, this research rules out two of the channels that were considered to be important. (1) Prosocial players self-select themselves into jobs with higher earnings and productivity. (2) Prosocial individuals earn more because they interact better with colleagues. Explanation 1 does not work because both types of sellers are found in the same profession and the second explanation does not work because this is a market in which the sellers are individual players. The authors conjecture that the most likely transmission mechanism is the one pointed out by Bowles et al. (2001). Since prosocial sellers are less likely to engage in opportunistic behavior with buyers, they “interact more smoothly,” which could have reputational benefits.

Rustagi et al. (2010) consider issues of forest conservation, a common property resource, in Ethiopia. The Bale Oromo people in the Bale region were given property rights over the forest in return for managing the forest cover through conservation efforts, sustainable tree felling, and monitoring misuse by others. In the first stage of the experiment, a public goods game was played with the subjects. Groups of two players were formed. Each of the players had to give a response to how much they would contribute, conditional on the seven possible levels of contributions of the other players; this is the *strategy method* of eliciting choices. One of the players was then picked at random and asked to make an offer, following which the other player's offer, revealed from the strategy method, is implemented.

A player is defined to be a conditional cooperator if his contribution is increasing in the perceived contribution of the other player. Based on the experimental results, players are categorized into four types. The most interesting types in the current context are the *free-riders*, or type 0 players (11.49%), *weak conditional cooperators*, or type 2 players (11.63%), and *strong conditional cooperators* or type 3 players (34.02%); the remaining players, type 1 players, have mixed preferences and it is difficult to classify them cleanly into any of these three categories. The main difference between weak and strong conditional cooperators is the difference in statistical significance of the correlation between their contributions and the contributions of others.

In terms of forest management, the main indicator of cooperation is the extent of costly personal monitoring of the forest, say, through forest patrols, to prevent misuse of the common resource. The main hypothesis is that cooperation in the public goods game and the degree of cooperation in managing the common forest resource are correlated. This is borne out by the evidence, as shown in Figure 5.19. There is a statistically significant relation between cooperation in the lab and in the field. The authors conclude on p. 964: “In sum, better forest management outcomes are not only a result of conditional cooperators being more likely to abide by the local rules of the group but also being more willing to enforce these rules at a personal cost.”

Karlan (2005) considers participants in a microcredit program in Peru. The participants are members of a non-profit group lending organization in Ayacucho, Peru that allows poor women to borrow and save. Loans are given for a period of four months and the organization actively encourages members to develop a savings habit. In the first step, these participants play a standard trust game. The amount given by the first mover (investor or trustor) is an indication of the degree of *trust*, while the amount sent back by the second mover (the responder or trustee) is often termed as the degree of *trustworthiness*.

The aim of this study is to see if actions taken in the trust game can predict the outcomes of the financial decisions a year later. In relation to the outcomes in the trust game, the two main hypotheses are the following.⁴⁴ (1) A greater degree of trustworthiness should be associated with a greater likelihood of repaying loans. (2) A higher degree of trust should be associated with a greater gambling instinct. Such players should save less. Both hypotheses are confirmed by the evidence.

Hargreaves Heap et al. (2012) test the external validity of lab experiments on prosociality on the Gisu people in eastern Uganda. The Gisu are known for individualistic behavior and relatively low levels of prosociality, even with insiders in the same village or people sharing a common lineage. The authors played the Trust game with the Gisu and tested two hypotheses. The first is that the Gisu are expected to exhibit relatively less prosocial behavior compared to the typical lab findings. The second is that even when one observes prosocial behavior, insiders will be favored

⁴⁴ The author also considers a public goods game and results of a General Social Survey, that we do not report here.

less relative to the typical experimental findings. The authors are unable to reject any of these hypotheses.

Baran et al. (2010) consider the entire cohort of 2008 Chicago MBA students. These students play the trust game in one of their courses. As a measure of trustworthiness, 83.8% of the students in their roles as the trustee, return at least 30% of the amount sent to them by the trustor. Eighteen months later, the same students are followed up to observe the amount of donations they make back to the school. Trustworthiness in the trust game is a significant predictor of the actual donations made by the students. Thus, lab experiments have high external validity and subjects do not just exhibit more trustworthiness in experiments to appear nice to the experimenter. The authors feel that their results are strong enough to conclude that: "In sum, our paper provides evidence that lab measures are a reasonably accurate way of predicting individual behavior in the field, bolstering support for using laboratory experiments to measure other-regarding preferences. It also supports the claim that reciprocity is an important—even characteristic—preference of many, but not all, individuals."

Benz and Meier (2008) consider University of Zurich students who are asked each semester, at the time of renewal of their registration, if they would like to anonymously and voluntarily contribute to one of two funds. Fund A helps students in financial difficulties and one can contribute CHF 7 (about USD 5) and Fund B supports foreign students at the University of Zurich and one can contribute CHF 5 (about USD 4). The students can also choose not to contribute to any fund. The decisions of the students are taken as the relevant field data.

These students subsequently participate in one of two experiments where they have to decide to allocate an endowment of CHF 12 given to them by the experimenter. In the first experiment, the social funds experiment, 99 students are asked to contribute to the same fund (or not contribute at all) that they did in the field experiment in the university. In the second experiment, 83 students are asked to choose to contribute between two randomly chosen charities outside the university. The students were not aware that they were participating in a scientific study that was comparing their field and experimental actions. The field and the experimental data are in close agreement. For instance, the average contribution of the students in the social funds experiment was CHF 9.46, while in the field study they had contributed CHF 9.07 in the previous semester and CHF 9.55 in the four semesters after the experiment took place. This indicates stable preferences that are picked up well by the field data and the experiments.

List (2006) reports on lab and field experiments conducted with sports card traders.⁴⁵ The lab experiments are carefully conducted in a location very near the field experiments and are closely matched in protocol. The study examines whether sellers reciprocate higher price offers of buyers by offering sports cards of higher quality, and whether this response differs in the lab relative to the field. Overall, quality for each price is lower in the field relative to that in the lab. For instance, the average quality offered by sellers for price offers of \$20 by buyers in the lab and the field are respectively 3.1 and 2.3; the corresponding figures for a price offer of \$65 are 4.1 and 3.1. However, the response of price to quality is comparable in the lab and in the field.

Levitt and List (2008) interpret the results in List (2006) as greater reciprocity in the lab relative to that in the field. However, Camerer (2015) re-examines this data in a within-subjects analysis in which the same individuals participated in the lab and the field experiments. He shows that the data reported in Levitt and List (2008) is for a smaller sample of non-local dealers only who account for just 30% of the sample. It turns out that the non-locals are indeed relatively more reciprocal in the lab. However, this result reverses for the local dealers (70% of the sample) who

⁴⁵ See also the introduction of this book for a more detailed account of this research.

are relatively more reciprocal in the field. Pooling across the two kinds of dealers, and using three different statistical tests of significance, no firm conclusions can be drawn for the difference between lab and field data. Camerer concludes (p. 271): “To be crystal clear, I am not sure whether dealers behave differently in the lab and the field, in the most closely matched comparison of lab-market and field (cards).” Camerer (2015) reviews a set of papers where the lab features are deliberately matched with field features to ensure comparability between the two. He finds only one paper, by Stoop et al. (2012), based on data collected from fishermen in Holland, where prosociality in the lab is weaker relative to the field experiments. Even in this case, he believes that (p. 275): “it is not strong evidence because there are many differences between field and lab.”

5.6 Indirect reciprocity

A variety of games studied above, e.g., the ultimatum game, gift exchange game, trust game, public goods game, illustrate the powerful role of reciprocity. *Indirect reciprocity*, on the other hand, refers to the reciprocation of kindness or unkindness between two parties, by a third party whose payoffs are not necessarily directly influenced. The term indirect reciprocity was used by Alexander (1987) who used it to provide an evolutionary basis for cooperation and punishment in human societies.

Seinen and Schram (2001) use the *helping game* to illustrate the importance of indirect reciprocity. Subjects in the experiment were paired randomly in repeated bilateral interactions. In each interaction, one of the subjects was given the role of a donor and the other, the role of a recipient. The only decision for the donor is to decide to *give* an amount of money, $m > 0$, at a cost $c > 0$ such that $c < m$, or to *pass* the opportunity to give, in which case, the game ends. The recipient is passive in each interaction. The act of giving (or helping) is what gives this game its name.

All individuals are given “scores” that reflect their social status. A score at any point in time, indicates the number of times that an individual chose to give (helpful choice) as a donor, in the past six decisions. Hence, the social status of an individual belongs to seven possible categories: 0, 1, . . . , 6. For instance, a social status of 4 means that the individual chose to give four times in the past 6 rounds, but declined the opportunity to give twice. Cost, c , can be either high (*HC* treatment) or low (*LC* treatment), and information on social status can either be public (*I* treatment), or private (*N* treatment). The interactions between these four categories are then considered. For instance, *LCI* is the treatment in which costs are low and information about social status is public. The results are as follows.

1. The highest fraction of helpful choices is in the *LCI* treatment and the lowest in the *HCN* treatment.
2. The difference in the fraction of helpful choices between the following pairs of treatments is statistically significant at the 5% level: *LCI-HCN* and *HCI-HCN*.
3. Subjects with high social status are almost always reciprocated.⁴⁶ This provides evidence of indirect reciprocity. Thus, it seems entirely rational for subjects to build a reputation for helping using the channel of indirect reciprocity.

⁴⁶ Hargreaves Heap and Varoufakis (2002) first consider the effect of endogenously generated social status in a hawk-dove game. Then, their subjects play a modified hawk-dove game that adds an extra pure strategy—cooperate. Subjects who were discriminated against in the first game were more likely to cooperate with each other in the second game.

4. Subjects are often found to be using cutoff rules, e.g., help the recipient if her social status is greater than some cutoff level.
5. There are interesting dynamics, which suggest that the initial level of social status in a critical minimum level of the population is crucial in determining whether, over time, the subjects will evolve towards higher or lower cooperation.

Engelmann and Fischbacher (2009) argue that the study by Seinen and Schram (2001) confounds two factors—indirect reciprocity and strategic considerations. So, donors might wish to give for two possible reasons. (1) For strategic reasons, in order to build a reputation in terms of social status, so that in their future roles as recipients, they receive greater help from the donors. (2) On account of indirect reciprocity, to reward recipients whose social status is high. In their experimental design, the donor can give up 6 units of the experimental money to enable the recipient to receive 15 units. The game was repeated over 80 rounds. For some subjects, the *social status* based on scores (number of times they helped in 5 previous times in the role of donors) was made public in the first 40 rounds, and for the rest, in the last 40 rounds.

Thus, in any round, one could observe the interaction among subjects with different social status. When information was made public, the donor was told about the social status of the recipient before making the decision to give. Evidence was found for both confounding factors—indirect reciprocity and strategic considerations. For instance, 25% of the subjects did not help when the social status was not made public but did help when it was made public. This is evidence of strategic considerations. There is a positive relation between the giving actions of donors and the social status of recipients, irrespective of the social status. However, the amount of help given to those with high social status is twice as much as that given to those with low social status, which provides evidence of indirect reciprocity.

In an interesting variant of the dictator game, Fehr and Fischbacher (2004) introduce the possibility of third party punishment. If the third party is willing to incur a private loss, but achieves no personal gain to enforce a “norm of giving,” then it furnishes evidence for indirect reciprocity. In this third party punishment game (TPG), there are three players. Player A (the proposer) has an endowment of 100 MU (unit of money in the experiments), player B (the respondent) has 0 MU, and player C (the third party) has 50 MU. A dictator game is played between players A and B. Player C observes the game, and in his role as the third party, decides whether to punish or reward player A for this actions. By spending 1 MU, C can reduce A’s payoff by 3 MU, however, there is no direct personal benefit to C from punishing player A. All players know the extensive form of the game. The experimenters conjecture that there is some sort of *fairness norm* which applies to the TPG, so that player C is predicted to punish low offers by player A.

Figure 5.20 shows that the magnitude of punishment meted out by player C is higher if the dictator makes a lower transfer. The very fact that punishments are undertaken by player C indicates that preferences are not self-regarding. Since 50–50 is a potentially salient fairness norm, in 55% of the cases, player C punishes A when offers to B fall below 50%. It is interesting that 70–80% of player Bs expect A to be punished when the offer falls below 50%. Many institutions in society, such as the police, law, third party intervention in bargaining, and regulation, ensure that powerful parties do not exploit their monopoly positions.

Charness et al. (2008) consider a trust game in which the material payoff of a third party is unaffected by the decisions of the other two parties who play a trust game. They consider three separate treatments. Treatment 1 is a baseline treatment, which is the standard trust game in the absence of a third party. Treatment 2 allows the third party to punish the trustee for not sending enough money back to the trustor. Treatment 3 allows the third party to reward the trustor for receiving an insufficient amount of money from the responder. In Treatments 2 and 3, the actions

Figure 5.20 Third party punishments in the dictator game.

of the trustee and the trustor are found to be altered towards greater trust and trustworthiness, relative to the baseline treatment in which the third party is absent. For instance, the trustor sends 60% more to the trustee in Treatment 2. However, there is no appreciable difference in the amount sent when there is the possibility of third party reward. This is the main result in the paper; recall that in the trust game, the trustor controls the surplus in the relationship, so he is the more important player. The interpretation of the results for the trustee are more complicated because he is influenced not just by the amounts sent by the trustor, but also by third party punishment. Yet, on the whole, trustees too return a higher amount to the trustor in the presence of third party punishment.

CHAPTER 6

Models of Other-Regarding Preferences

6.1 Introduction

An impressive range of theoretical models have been developed to address the empirical findings on social preferences. To organize the discussion in this chapter, we have found it useful to employ the following distinction among the alternative models.

In *models of social preferences*, decision makers care not only about their own payoffs but also the payoffs of others in some reference group. In *models of interdependent preferences*, decision makers respond to the actions of others, conditional on the perceived type of others. For instance, altruistic individuals may respond in an altruistic manner if they perceive others to be altruistic, but not if others are perceived to be self-regarding. In *models of intention-based reciprocity*, the perceived *intentions* of others are the critical determinant of how one responds to the actions of others. The types of others (e.g., altruistic or self-regarding) are irrelevant in these models. Finally, there are *hybrid models* that combine two or more of the earlier models and/or use a richer array of social objectives that individuals might have, such as the *maximization of efficiency* or the *utility of the worst-off member* of society.¹

We begin with some simple examples. Consider a set of individuals $i \in N = \{1, 2, \dots, n\}$ whose respective monetary payoffs are denoted by $y_1, y_2, \dots, y_n$. Suppose that the preferences of any individual $i \in N$ can be represented by a utility function.

Example 6.1 (*Altruism*): Individual $i \in N$ has purely self-regarding preferences if, his utility function is $u_i = u_i(y_i)$. Such preferences are unable to explain the results of the experimental games considered in Chapter 5 such as the ultimatum game, the trust game, the gift exchange game, and the public goods game.

Let $\mathbf{y}_{-i}$ be the vector of payoffs of all individuals other than individual i . Preferences of individual $i \in N$, are said to be altruistic if the utility function can be written as $U_i = U_i(y_i, \mathbf{y}_{-i})$, such that (1) there exists at least one element y_j in $\mathbf{y}_{-i}$ such that $\frac{\Delta U_i}{\Delta y_j} > 0$, and (2) there does not exist any y_k in $\mathbf{y}_{-i}$ such that $\frac{\Delta U_i}{\Delta y_k} < 0$. From the evidence reviewed in Chapter 5 we know the following. Behavior in dictator games seems to accord with such preferences, and

¹ This distinction is by no means unique, or universally agreed upon (see footnote 1 in Dufwenberg and Kirchsteiger 2004, p. 269). For instance, our suggested terminology does not readily admit emotions such as *guilt* and *anger*. However, psychological game theory is treated separately in Part 4 of the book.

is, in some cases, enhanced when players feel that they are being watched. In a modified dictator game, Andreoni and Miller (2002) found that the behavior of subjects was consistent with the generalized axiom of revealed preference (GARP), so such preferences are not irrational. There was substantial heterogeneity in the actions of subjects. The behavior of 23% of the subjects was spiteful, i.e., they acted so as to reduce the payoffs of others. Purely altruistic preferences cannot also explain the behavior in trust games as well as in public goods games with punishments.

Example 6.2 (Envy): Suppose that we have only two players, $n = 2$. Consider the utility function due to Bolton (1991),

$$U_i = U_i \left(y_i, \frac{y_i}{y_j} \right); i, j = 1, 2 \text{ and } i \neq j,$$

where $\frac{\partial U_i}{\partial y_i} > 0$, and $\frac{\partial U_i}{\partial \frac{y_i}{y_j}} > 0$ if $y_i < y_j$, which captures envy, but $\frac{\partial U_i}{\partial \frac{y_i}{y_j}} = 0$ if $y_i \geq y_j$.

However, envy alone cannot explain why individuals give a positive amount in the dictator and the ultimatum games. It also does not explain behavior in the trust game or the gift exchange game.

Examples 6.1 and 6.2 suggest that neither altruism, nor envy, alone, can provide the foundations for a model of social preferences. A more complete description of human behavior requires an integration of selfishness, altruism, and envy. The model of Fehr and Schmidt (1999) (henceforth, FS) that we consider in Section 6.2, incorporates these diverse concerns. Furthermore, any model that aspires to explain social preferences must, at a minimum, explain the findings of the basic experimental games in Chapter 5.

In the FS model, inequity is self-centered. Individuals compare their own payoff with the payoffs of those who are better off (envy) and those who are worse off than them (altruism). The FS model does not invoke the beliefs of players about others (first order beliefs) or the beliefs of players about the beliefs of others (second order beliefs), so, it does not model the role of *intentions*; a rigorous analysis of these concerns requires the machinery of psychological game theory (see Part 4 for details).

The FS model can successfully explain many of the findings of the experimental games in Chapter 5; these include the ultimatum game (Section 6.2.1, below), the dictator game, the gift exchange game, and the public goods game with and without punishments (Section 6.2.2, below). The channel through which the FS model explains positive giving in ultimatum and dictator games is altruism. A similar channel facilitates *trust* and *trustworthiness* in the trust game. However, envy and altruism, jointly, need to be invoked to explain the results of the public goods games with punishments. One difficulty that the FS model faces is in the explanation of some of the results from the dictator games that we reviewed in Chapter 5. This includes, in particular, the empirical finding of reluctant altruism; yet, these results are far less important in games that include a modicum of strategic concerns such as the ultimatum game.

Another great merit of the FS model is that it can simultaneously explain other-regarding behavior in bilateral or small group interaction and self-regarding behavior in competitive market settings. We explore these issues in Section 6.2.1 through an example of the ultimatum game by successively allowing for *proposer competition* and *responder competition*. Once we allow for such competition, the outcome of the ultimatum game with social preferences, under certain restrictions on the magnitude of altruism and envy, is identical to the outcome with self-regarding preferences. For instance, in the presence of responder competition, each responder is reluctant to

reject an unfair offer by the proposer because another responder might accept it. This allows the proposer to get away with offering the minimum possible amount. Will the proposer wish to offer the minimum amount? The answer is affirmative, if the altruism of the proposer is low enough.

A second model of inequity aversion that we consider, in Section 6.3, is the *equity, reciprocity, and competition* (ERC) model of Bolton and Ockenfels (2000). In this model, players care about the absolute magnitude of their payoff, and their payoff relative to the total payoff of others, but do not care about the distribution of payoffs of others. In two-player games, such as ultimatum and dictator games, the ERC model and the FS model often yield similar predictions.² In games with three or more players, however, the predictions of the two models may differ substantially. The reason is that in the ERC model, a player does not care about the payoffs received by each of his opponents individually as long as the average payoff remains constant. For example, in the public goods game with punishment, ERC predicts that a contributor is indifferent whether to punish a free-rider or another contributor, because punishing either of them affects the average payoff in the same way, while FS predicts that the free-rider will be punished.

The predictive ability of many theoretical models of self-regarding preferences hinges critically on answering the following question: Given two income distributions P and Q , which does the individual prefer? In a major advance, Rothschild and Stiglitz (1970, 1971) showed that the relevant concepts are *first and second order stochastic dominance*. However, these concepts are not sound for individuals who have social preferences, such as those of the Fehr–Schmidt form. In Section 6.4, we outline newer statistical concepts that are appropriate for individuals with Fehr–Schmidt preferences (Dhami and al-Nowaihi, 2013). We also clarify the relation of these newer dominance concepts with Lorenz dominance, which should facilitate applications of social preferences in the income distribution literature.

The FS model fits well the evidence on the behavior of subjects in experiments on societal redistribution. This evidence suggests that explanations for societal redistribution could be underpinned by social preferences and the innate desire of humans to be fair. By contrast, the existing theoretical literature on political economy assumes self-regarding preferences. Section 6.5 explores the implication of other-regarding preferences for understanding societal redistribution in a simple general equilibrium model with endogenous labor supply (Dhami and al-Nowaihi, 2010a,b). Two main results are established in this section. First, the conditions for the existence of a *Condorcet winner* under social preferences are natural and intuitive. Second, when there is a mixture of self-regarding and other-regarding voters, then the outcomes can be counter intuitive. Even if self-regarding voters are in a majority, the preferred policy of the other-regarding voters may prevail, i.e., be a Condorcet winner, and vice versa. An important determinant of the eventual redistributive outcome is the skill distribution and the inequality aversion of other-regarding voters.

Section 6.6 considers the Walrasian competitive equilibrium and the fundamental welfare theorems when consumers have other-regarding preferences (Dufwenberg et al., 2011). Using a separability condition on preferences, we establish a link between the Walrasian equilibria of an economy with other-regarding preferences and a related economy with self-regarding preferences. In general, the fundamental welfare theorems need not hold. But with an appropriate *social monotonicity condition*, restrictions on preferences to *well-being externalities*, and lump-sum transfers, we establish the analogue of the second fundamental welfare theorem. Interestingly,

² An interesting exception is a variant of the ultimatum game in which the proposer receives ϵ and the responder receives 0 if the proposer's offer is rejected. In this game, ERC predicts that any positive offer will be accepted because the relative payoff position of the responder is always worse than if he accepts the offer. In contrast, the FS model predicts that unfair offers are rejected.

there is a close link between some of these results and the simple general equilibrium model of redistribution that we consider in Section 6.5, above.

Section 6.7 considers the evidence on models of fairness and reciprocity. Formal models of reciprocity require the apparatus of *psychological game theory* that is postponed to Part 4 of the book. In Section 6.7.1, we consider a range of evidence that incorporates a desire for efficiency and surplus maximization over inequity aversion (Charness and Rabin, 2002; Engelmann and Strobel, 2004). However, evidence has also accumulated for the opposite view, in favor of inequity aversion (Bolton and Ockenfels, 2006). On account of their training, economics students may bias results in favor of efficiency, while inequity aversion remains fairly salient for non-economics students (Fehr et al., 2006).³ The evidence against inequity aversion has typically come from dictator games. However, in games where each party has an economically meaningful action, there is support for models of inequity aversion. For instance, in a gift exchange game, when workers have a chance to maximize the surplus in the relationship at a personal cost, they typically do not do so (Fehr et al., 1993, 1998). If surplus maximization were the overriding concern then, in gift exchange experiments, for any wage offered by the firm, we should always observe the worker putting in the maximum level of effort. But, as we saw in Chapter 5, what we observe is a positive relation between effort and wages (gift exchange).

In models of social preferences, such as Fehr and Schmidt (1999) and Bolton and Ockenfels (2000), intentions of other players do not matter. By contrast, intentions seem important to humans, e.g., the law makes a distinction between murder and manslaughter. Section 6.7.2 considers the experimental evidence for the role of intentions (Falk et al., 2008). This evidence rejects models of pure social preferences and models of pure reciprocity. It seems that the evidence is best described by models that combine the role of intentions, social preferences, and reciprocity such as the model by Falk and Fischbacher (2006).

Section 6.7.2 considers some caveats to the evidence on intentions. First, the early literature did find it hard to discover clinching evidence of intentions that could not be explained by other-regarding preferences (Blount, 1995; Charness, 2004; Bolton et al., 1998). Second, more recent evidence shows that in some cases, other-regarding preferences explain the evidence better than intentions. However, in other cases, both intentions and other-regarding motives are unable to explain the evidence (Bolton and Ockenfels, 2005). In this case, one may need to explore other avenues, possibly *procedural theories of fairness*, fairness norms, or bring into consideration reference points for fairness.

Section 6.8 considers several *hybrid models* that combine elements of social preferences and reciprocal intentions. Some models combine intentions with social preferences and other social objectives such as efficiency (Charness and Rabin, 2002). In models of *interdependent preferences*, people favor others who are perceived to be similarly fairness-minded (Levine, 1998; Cox et al., 2007). These models analyze intentions in a reduced form manner and do not employ the tool of psychological game theory. The section concludes with a note on the axiomatic foundations of social preference models (Segal and Sobel, 2007; Neilson, 2006).

6.2 The Fehr–Schmidt model

Fehr–Schmidt (1999), henceforth FS, develop a model of social preferences that simultaneously explains both fairness induced behavior in small group interaction and self-regarding behavior

³ In Charness and Rabin (2002) and Engelmann and Strobel (2004), the predominant subject pool is economics students.

in market settings. They also find that the presence of a small fraction of self-regarding individuals within a group of individuals who have social preferences (and vice versa) has important implications for the observed outcome.

Formally, consider a set of n individuals, $N = \{1, 2, \dots, n\}$. For any player $j \in N$ define the set $N_{-j} = N - \{j\}$. N_{-j} is called the reference set with respect to individual j . The respective monetary payoffs of the individuals are $y_1, y_2, \dots, y_n$. The payoffs of all individuals other than i are denoted by the vector $\mathbf{y}_{-i}$. For any $i \in N$ the Fehr-Schmidt utility function of an individual (or FS utility function) is given by

$$U_i(y_i, \mathbf{y}_{-i}; \alpha_i, \beta_i) = y_i - \frac{\alpha_i}{n-1} \sum_{j \neq i} \max\{y_j - y_i, 0\} - \frac{\beta_i}{n-1} \sum_{j \neq i} \max\{y_i - y_j, 0\}, \quad (6.1)$$

where $\alpha_i \geq 0$ and $0 \leq \beta_i < 1$. Most experimental evidence indicates that $\beta_i \in [0, 1)$, $\beta_i < \alpha_i$. An individual is said to have *social preferences* or *other-regarding preferences*, if at least one of β_i and α_i is non-zero.

The FS utility function has several important features. First, inequity is modeled as *self-centered inequity aversion*, i.e., one's own income becomes the reference point with respect to which incomes of others are compared. Furthermore, inequity among other members of the reference group, i.e., among N_{-i} , is not taken into account by individual i . Second, the theory is silent on the composition and size of the reference group, N_{-i} . Third, the FS utility function reduces to that of a self-regarding individual when $\beta_i = \alpha_i = 0$. Fourth, although (6.1) restricts itself to the linear payoffs case, the theory allows U_i to be non-linear in the payoffs. Fifth, intentions, as in Rabin (1993), or average income, as in Bolton and Ockenfels (2000), do not play a role. Sixth, $\beta_i < 0$, on account of individuals who might derive pleasure from being better off than others (e.g., status-seeking individuals), is ruled out. However, in most cases this feature does not affect the results considered by FS. Seventh, while there is an upper bound on β_i there is none on α_i .⁴ Eighth, $\beta_i < \alpha_i$ implies that the player suffers more from *disadvantageous inequity* (the second term in (6.1)) rather than *advantageous inequity* (the third term in (6.1)). Ninth, payoffs arising from advantageous and disadvantageous inequality are normalized to take account of the number of players, hence, the second and third terms in (6.1) are divided by $n - 1$.

Unlike models that incorporate only altruism or envy (see Examples 6.1, 6.2 above), the FS model incorporates both concerns. Individuals with such preferences, therefore, care about how unequal their incomes are, relative to those who are richer and those who are poorer. For this reason, the class of such models is also sometimes known as *models of inequity aversion*. Table 6.1 gives the reader an indication of the magnitudes of α, β from various studies reported in Eckel and Gintis (2010). The estimates suggest that $\beta < 1$ and typically $\beta < \alpha$. Most tests of inequity averse preferences have been done on aggregate level data. Using a within-subjects design, Blanco et al. (2011) report differences in the estimated parameters of inequity aversion at the aggregate level and the individual level. Fisman et al. (2007) report substantial heterogeneity at the level of individuals in social preferences. For a debate on the calibration of the Fehr-Schmidt model, see the 2010 issue of the *Journal of Economic Behavior and Organization*, Volume 73.

⁴ To see why β_i is restricted to be less than one for all i , consider the following simple example. Suppose that the incomes are arranged in increasing order, so $y_n = \max\{y_1, y_2, \dots, y_n\}$ and $\beta_n \geq 1$. Then (6.1) implies that

$$U_n(y_n, \mathbf{y}_{-n}; \alpha_n, \beta_n) = (1 - \beta_n)y_n + \frac{\beta_n}{n-1} [y_1 + y_2 + \dots + y_{n-1}].$$

If $\beta_n \geq 1$ then the RHS is non-increasing in y_n , so (provided this does not change the income rankings) throwing away a dollar increases the payoff of player n , which seems unreasonable.

Table 6.1 Parameter estimates of the Fehr and Schmidt (1999) model of inequality aversion.

Study and population	Mean parameter values	
	α	β
Fehr and Schmidt (1999)		
Calibration (calculated from reported distributions)	0.85	0.315

The model described in (6.1) is the linear version of the FS model. The non-linear version has also been used to explain important phenomena such as societal redistribution. See for instance, Dhami and al-Nowaihi (2010a,b), which is discussed in Section 6.5 below.

6.2.1 Fairness and market competition

We now demonstrate how the FS model can explain the anomalies generated by the ultimatum game. Denote the proposer and the responder in the ultimatum game as, respectively, players 1 and 2. The share received by the responder is denoted by s , while the proposer's share is $1 - s$.

Lemma 6.1 *The responder accepts all offers $s \geq 0.5$. There is a critical share, $s_c < 0.5$, such that the responder (1) rejects all offers $s < s_c$, and (2) accepts all offers $s \geq s_c$.*

Proof of Lemma 6.1: Suppose that $s \geq 0.5$. From (6.1), the responder's utility is $U_2 = s - \beta_2 [s - (1 - s)] = \beta_2(1 - s) + s(1 - \beta_2)$, which is positive because $\beta_i \in [0, 1)$. Hence, the responder will always accept $s \geq 0.5$. Now suppose that $s < 0.5$. From (6.1), the respon-

der's utility is $U_2 = s - \alpha_2 [(1-s) - s] = s(1 + 2\alpha_2) - \alpha_2$. For this to be positive we require that

$$s \geq s_c = \frac{\alpha_2}{1 + 2\alpha_2}, s_c < 0.5. \quad (6.2)$$

Hence, the responder will accept all offers $s \geq s_c$ and reject all offers $s < s_c$. ■

The critical threshold, s_c , is increasing and strictly concave in α_2 . In the limiting case $\alpha_2 \rightarrow \infty$, $s_c = 0.5$.

Proposition 6.3 *The equilibrium share offered by the proposer to the responder is given by*

$$s^* = \begin{cases} s_c & \text{if } \beta_1 < 0.5 \\ 0.5 & \text{if } \beta_1 > 0.5 \\ s \in [s_c, 0.5] & \text{if } \beta_1 = 0.5 \end{cases}.$$

Proof of Proposition 6.3: It is simple to check that the proposer will not offer a share $s > 0.5$ to the responder. From Lemma 6.1 we know that the responder will accept any share $s : s_c \leq s \leq 0.5$. Let us consider such a share, s . From (6.1), the proposer's utility is $U_1 = (1-s) - \beta_1 [(1-s) - s]$, so $\frac{\partial U_1}{\partial s} = 2\beta_1 - 1$. Thus, if $\beta_1 < 0.5$, then $\frac{\partial U_1}{\partial s} < 0$, so the proposer should offer the minimum share that will be accepted by the responder, i.e., $s^* = s_c$. If $\beta_1 = 0.5$, then $\frac{\partial U_1}{\partial s} = 0$, so any feasible share $s^* \in [s_c, 0.5]$ that will be accepted is offered. If $\beta_1 > 0.5$, then $\frac{\partial U_1}{\partial s} > 0$, so we have a corner solution, $s^* = 0.5$. ■

The predictions of the theory seem to match the stylized facts reasonably well in Western societies. First, there are rarely any offers above 0.5. Second, offers of 0.5 are readily accepted and low offers (presumably below s_c) are rejected.

It is possible that one (or both) of the parties has asymmetric information about the preference parameters of the other party. For instance, suppose that the proposer has asymmetric information about the responder's disadvantageous inequity parameter, α_2 . In particular, suppose that the proposer knows that α_2 has support $[\underline{\alpha}, \bar{\alpha}]$ and a distribution function $F(\alpha_2)$. From Lemma 6.1, we know that the offer will only be accepted by the responder if $s \geq s_c$. So, using (6.2), $\Pr(s \geq s_c) \Leftrightarrow \Pr\left(\alpha_2 \leq \frac{s}{1-2s}\right) = F\left(\frac{s}{1-2s}\right)$, which is increasing in s . Hence, the probability that an offer is accepted by the responder is increasing in the offer, s . This is also consistent with the empirical evidence.

The results derived above change dramatically when there is one-sided market competition either among proposers or among respondents. This is well known in experimental economics. For instance, Davis and Holt (1993) make six concluding remarks to their book. In the very first, they state that *competitive market predictions have been observed in a rich variety of circumstances and in literally hundreds of instances*. Furthermore, they remark that experimental behavior approximates the competitive outcome even in the absence of the limiting cases (i.e., a large number of traders or complete information). These insights also apply to the predictions of the FS model for the ultimatum game as we now see.

MARKET GAMES WITH PROPOSER COMPETITION

Consider $n > 2$ players, where the first $n-1$ players are proposers and the n th player is the single responder in an ultimatum game. The proposers simultaneously make an offer to the responder. Each proposer's offer takes the form of a share $s \in [0, 1]$ that is offered to the responder. Denote

the maximum offer among the proposers by $\bar{s} = \max \{s_i\}$, $i \in N/n$. If $\bar{s}$ is unique, then the corresponding proposer gets to make that offer, with probability 1, to the responder. If, however, $k > 1$ proposers make the same offer, $\bar{s}$, then each of these proposers makes an offer to the responder with probability $1/k$. If the responder rejects the offer, everybody gets zero. If the responder accepts an offer s from the j th proposer, then their respective payoffs are $s, 1 - s$ and everybody else gets zero.

We first consider the benchmark result when all players have self-regarding preferences.

Lemma 6.2 *Suppose that all individuals are self-regarding. In any subgame perfect outcome, at least two proposers must offer $\bar{s} = 1$, which is accepted by the responder.*

Proof of Lemma 6.2: Suppose to the contrary that there is some $s : 0 < s < 1$ that is an equilibrium. Any of the proposers can now offer $s + \epsilon$, $\epsilon > 0$, which will be accepted by the responder and improves the payoff of the proposer. Furthermore, there cannot be a single proposer who offers $\bar{s} = 1$ in equilibrium. If this is the case, then let the next best offer by any proposer be $\tilde{s}$. The original proposer can now lower his offer to any number in $(\tilde{s}, 1)$. Such an offer is accepted by the responder and improves the payoff of the original proposer. Hence, the unique equilibrium offer is $\bar{s} = 1$, which is made by at least two proposers. ■

In the face of proposer competition, the responder reaps all gains from trade. These results are consistent with the experimental evidence in Roth et al. (1991).

What is the equilibrium outcome when all n players have social preferences? It turns out that the outcome is identical to that obtained under self-regarding individuals. We start by proving an intermediate result that is similar to Lemma 6.1.

Lemma 6.3 *The other-regarding responder will accept any offer $s \geq 0.5$.*

Proof of Lemma 6.3: For $s \geq 0.5$, the utility of the responder from accepting the offer is

$$U_n = s - \frac{\beta_n}{n-1} [s - (1-s)] - \frac{(n-2)\beta_n}{n-1} (s-0). \quad (6.3)$$

Since $0 < \beta < 1$, so $U_n \geq 0$. Since, $U_n \geq 0$ if an offer $s \geq 0.5$ is accepted and $U_n = 0$ if the offer is rejected, hence, the offer is accepted. ■

Proposition 6.4 *Suppose that all agents have other-regarding preferences given in (6.1). In the ultimatum game with proposer competition, the unique subgame perfect equilibrium outcome is for at least two proposers to offer $s = 1$, which is accepted by the responder. All gains from trade accrue to the responder.*

Proof of Proposition 6.4: Using Lemma 6.3, the responder will accept $s = 1$. We want to show that there cannot be an equilibrium in which $0.5 \leq s < 1$ is offered and accepted by the responder. Suppose that $\hat{n}$ proposers, such that $1 \leq \hat{n} < n-1$, offer $0.5 \leq \bar{s} < 1$ in equilibrium and their offer is accepted. Order, without loss of generality, the proposers as follows $1, 2, \dots, \hat{n}, \hat{n}+1, \dots, n-1$. The proposers $\hat{n}+1, \dots, n-1$ offer less than $\bar{s}$, say, 0 (this does not alter the proof). Now choose any proposer i from among $\hat{n}+1, \dots, n-1$. If he offers some $s_i < \bar{s}$, then proposer i does not win the contest and there are two other players who have a greater payoff: the proposer who wins and the responder, hence, using (6.1), his payoff is

$$U_i(s_i) = 0 - \frac{\alpha_i}{n-1} [(1-\bar{s}-0) + (\bar{s}-0)] = -\frac{\alpha_i}{n-1}. \quad (6.4)$$

If proposer i instead offers $\bar{s} + \epsilon$, $\epsilon > 0$, then he wins the contest for sure. In this case one player, the responder has a greater payoff than him (on account of Lemma 6.3), while $n - 2$ players have a lower payoff. Using (6.1), his payoff is

$$U_i(\bar{s} + \epsilon) = [1 - (\bar{s} + \epsilon)] - \frac{\alpha_i}{n-1} [(\bar{s} + \epsilon) - [1 - (\bar{s} + \epsilon)]] - \frac{\beta_i(n-2)}{n-1} [1 - (\bar{s} + \epsilon)]. \quad (6.5)$$

From (6.4), (6.5), it is easily checked that $U_i(\bar{s} + \epsilon) - U_i(s_i) > 0$. Hence, we derive a contradiction, so any $s < 1$ cannot be an equilibrium offer.

Now let $\hat{n} = n - 1$ and an offer $0.5 \leq \bar{s} < 1$ that is accepted (see Lemma 6.3). Each proposer then wins the contest with probability $\frac{1}{n-1}$. Any of the proposers can offer an amount $\bar{s} + \epsilon$, ϵ sufficiently small and be ensured to win with probability 1. This improves the payoff of the proposer and contradicts the original equilibrium.

Hence, any $s < 1$ cannot be an equilibrium offer. ■

MARKET GAMES WITH RESPONDER COMPETITION

Now consider the possibility of responder competition. Suppose that the first player is the proposer, while players $2, 3, \dots, n$ are responders. The proposer makes an offer, followed by the responders' decisions to accept or reject. Among the set of responders who accept the offer, one is randomly chosen with uniform probability. The payoffs of the proposer and the winning responder are $1 - s$, s , while all others get zero. If no responder accepts, then all players get zero.

Lemma 6.4 *Suppose that all players are self-regarding. In any subgame perfect outcome, the proposer offers $\bar{s} = 0$, which is accepted by at least one responder.*

Proof of Lemma 6.4: Analogous to the proof of Lemma 6.2, so it is omitted. ■

There is less experimental evidence for market games with responder competition, relative to those with proposer competition. In ultimatum games with two responders, if any responder rejects an offer, the other responder might accept it. Hence, punishing the proposer for low offers is more difficult. One should expect that the same offers are less likely to be rejected in the presence of responder competition.

These predictions are borne out in Fischbacher et al. (2009) where subjects were randomly rematched every period to ensure that the game remained a one-shot interaction. When a single proposer is matched with a single responder, the responder gets, on average, about 40%. In the case of two responders, the share is about 14% lower, and in the final period, it dips below 20%. When there are five responders, the responder's share is about 10% in the last 10 rounds of a 20 round experiment.

An important implication of these results is that if individuals have self-regarding preferences, then adding another responder (competition) should have no impact on the outcome and the proposer receives the entire surplus. Thus, the introduction of competition is neutral in terms of the outcome. However, the introduction of competition when agents have social preferences alters the outcomes significantly. Hence, the self-interest model understates the role of competition. The experimental results of Güth et al. (1997) also bear out these results.

The next proposition shows that in the presence of social preferences, the outcome under responder competition is identical to that under self-regarding preferences. We leave the proof as an exercise for the reader.

Proposition 6.5 *Let the advantageous inequality parameter of the proposer, β_1 , be bounded above by $(n-1)/n$. Suppose that we limit attention to $s < 0.5$. Then there exists a subgame perfect outcome in which each responder accepts any $0 \leq s < 0.5$ and the proposer offers $s = 0$.*

This is not the only equilibrium of the model; an exercise at the end of the chapter asks for other equilibria.

Propositions 6.4, 6.5 show that in the presence of competition, the preferences of individuals, self-regarding or other-regarding, do not matter for the results. Why? The reason is that each individual is too small to influence the degree of inequality in society. Hence, this makes the pursuit of individual self-interest more beneficial (through the first term in (6.1)), while at the same time turning the inequality to his advantage, which is preferable because $\beta_i < \alpha_i$. When individuals have a greater opportunity to influence the degree of inequality, e.g., by altering the level of effort in a principal-agent relationship, then other-regarding preferences have greater bite, as we shall see later.

An important implication is that if individuals are “small,” then fairness issues are less important in the market for goods (as Propositions 6.4, 6.5 exemplify) but of greater importance in labor markets where issues of endogenous effort in firms are rather more salient.

6.2.2 Fairness and cooperation

We now apply the FS preferences to an explanation of the results from public goods games. The implications of these results go beyond the public goods game. In multi-stage games with self-regarding players, cooperation is difficult to achieve under full information, because the tendency for opportunistic behavior in the last stage unravels all the way back to the initial stage. However, if players have other-regarding preferences, then they might not engage in opportunistic behavior in the last stage because of inequity aversion. Furthermore, if some players have initially managed to increase their relative payoffs by behaving in an opportunistic manner, they might be punished by the other-regarding players, who desire greater equality of payoffs. This imparts credibility to the punishment of opportunistic behavior. Contrast this with the non-credibility of punishments in a finite multi-stage full information game with self-regarding players.

To examine the issues involved, we use the public goods game, described in Section 5.4. The monetary payoffs in the game without punishment and with punishment are given by (5.1), (5.2). The utility of an other-regarding individual i is of the FS form,

$$U_i = m_i - \frac{\alpha_i}{n-1} \sum_{j \neq i} \max \{m_j - m_i, 0\} - \frac{\beta_i}{n-1} \sum_{j \neq i} \max \{m_i - m_j, 0\}. \quad (6.6)$$

PUBLIC GOODS GAME WITHOUT PUNISHMENTS

Using (5.1), in the public goods game without punishments, $m_j - m_i = g_i - g_j$. Thus, using (6.6), the utility of player $i \in N = \{1, 2, \dots, n\}$ is

$$U_i = y - g_i + rG - \frac{\alpha_i}{n-1} \sum_{j \neq i} \max \{g_i - g_j, 0\} - \frac{\beta_i}{n-1} \sum_{j \neq i} \max \{g_j - g_i, 0\}. \quad (6.7)$$

Lemma 6.5 *A sufficient condition for an other-regarding player with preferences given in (6.7) to choose $g_i^* = 0$ is that $r + \beta_i < 1$.*

Proof of Lemma 6.5: From (6.7), by contributing an extra unit to the public good, the monetary cost to an individual is $1 - r$. To see the maximum possible monetary benefit from this action, suppose that, among the set of contributors, this agent contributes the least. From (6.7), by contributing an extra unit, the benefit to this lowest contributor is a reduction in advantageous inequity by $\frac{\beta_i(n-1)}{n-1} = \beta_i$. Hence, the maximum possible benefit to player i is $\beta_i - (1 - r)$, which is negative if $r + \beta_i < 1$. ■

Proposition 6.6 *Let $\tilde{n} \in \{0, 1, \dots, n\}$ be the number of other-regarding players with $r + \beta_i < 1$. If $\tilde{n} \geq \frac{r}{2}(n - 1)$, then there is a unique equilibrium in Nash contributions such that $g_i^* = 0$ for all i .*

The proof of Proposition 6.6 is left to the reader as an exercise. From Lemma 6.5, $r + \beta_i < 1$ guarantees free-riding. Proposition 6.6 shows that if a lower bound is put on the number of free-riders, then all other-regarding players do not contribute. If the number of free-riders is large enough, in the sense specified in Proposition 6.6, then contributors to the public good would suffer too much disadvantageous inequity from contributing. Hence, they do not contribute. In this case, the result in Proposition 6.6 matches with the empirical evidence that there is little voluntary contribution in public goods games without punishments. There are, however, other equilibria in which a fraction of the agents contribute a positive amount; an exercise asks you to show this.

PUBLIC GOODS GAME WITH PUNISHMENTS

The possibility of punishment alters the results of public goods games with other-regarding individuals quite dramatically. Suppose that there are some free-riders in the first stage. Then first stage contributors, who are other-regarding, have an incentive to punish the free-riders in the second stage. Contributors in the second stage face disadvantageous inequity relative to the free-riders, because the latter get exactly the same level of benefit from the public good but have not paid for it. How much do the contributors care about this inequity? The answer depends on their inequity aversion parameter α_i . If this is large enough, then a contributor can make a credible threat to punish the free-riders. If the punishment has sufficient bite for the non-contributors, then it can reduce or eliminate free-riding, which is in line with the experimental evidence. These ideas are formalized below.

Definition 6.6 *A conditionally cooperative enforcer is characterized by two conditions: (1) $r + \beta_i > 1$, and (2) a willingness to cooperate if others cooperate.*

Proposition 6.7 *Suppose that there are $n_c \in \{0, 1, \dots, n\}$ conditionally cooperative enforcers. Order the players such that the first n_c are conditional cooperators, $1, 2, \dots, n_c, n_c + 1, \dots, n$. The remaining players are self-regarding, i.e., $\alpha_j = \beta_j = 0, j = n_c + 1, \dots, n$. Let*

$$\frac{\alpha_i}{(n-1)(1+\alpha_i) - (n_c-1)(\alpha_i + \beta_i)} > c, \quad (6.8)$$

where c is the cost per unit to punish another player; $\frac{1}{c}$ is also known as the efficiency of punishment (see Definition 5.4). The following constitutes a subgame perfect equilibrium. In the first stage, all individuals contribute an identical amount $g_i = \bar{g} \in [0, y]$. The second stage strategies are as follows. If all individuals contribute $\bar{g}$ in the first period, then there are no punishments. If player $j \in \{n_c + 1, \dots, n\}$ contributes $g_j < \bar{g}$, then each player $i \in \{1, 2, \dots, n_c\}$ inflicts a punishment $p_{ij} = (\bar{g} - g_j)/(n_c - c)$. There is no punishment inflicted by any players outside this set. If any of the conditionally cooperative enforcers $i \in \{1, 2, \dots, n_c\}$

contributes $g_i < \bar{g}$ or any player chooses $g > \bar{g}$, then a Nash equilibrium of the punishment game is played.

Proof of Proposition 6.7: Suppose that some player $j \in \{n_c + 1, \dots, n\}$ contributes $g_j < \bar{g}$ and all other players follow their equilibrium action. Then, given the punishment strategies outlined in the proposition, in conjunction with the monetary payoff given in (5.2), it can be checked that

$$m_j = y - g_j + r[(n-1)\bar{g} + g_j] - n_c \left(\frac{\bar{g} - g_j}{n_c - c} \right),$$

and for any player $i \in \{1, 2, \dots, n_c\}$,

$$\begin{aligned} m_i &= y - \bar{g} + r[(n-1)\bar{g} + g_j] - c \left(\frac{\bar{g} - g_j}{n_c - c} \right), \\ \Rightarrow m_i &= y - \left(\frac{n_c - c}{n_c - c} \right) (\bar{g} - g_j + g_j) + r[(n-1)\bar{g} + g_j] - c \left(\frac{\bar{g} - g_j}{n_c - c} \right), \\ \Rightarrow m_i &= y - g_j + r[(n-1)\bar{g} + g_j] - \left(\frac{\bar{g} - g_j}{n_c - c} \right) (n_c - c + c) = m_j. \end{aligned}$$

Thus, the deviator gets the same payoff as the enforcer. Because the non-deviating, non-enforcers, do not punish they get the highest payoff. Hence, it is better for a deviating non-enforcer to be a non-deviating, non-enforcer.

We now need to check two conditions.

I. Each of the enforcers finds it worthwhile to carry out the stated punishment: Suppose that an enforcer $i \in \{1, 2, \dots, n_c\}$ reduces punishment of some deviating player j by an amount $\epsilon > 0$ from the stated level $p_{ij} = (\bar{g} - g_j)/(n_c - c)$. This has three main effects.

1. Relative to the other non-deviating, non-enforcers, $n_c + 1, \dots, n$, enforcer i increases their own payoff by $c\epsilon$ (the effective cost of the punishment) for a benefit in disadvantageous inequity of

$$\frac{\alpha_i}{n-1} [n - (n_c - 1)] c\epsilon. \quad (6.9)$$

2. Relative to the other $n_c - 1$ enforcers who stick to the stated level of punishment, the payoff of a deviating enforcer goes up. This results in an additional cost to enforcer i in terms of advantageous inequity of

$$\frac{\beta_i (n_c - 1)}{n - 1} c\epsilon. \quad (6.10)$$

3. Relative to the defector, the payoff of player i has gone up by ϵ on account of the reduction in punishment. So player i finds that disadvantageous inequity has gone up by an amount

$$\frac{\alpha_i}{n-1} [\epsilon - c\epsilon]. \quad (6.11)$$

Subtracting (6.10), (6.11) from (6.9) and simplifying, we get the required condition (6.8).

II. Each of the enforcers finds it worthwhile to contribute $\bar{g}$: Suppose that one of the conditional enforcers $i \in \{1, 2, \dots, n_c\}$ reduces his contribution of the public good from the stated level $\bar{g}$ to $\bar{g} - \eta$, $\eta > 0$. Ignore punishments in the second stage for the moment. This increases the monetary payoff by $(1 - r)\eta$ but creates more advantageous inequality (a cost) with respect to all other players by an amount $\frac{\beta_i(n-1)}{n-1}\eta$. The net effect is $\eta(1 - r - \beta_i)$ which, using Definition 6.6, is negative for a conditionally cooperative enforcer. If we include second stage punishments, the net effect is even more negative. Hence, it does not pay to reduce contributions from the stated amount. ■

6.3 The ERC model

Bolton and Ockenfels (2000) propose a model of *equity, reciprocity, and competition* (ERC), a model of social preferences that is closely related to a model in Bolton (1991).⁵ ERC applies to both extensive form and normal form games. Suppose that there are n players, $i = 1, 2, \dots, n$. Payoffs to all players are non-negative monetary payoffs. Denote by $x_i \geq 0$, the payoff of player i . The sum of the total payoffs is $S = \sum_{i=1}^n x_i$. The relative payoff of player i , also called the *motivation factor*, is given by

$$r_i = r_i(x_i, S, n) = \begin{cases} x_i/S & \text{if } S > 0 \\ \frac{1}{n} & \text{if } S = 0 \end{cases} . \quad (6.12)$$

The utility function (the authors prefer the term, *motivation function*) of player i is $u^i = u^i(x_i, r_i)$. Using (6.12), it is given by

$$\begin{cases} u^i(x_i, \frac{x_i}{S}) & \text{if } S > 0 \\ u^i(x_i, \frac{1}{n}) & \text{if } S = 0 \end{cases} . \quad (6.13)$$

The assumptions on the utility function are as follows.

- A1: u^i is twice continuously differentiable in x_i, r_i .
- A2: u^i is increasing and concave in x_i ($u^i_1 \geq 0$, $u^i_{11} \leq 0$).
- A3: For any given monetary payoff, the utility function u^i is maximized at $r_i = 1/n$ and is strictly decreasing and strictly concave in r_i around this point.

Assumption A3 builds into the model the importance of an equal division of the social surplus (the authors term equal division as the *social reference point*). The crux of the model is the trade-off created by assumptions A2 and A3. From A2, the individual prefers to increase her monetary payoff. However, from A3, for any monetary payoff, the individual prefers equal division. Population heterogeneity is introduced by how different individuals view this trade-off.

ERC and FS preferences do not nest each other, and nor do their empirical predictions. ERC is able to explain several stylized facts from experimental results, among them, the following. Why do proposers give more in ultimatum, as compared to dictator games? Why is there a positive association between effort and rents in the gift exchange game? In dictator games, ERC predicts that the proposer will keep between half and all of the money. It also predicts that zero offers will be rejected in ultimatum games and the rejection rates will increase as the proposer's offer

⁵ For an understanding of the evolution of this model see the section on bargaining games in Chapter 12. For an earlier published motivation behind the ERC model, see Bolton and Ockenfels (1998).

falls. The ERC model also explains the competitive outcomes under proposer competition in an ultimatum game. The ERC model allows for asymmetric information, and it can also explain the data in three-player ultimatum games where a passive third party appears to be treated unfairly, relative to the predictions of the Fehr–Schmidt model (Bolton and Ockenfels, 1998).

By contrast, there are other predictions of the ERC theory that are at variance with the evidence. In the ERC model, individuals compare their payoff with the aggregate payoff of others. In this sense, ERC has a less nuanced notion of inequality, relative to the FS model. In particular, individuals using ERC preferences do not care about interpersonal comparisons of their own payoff and the payoffs of others. The following experimental games show that this gives rise to different predictions relative to the FS model.

Suppose that a player has the mean payoff. Now consider a mean preserving spread of the payoff distribution. ERC predicts that the player's utility should be unaffected. However, the experimental results of Charness and Rabin (2002) do not support this prediction; utility falls with the mean preserving spread. By contrast, the FS utility of a player will be affected by such mean preserving changes.

The ERC model is not able to explain the outcomes in public goods games with punishments. In the second stage of this game, individuals with ERC preferences will not punish the non-contributors because they are not concerned with individual payoffs. Sensing this, potential non-contributors will not contribute. Hence, the prediction of the ERC model is that the outcome of the public goods games with and without punishments should be identical. This is strongly refuted (see Section 5.4.3). Antisocial punishments (see Section 5.4.6) are inconsistent not just with the ERC model but also many other models of social preferences. However, observed punishments in most experiments conducted in Western societies are prosocial. When the institution of punishment is enshrined via an upfront referendum, then punishments are not antisocial, nor are punishments antisocial when there is a norm for punishing non-cooperative behavior, or punishments elicit feelings of guilt and shame (Tyran and Feld, 2006; Herrmann et al. 2008; Carpenter et al., 2009). These kinds of punishments have relatively greater external validity, and the FS model explains them well.

The ERC model also finds it difficult to explain the results of games that demonstrate indirect reciprocity (see Section 5.6). Consider, for instance, the following variant of the third party punishment game. There are three players A, B, and C with respective endowments S , 0 , $S/2$. Players A and B play a dictator game with A being the first mover (so B has no meaningful actions to take). Player C can punish player A if the offer of player A to B is considered inadequate. For each unit of money that player C spends on the punishment, the monetary payoff of player A is reduced by three units. The total surplus in the game is $S + S/2 = 3S/2$. The relative share of player C, in the absence of punishment, is $1/3$, thus, given assumption A3, the Bolton–Ockenfels model predicts no punishment. In most experiments, the majority of C players undertake some form of punishment, which is at variance with the ERC model.

Charness and Rabin (2002) consider a variant of the third party punishment game. Suppose that three players A, B, and C have respective shares given by (x_1, x_2, x_3) . Player C is now given a choice between the following two allocations: $(575, 575, 575)$ and $(900, 300, 600)$. Player C gets the fair share (a third) in both allocations. The Bolton–Ockenfels model predicts that player C will choose the second allocation because, among the two, it gives player C a higher material payoff (Assumption A2). The experimental evidence is that 54% of the subjects prefer the first allocation. Self-interest alone predicts that C will choose the second allocation, hence, we cannot conclude that the choice of the remaining 46% supports the Bolton–Ockenfels model.

Although the experimental evidence from the simple games considered above does not always support the Bolton–Ockenfels model, as no model of other-regarding preferences is supported in

all possible experiments, it is nevertheless an important milestone in the development of models of social preferences. It formalizes an important intuitive insight about how people may behave. The model may perhaps perform even better in more cognitively challenging games with a very large number of players, where one might only have a rough notion of one's position relative to the aggregate.

6.4 Fairness and stochastic dominance

Given two probability distributions over outcomes, it is critical to be able to answer the question of which distribution an individual prefers. Under self-regarding preferences, this question has been the cornerstone of many important advances in economic theory. The relevant machinery to deal with these issues is *first and second order stochastic dominance* and *generalized Lorenz dominance*.⁶ What can we say when individuals have social preferences?

Dhami and al-Nowaihi (2013) show that the standard concepts of *first order and second order stochastic dominance* as well as *generalized Lorenz dominance* are no longer valid when one has social preferences of the FS form. They propose alternative dominance concepts that are suitable for such social preferences. In this section we consider their work.

Consider n possible income classes. Income, y , of any member belongs to the set of possible incomes $Y = \{y_1 < y_2 < \dots < y_n\}$. Under any distribution function, P , over this set of incomes, the proportion of individuals with income y_i is denoted by $p_i \geq 0$, $\sum_{i=1}^n p_i = 1$. The *cumulative probability distribution* is given by $P_0 = 0$, $P_j = \sum_{i=1}^j p_i$, $j = 1, 2, \dots, n$. Denote by Π , the set of all such distributions over Y .

The *cumulative of the cumulative distribution* is given by $\tilde{P}_0 = 0$, $\tilde{P}_j = \sum_{i=1}^j P_i$, $j = 1, 2, \dots, n$. Let $\tilde{\Pi}$ be the set of all such distributions. The average, or mean, of $y_1, y_2, \dots, y_n$ under the distribution $P \in \Pi$ is

$$\mu_P = \sum_{i=1}^n p_i y_i.$$

Let $u(y_i)$ be the utility function of an individual who has self-regarding preferences and has the income y_i . Denote by $\mathbf{u}$ the class of all non-decreasing utility functions.

In this section we will work with the general form of Fehr–Schmidt preferences, sometimes known as the *non-linear form of Fehr–Schmidt preferences*. These preferences modify the linear form of FS preferences given in (6.1) as shown in the next definition. For axiomatic foundations of such preferences, see Section 6.8.4 below.

Definition 6.7 (*General form of FS utility*): Consider the income distribution, P and $u \in \mathbf{u}$. The general form of the Fehr–Schmidt utility function (FS) for an individual with income $y_j \in Y$ is given by

$$U(y_j, P) = u(y_j) - \beta \sum_{i=1}^{j-1} p_i [u(y_j) - u(y_i)] - \alpha \sum_{k=j+1}^n p_k [u(y_k) - u(y_j)], \alpha \geq 0, 0 \leq \beta < 1.$$

(6.14)

⁶ See Rothschild and Stiglitz (1970, 1971).

$$U(y_j, P) - U(y_j, Q) = \beta \sum_{i=1}^{j-1} (q_i - p_i) [u(y_j) - u(y_i)] + \alpha \sum_{k=j+1}^n (q_k - p_k) [u(y_k) - u(y_j)]. \quad (6.15)$$

For an individual with self-regarding preferences, $\alpha = \beta = 0$, so

$$U(y, P) = u(y). \quad (6.16)$$

The approach in the literature is to begin with a purely statistical definition of a dominance concept and then to establish its economic relevance (or *soundness*) by relating it to the relevant decision theory. In the discrete case, first and second order dominance are defined as follows.

Definition 6.8 (First order stochastic dominance): Let $P, Q \in \Pi$. Then P first order stochastically dominates Q ($P \succsim_1 Q$) if $P_j \leq Q_j$ for $j = 1, 2, \dots, n$. If, in addition, the inequality is strict for some j , then P strictly first order stochastically dominates Q ($P \succ_1 Q$).

Definition 6.9 We say that the income levels are equally spaced if for some positive real number, δ , $y_{i+1} - y_i = \delta$ for $i = 1, 2, \dots, n-1$.⁷

Definition 6.10 (Second order stochastic dominance): Suppose that incomes are equally spaced (Definition 6.9).⁸ Let $P, Q \in \Pi$. Then P second order stochastically dominates Q ($P \succsim_2 Q$) if $\tilde{P}_j \leq \tilde{Q}_j$ for $j = 1, 2, \dots, n$ and if $\mu_P \geq \mu_Q$.⁹ If, in addition, one of these inequalities is strict, then P strictly second order stochastically dominates Q ($P \succ_2 Q$).

Propositions 6.8 and 6.9 consider the classical case in which self-regarding individuals maximize their expected utility with respect to a given distribution, behind a veil of ignorance (Mas-Colell et al., 1995, ch. 6).

Proposition 6.8 Let $P, Q \in \Pi$. Then $P \succsim_1 Q$ if, and only if, for any $u \in \mathbf{u}$,

$$\sum_{i=1}^{i=n} p_i u(y_i) \geq \sum_{i=1}^{i=n} q_i u(y_i), \quad (6.17)$$

and $P \succ_1 Q$ if, and only if, the inequality in (6.17) is strict for all strictly increasing $u \in \mathbf{u}$.

Choosing $u(y) = y$ as a candidate function in Proposition 6.8 we get that if $P \succsim_1 Q$ ($P \succ_1 Q$), then the restrictions on the means under P and Q is $\mu_P \geq \mu_Q$ ($\mu_P > \mu_Q$).

⁷ This is not restrictive because we can always introduce extra income levels, each with probability zero, to achieve equal spacing. For example, suppose $y_1 = 5, y_2 = 7, y_3 = 11$, which is not equally spaced, and $P_1 = \frac{1}{3}, P_2 = \frac{2}{3}$. Consider $y_1 = 5, y_2 = 7, y_3 = 9, y_4 = 11$, which are equally spaced, and $Q_1 = \frac{1}{3}, Q_2 = \frac{2}{3}, Q_3 = \frac{2}{3}$. Both P and Q describe the same reality.

⁸ Often "equal spacing" is not stated as part of the definition of second order stochastic dominance. But then it has to be stated in the propositions. We find it more convenient to state this in the definition. This assumption is not needed in the continuous case.

⁹ Often the condition $\mu_P \geq \mu_Q$ is not included as part of the definition of second order stochastic dominance. But then it needs to be included in the statement of the relevant propositions. It is slightly simpler to include $\mu_P \geq \mu_Q$ as part of the definition of second order stochastic dominance.

Proposition 6.9 Let $P, Q \in \Pi$. Then $P \succsim_2 Q$ if, and only if, for any concave $u \in \mathbf{u}$,

$$\sum_{i=1}^{i=n} p_i u(y_i) \geq \sum_{i=1}^{i=n} q_i u(y_i), \quad (6.18)$$

and $P \succ_2 Q$ if, and only if, the inequality in (6.18) is strict for all strictly increasing strictly concave $u \in \mathbf{u}$.

Propositions 6.8 and 6.9 no longer hold under FS preferences once individuals know their income levels and the income levels of others.

Example 6.3 Consider three income levels, 0, 25, 50 and two distributions, P, Q defined in the table below, where $\frac{1}{6} \leq \varepsilon \leq \frac{5}{6}$.

y	$y_1 = 0$	$y_2 = 25$	$y_3 = 50$
$p(y)$	0	1/3	2/3
$q(y)$	1/6	ε	$(5/6) - \varepsilon$
$P(y)$	0	1/3	1
$Q(y)$	1/6	$(1/6) + \varepsilon$	1
$\tilde{P}(y)$	0	1/3	4/3
$\tilde{Q}(y)$	1/6	$(1/3) + \varepsilon$	$(4/3) + \varepsilon$

From the above table it can be easily seen that $P \succ_1 Q$. Also from the above table it is clear that $P \succ_2 Q$ ($\mu_P = \frac{125}{3} > \frac{125}{3} - 25\varepsilon = \mu_Q$). For the individual with income $y_2 = 25$, we can find from (6.15)

$$U(25, Q) - U(25, P) = \alpha \left(\varepsilon - \frac{1}{6} \right) [u(50) - u(25)] + \frac{\beta}{6} [u(0) - u(25)]. \quad (6.19)$$

It is easy to construct examples where an individual with Fehr–Schmidt preferences strictly prefers Q to P . For example, let $\varepsilon = \frac{1}{3}$ and take u to be any strictly increasing own utility function. Take $\alpha = 1$ and $\beta = 0$. Consider an individual with income 25. Then, from (6.19) we get $U(25, Q) - U(25, P) = \frac{u(50) - u(25)}{6} > 0$.

Consider now some implications of pride ($\beta < 0$) rather than altruism ($\beta > 0$). Let u be any strictly increasing own utility function. Take $\alpha = 1$ and $\varepsilon = \frac{1}{6}$. Then $U(25, Q) - U(25, P) = -\frac{\beta}{6} [u(25) - u(0)]$. Clearly the choice between P, Q now hinges solely on the sign of β . An individual with altruism prefers P to Q but an individual with pride prefers Q to P . This example makes the more general point that an individual with pride will always prefer the dominated distribution.

Example 6.4 In FS preferences, see (6.14), $\beta > 0$ captures altruism or compassion towards individuals who are poorer. Hopkins (2008) differentiates between the sign of β in two different literatures. In behavioral economics, where models of social preferences have gained increasing acceptance, $\beta > 0$. But in happiness economics, $\beta < 0$ is allowed for. Hopkins (2008) refers to $\beta < 0$ as “pride,” “competitiveness,” or “downward envy.” Consider now some implications of pride ($\beta < 0$) rather than altruism ($\beta > 0$) in the data given in Example 6.3. Let u be any strictly increasing own utility function. Take $\alpha = 1$ and $\varepsilon = \frac{1}{6}$. Then, from (6.19) we get that $U(25, Q) - U(25, P) = -\frac{\beta}{6} (u(50) - u(25))$. Clearly the choice between P, Q now hinges solely on the sign of β . An individual with altruism prefers P to Q but an

individual with pride prefers Q to P . Dhami and al-Nowaihi (2013) show formally that an individual with pride will always prefer the dominated distribution.

These examples beg the question: what are the appropriate dominance concepts for FS preferences? The next remark provides a clue to the answer.

Remark 6.1 Begin with an income distribution $P \in \Pi$, under which an individual has the Fehr–Schmidt preferences given in (6.14) and has income y_j . Consider two income levels, y_s, y_t , such that $y_s < y_t < y_j, p_s < 1$ and $p_t > 0$. Suppose that we obtain the distribution Q from P by transferring a fraction Δ of individuals from the income class y_t to y_s , where $0 < \Delta < \min \{1 - p_s, p_t\}$, then from (6.15) $U(y_j, P) - U(y_j, Q) = \beta \Delta [u(y_t) - u(y_s)] > 0$. Thus individuals with FS preferences dislike “rich to poor transfers” among people poorer than them. Now consider two income levels, y_l, y_m , such that $y_j < y_l < y_m, p_s < 1$ and $p_m > 0$. Now obtain a new distribution Q by transferring a fraction Δ of individuals from the income class y_m to y_l , where $0 < \Delta < \min \{1 - p_l, p_m\}$, then from (6.15) $U(y_j, Q) - U(y_j, P) = \alpha \Delta (u(y_m) - u(y_l)) > 0$. Thus, individuals with FS preferences like “rich to poor transfers” among people richer than them.

Consider the following example that illustrates some of the main ideas in Dhami and al-Nowaihi (2013). Consider the data given in the table below, where $0 < \epsilon < \frac{1}{6}$. We are interested in the individual with income of $y_3 = 50$ who has FS preferences.

y	$y_1 = 0$	$y_2 = 25$	$y_3 = 50$	$y_4 = 75$	$y_5 = 100$
$p(y)$	0	$1/3$	$(1/3) + 2\epsilon$	$(1/3) - 2\epsilon$	0
$q(y)$	ϵ	$(1/3) - \epsilon$	$1/3$	$(1/3) - \epsilon$	ϵ
$P(y)$	0	$1/3$	$(2/3) + 2\epsilon$	1	1
$Q(y)$	ϵ	$1/3$	$2/3$	$1 - \epsilon$	1
$\tilde{P}(y)$	0	$1/3$	$1 + 2\epsilon$	$2 + 2\epsilon$	$3 + 2\epsilon$
$\tilde{Q}(y)$	ϵ	$(1/3) + \epsilon$	$1 + \epsilon$	2	3

Below income $y_3 = 50$, distribution Q moves some richer individuals to a poorer income level and above income $y_3 = 50$ it move some poorer individuals to a richer income level. Thus, using Remark 6.1, we would expect such an individual to prefer the distribution P to the distribution Q . What inferences can we draw from this unambiguous preference for P ? An examination of the table reveals that the following restrictions apply

$$P_i \leq Q_i, P_k \geq Q_k; i < 3, k \geq 3. \quad (6.20)$$

$$\tilde{P}_i \leq \tilde{Q}_i, \tilde{P}_k \geq \tilde{Q}_k; i < 3, k \geq 3. \quad (6.21)$$

From (6.20), neither distribution first order stochastically dominates the other, and, from (6.21), neither distribution second order stochastically dominates the other. Thus, a priori, one cannot predict which distribution would be preferred by an individual with self-regarding preferences. But we shall see that these restrictions are ideal to determine which of the distributions is preferred by an individual with FS preferences whose income is $y_3 = 50$. One can make the following simple calculations using (6.15), for any $u \in \mathbf{u}$,

$$U(50, P) - U(50, Q) = \beta \epsilon [u(25) - u(0)] + \epsilon \alpha [u(75) - u(50) + u(100) - u(50)] > 0,$$

as claimed. We did not need to invoke the concavity of the utility function for this example because it satisfies (6.20), in which case it is sufficient that $u \in \mathbf{u}$.

In the case of first and second stochastic dominance (Definitions 6.8, 6.9) the dominant distribution, P , has a mean that is no lower than the dominated distribution, Q . This need not be the case under FS dominance. From the data given to us,

$$\mu_Q - \mu_P = 50\epsilon > 0.$$

Thus, the preferred distribution in this case, P , has a lower mean. The reason is that, for $\alpha > 0$, a reduction in the mean can be associated with a reduction in disadvantageous inequality for an individual with income y_j without affecting that individual's income. For instance, this could happen by destroying some of the wealth of individuals with income higher than y_j (but still leaving them with incomes no less than y_j). This is supported by the evidence where subjects in experiments prefer a smaller cake which is more equitably distributed.¹⁰

The conditions in (6.20), (6.21) are examples of the more general conditions that are developed in Dhami and al-Nowaihi (2013). They call these conditions, respectively, *first order FS dominance* and *second order FS dominance*. We state these conditions and some of the relevant results below that the reader is asked to prove in the exercises.

Definition 6.11 (*First order Fehr–Schmidt dominance*): Consider an individual with income $y_j \in \mathbf{Y}$. Let $P, Q \in \Pi$. Then P first order FS_{y_j} dominates Q ($P \succeq_{FS1_{y_j}} Q$) if

- (a) $P_i \leq Q_i$ for each $i = 1, 2, \dots, j-1$, and
- (b) $P_k \geq Q_k$ for each $k = j, j+1, \dots, n-1$.

If, in addition, one of these inequalities is strict, then we say that P strictly first order FS_{y_j} dominates Q ($P \succ_{FS1_{y_j}} Q$).

Thus, distribution P first order FS dominates Q for an individual of income level $y_j \in \mathbf{Y}$ if it first order stochastically dominates below y_j and is first order stochastically dominated above y_j . Second order FS dominance that we now define relies on a similar interpretation.

Definition 6.12 (*Second order Fehr–Schmidt dominance*): Let $P, Q \in \Pi$, $y_j \in \mathbf{Y}$. Then P second order FS_{y_j} dominates Q ($P \succeq_{FS2_{y_j}} Q$) if

- (a) Incomes are equally spaced (Definition 6.9),
- (b) $\tilde{P}_i \leq \tilde{Q}_i$ for each $i = 1, 2, \dots, j-1$, and
- (c) $\tilde{P}_k \geq \tilde{Q}_k$ for each $k = j, j+1, \dots, n-1$.

If, in addition, one of the inequalities in (b) or (c) is strict, then we say that P strictly second order FS_{y_j} dominates Q ($P \succ_{FS2_{y_j}} Q$).

Proposition 6.10 (Dhami and al-Nowaihi, 2013): Consider an individual with income $y_j \in \mathbf{Y}$. Let $P, Q \in \Pi$. Then P first order FS_{y_j} dominates Q ($P \succeq_{FS1_{y_j}} Q$) if, and only if, $U(y_j, P) \geq U(y_j, Q)$ for all $u \in \mathbf{u}$, $\alpha \geq 0$ and $\beta \in [0, 1)$.

Proposition 6.11 (Dhami and al-Nowaihi, 2013): Let $P, Q \in \Pi$, $y_j \in \mathbf{Y}$. Let P second order FS_{y_j} dominate Q ($P \succeq_{FS2_{y_j}} Q$). Then $U(y_j, P) \geq U(y_j, Q)$ for all $\alpha \geq 0$, $\beta \in [0, 1)$ and all concave $u \in \mathbf{u}$.

The next proposition establishes a partial converse of Proposition 6.11.

¹⁰ See, for instance, Ackert et al. (2007), Bolton and Ockenfels (2006), and Tyran and Sausgruber (2006).

Proposition 6.12 (Dhami and al-Nowaihi, 2013): Let $P, Q \in \Pi$ and $y_j \in Y$. Suppose incomes are equally spaced (Definition 6.9). Suppose $\tilde{P}_{j-1} = \tilde{Q}_{j-1}$. If $U(y_j, P) \geq U(y_j, Q)$ for all $\alpha \geq 0$, all $\beta \in [0, 1)$ and all concave $u \in \mathbf{u}$, then P second order FS_{y_j} dominates Q ($P \succeq_{FS_{y_j}} Q$).

In the model with self-regarding preferences, the relation between second order stochastic dominance and generalized Lorenz dominance is a crucial one.¹¹ Indeed, such a relation is often used in a justification of cross-country ranking of income distributions. Dhami and al-Nowaihi (2013) show that an analogous result holds for the case of FS preferences. It turns out that a slight modification of second order FS dominance is equivalent to a particular modification of generalized Lorenz dominance. This makes available the full toolkit of dominance concepts for social preferences of the FS form.

6.5 Behavioral political economy

The explanation of societal redistribution is one of the central problems in political economy. Existing explanations rely on voters who have self-regarding preferences.¹² In the literature, the simplest political institution is *direct democracy* in which voters vote directly to choose between alternative policies. This is not only an important benchmark institution, its role in actual policy choice has been expanding.¹³ For these reasons, we restrict ourselves to direct democracy in this section.

The recent empirical literature strongly supports the role of social preferences in voting models (Ackert et al., 2007; Bolton and Ockenfels, 2006; Tyran and Sausgruber, 2006). These papers establish that voters often choose policies that promote equity/fairness over purely self-regarding considerations. Bolton and Ockenfels (2006), for instance, examine the preference for equity versus efficiency in a voting game. Groups of three subjects are formed and are presented with two alternative policies. One policy promotes equity, while the other promotes efficiency. The final outcome is chosen by a majority vote. About twice as many subjects in experiments preferred equity as compared to efficiency.¹⁴

Experimental results on voting under direct democracy lend support to the FS model. Tyran and Sausgruber (2006) explicitly test for the importance of the FS framework in explaining the experimental results on voting. They conclude that the FS model predicts much better than the standard model with self-regarding preferences. In addition, for the three income classes in their experiments, the FS model provides, in their words, “strikingly accurate predictions for individual voting in all three income classes.”

The econometric results of Ackert et al. (2007), based on their experimental data, lend further support to the FS model in the context of redistributive taxation. The estimated coefficients of altruism and envy in the FS model are statistically significant and, as expected, negative in sign. In the context of voting experiments, Bolton and Ockenfels (2006) conclude that “while not everyone measures fairness the same way, the simple measures offered by [Bolton and Ockenfels (2000)] or FS provide a pretty good approximation to population behavior over a wide range of scenarios that economists care about.”

¹¹ See Lambert (2001) for a statement and proofs of the relevant results as well as a good discussion of the issues.

¹² For a wide-ranging review, see Persson and Tabellini (2000).

¹³ See, for instance, Matsusaka (2005).

¹⁴ Furthermore, even those willing to change the status quo for efficiency are willing to pay, on average, less than half relative to those who wish to alter the status quo for equity.

Economy-wide voting under direct democracy is impersonal and anonymous, thereby making it unlikely that intentions play any important role. Hence, FS preferences are a particularly good vehicle through which to model social preferences in a voting context. In the discussion below we use the term *self-regarding voter model* when all voters have self-regarding preferences and the term *other-regarding voter model* when at least some voters have social preferences.

Dhami and al-Nowaihi (2010a, 2010b) provide the relevant theoretical results that are motivated by the experimental results and open the way for further applications of the other-regarding voter model. In particular, the neoclassical results on the existence of Condorcet winner derived for self-regarding voters no longer apply for fair voters. Dhami and al-Nowaihi (2010a) derive conditions for the existence of a Condorcet winner when all voters have a social preference of the FS form. Dhami and al-Nowaihi (2010b) consider the implications for societal redistribution when there is a mixture of other-regarding and self-regarding voters. We consider these two contributions below.

6.5.1 Existence of a Condorcet winner when voters have social preferences

We consider a standard, general equilibrium model with endogenous labor supply that gives the simplest trade-off between equity and efficiency.¹⁵ Let there be $n = 2m - 1$ voters who combine the roles of producer-consumers and voters. Let the skill level of voter j be s_j , $j = 1, 2, \dots, n$, where $0 < s_i < s_j < 1$, for $i < j$. Denote the skill vector by $\mathbf{s} = (s_1, s_2, \dots, s_n)$ and the median skill level by s_m . Each voter has a fixed time endowment of one unit, so supplies l_j units of labor and enjoys $1 - l_j$ units of leisure, where $0 \leq l_j \leq 1$. Labor markets are competitive and each firm has access to a linear production technology. Thus, firm j , represented by voter j , produces an amount y_j such $y_j = s_j l_j$. Hence, the wage rate offered to each voter coincides with the marginal product, i.e., the skill level, s_j . Thus, the before-tax income of voter j is given by $y_j = s_j l_j$. Denote the average before-tax income by $\bar{y} = \frac{1}{n} \sum_{j=1}^n y_j$.

The government operates a linear progressive income tax system. This is characterized by a constant marginal tax rate, t , $t \in [0, 1]$, and a uniform transfer, b , to each voter that equals the average tax proceeds, thus, $b = t\bar{y}$. The budget constraint of voter j is given by $0 \leq c_j \leq (1 - t)y_j + b$, which can be written as

$$0 \leq c_j \leq (1 - t)s_j l_j + b. \quad (6.22)$$

We define a voter's preferences in two stages. First, let voter j have a continuous *own-utility* function, $\tilde{u}_j(c_j, 1 - l_j)$, defined over own-consumption, $c_j > 0$, and own-leisure, $1 - l_j$, $0 \leq l_j \leq 1$. Each voter has a twice continuously differentiable, and identical, utility function

$$\tilde{u}_j = \tilde{u}(c_j, 1 - l_j). \quad (6.23)$$

Differences in c_j and l_j across voters arise only due to differences in skill levels but not due to differences in the utility functions. We assume that own-consumption is always desirable, so $\tilde{u}_j$ is a strictly increasing function of c_j . Second, voters have *other-regarding preferences* as in

¹⁵ This is also known as the Roberts–Romer–Meltzer–Richards model (or RRMR model) based on the names of economists who formally articulated it in seminal contributions to political economy. For the relevant references, see, for instance, Persson and Tabellini (2000) and Dhami and al-Nowaihi (2010 a,b).

Fehr–Schmidt (1999). Let c_{-j} and l_{-j} be the vectors of consumption and labor supplies, respectively, of voters other than voter j . Then the FS-utility of voter j is¹⁶

$$\tilde{U}_j(c_j, l_j; c_{-j}, l_{-j}, t, b, \alpha, \beta, s) = \tilde{u}_j - \frac{\alpha}{n-1} \sum_{k \neq j} \max\{0, \tilde{u}_k - \tilde{u}_j\} - \frac{\beta}{n-1} \sum_{i \neq j} \max\{0, \tilde{u}_j - \tilde{u}_i\},$$

where, for fair voters, $0 < \beta < 1$ and $\alpha > 0$ with the typical experimental finding suggesting that $\alpha > \beta$. For *self-regarding* voters $\alpha = \beta = 0$, so $\tilde{U}_j = \tilde{u}_j$. Thus, $\tilde{u}$ is also the utility function of a self-regarding voter, as in the standard model. The other-regarding voter cares about own payoff (first term), payoff relative to those where inequality is disadvantageous (second term) and payoff relative to those where inequality is advantageous (third term).

Since $\tilde{u}_j$ is a strictly increasing function of c_j , and since $\alpha \geq 0$ and $0 \leq \beta < 1$, it follows that $\tilde{U}_j$ is also a strictly increasing function of c_j . Hence, the budget constraint (6.22) holds with equality. Substituting $c_j = (1-t)s_j l_j + b$, from (6.22), into the utility function of a self-regarding voter, $\tilde{u}_j(c_j, 1-l_j)$, we get

$$u_j = u(l_j; t, b, s_j) = \tilde{u}((1-t)s_j l_j + b, 1-l_j) \quad (6.24)$$

Correspondingly, the FS-utilities take the form

$$U_j(l_j; l_{-j}, t, b, \alpha, \beta, s) = u_j - \frac{\alpha}{n-1} \sum_{k \neq j} \max\{0, u_k - u_j\} - \frac{\beta}{n-1} \sum_{i \neq j} \max\{0, u_j - u_i\}. \quad (6.25)$$

We consider a two-stage game. In the first stage, all voters vote directly for their most preferred redistributive tax rate. If a median voter equilibrium exists, then the tax rate preferred by the median voter is implemented—the outcome in this case is known as a *Condorcet winner*. In the second stage, all voters make their labor supply decision, conditional on the tax rate chosen by the median voter in the first stage. On choosing their labor supplies in the second stage, the announced first period tax rate is implemented. In the second stage, the voters play a one-shot Nash game: each voter, j , chooses his/her labor supply, l_j , given the vector, l_{-j} , of labor supplies of the other voters, so as to maximize his/her FS-utility (6.25).

The solution is by backward induction. So consider first, the second stage. Given the tax rate, t , and the transfer, b , both determined in the first stage, the voters play a one-shot Nash game to determine their labor supplies (in the subgame determined by t and b).

Proposition 6.13 (Dhami and al-Nowaihi, 2010a): *In the second stage of the game, voter j , whether other-regarding or self-regarding, chooses own labor supply, l_j , so as to maximize own-utility, u_j defined in (6.24), given t , b and s_j .*

The proof of Proposition 6.13 is left as an exercise for the reader. From Proposition 6.13, an other-regarding voter, despite having social preferences, chooses labor supply exactly like a self-regarding voter. However, when making a decision on the redistributive tax rate in the first stage (see below), the two kinds of voters make different choices. In other words, in two separate domains, labor supply and redistributive choice, the other-regarding voter behaves *as if* he had self-regarding preferences in the first domain and social preferences in the second. In this respect, these results are similar to the contrast between the results in the ultimatum game with

¹⁶ Here, we consider the non-linear version of FS preferences; see Fehr and Schmidt (1999) and Definition 6.7.

and without proposer (or responder) competition in Section 6.2.1.¹⁷ Note that Proposition 6.13 would not hold if in the FS utility function of voter j in (6.25), the u_i , $i \neq j$, entered non-additively. However, the empirical evidence supports the adopted form for the FS-utility function in the voting domain.

For the generic utility function $\tilde{u}(c, 1-l)$, defined in (6.23), we use the standard notation $\tilde{u}_1 = \frac{\partial \tilde{u}(c, 1-l)}{\partial c}$ and $\tilde{u}_2 = \frac{\partial \tilde{u}(c, 1-l)}{\partial (1-l)}$. The utility function has the following, plausible, properties:

$$(a) \tilde{u}_1 > 0, (b) l > 0 \Rightarrow \tilde{u}_2(c, 1-l) > 0, (c) \tilde{u}_2(c, 1) = 0, (d) \tilde{u}_1(c, 0) \leq \tilde{u}_2(c, 0), \quad (6.26)$$

$$(a) \tilde{u}_{11} \leq 0, (b) \tilde{u}_{12} \geq 0, (c) l > 0 \Rightarrow \tilde{u}_{22}(c, 1-l) < 0, (d) (\tilde{u}_{12})^2 \leq \tilde{u}_{11}\tilde{u}_{22}. \quad (6.27)$$

From (6.26a), the marginal utility of consumption is positive, while (6.26b) implies that marginal utility of leisure is positive, unless $l = 0$ in which case (6.26c) says that the consumer is satiated with leisure. From (6.26d), when a consumer has no leisure, she always (weakly) prefers one extra unit of leisure to one extra unit of consumption. (6.27a) says that marginal utility of consumption is non-increasing. From (6.27b), consumption and leisure are complements, while (6.27c) implies that the marginal utility of leisure is strictly declining unless, possibly, the consumer is satiated with leisure (in which case $\tilde{u}_{22}(c, 1) = 0$). Conditions (6.26) and (6.27) guarantee that a maximum exists, that it is unique and that it is an interior point ($0 < l_i < 1$), unless $t = 1$ in which case the maximum will lie at $l_i = 0$. Conditions (6.27a,c,d) guarantee that $\tilde{u}$ is concave.

We list, in Lemmas 6.6 and 6.7 below, some useful results; the proofs are left as an exercise for the reader. Lemma 6.6 shows that there is a unique solution to the labor supply of an individual and characterizes other useful properties of labor supply. For instance, the optimal labor supply is decreasing in the redistributive tax rate (conflict between efficiency and equity).

Lemma 6.6 (*Properties of labor supply; Dhami and al-Nowaihi, 2010a*):

- (a) Given t, b , and s_j , there is a unique labor supply for voter j , $l_j = l(t, b, s_j)$, that maximizes own-utility $u(l_j; t, b, s_j)$ defined in (6.24),
- (b) $t \in [0, 1] \Rightarrow 0 < l_j < 1$,
- (c) $l_j = 0$ at $t = 1$,
- (d) $t \in [0, 1] \Rightarrow \left[\frac{\partial u}{\partial l_j}(l_j; t, b, s_j) \right]_{l_j=l(t, b, s_j)} = 0$,
- (e) $l(t, b, s_j)$ is continuously differentiable,
- (f) $\frac{\partial l(t, b, s)}{\partial b} \leq 0$,
- (g) for each $t \in [0, 1]$, the equation $b = \frac{1}{n} t \sum_{i=1}^n s_i l(t, b, s_i)$ has a unique solution $b(t, s) \geq 0$; and $b(t, s)$ is continuously differentiable.

Substituting optimal labor supply, given by Lemma 6.6(a), in $u(l_j; t, b, s_j)$ we get the indirect own-utility function of voter j ,

$$v_j = v(t, b, s_j) = u(l(t, b, s_j); t, b, s_j). \quad (6.28)$$

Lemma 6.7 lists some useful properties of the indirect utility function, v . In particular, v is increasing in the lump-sum transfer, b . If the tax rate is bounded away from 1, then v is increasing in the skill level of the individual, s , and decreasing in the redistributive tax rate, t (holding fixed, b).

¹⁷ In other contexts, individuals might, for instance, send their own children to private schools (self-interest) but could at the same time vote for more funding to government run schools in local or national elections (public interest). Thus, individuals can put on different hats in different situations.

In Lemma 6.7, the distinction between the results at $t = 1$ and $t \in [0, 1)$ follow from Lemma 6.6(b), (c)

Lemma 6.7 (*Properties of the indirect own utility function; Dhimi and al-Nowaihi, 2010a*):

$$\begin{aligned} (a) \quad & \frac{\partial v}{\partial b} > 0, \\ (bi) \quad & \left[\frac{\partial v}{\partial s} \right]_{t=1} = 0, & (bii) \quad t \in [0, 1) \Rightarrow \frac{\partial v}{\partial s} > 0, \\ (ci) \quad & \left[\frac{\partial v}{\partial t} \right]_{t=1} = 0, & (cii) \quad t \in [0, 1) \Rightarrow \frac{\partial v}{\partial t} < 0, \\ (di) \quad & \frac{\partial^2 v}{\partial s \partial b} \leq 0, & (dii) \quad \left[\frac{\partial^2 v}{\partial s \partial b} \right]_{t=1} = 0. \end{aligned}$$

Substituting labor supply, $l(t, b, s_j)$, into $y_j = s_j l_j$ gives before-tax income $y_j(t, b, s_j) = s_j l(t, b, s_j)$.

We now solve the first stage problem of the choice of the optimal tax rate. Substituting labor supply, $l(t, b, s_j)$, into the utility function, $U_j(l_j; 1-j, t, b, \alpha, \beta, s)$, and using (6.25) and (6.28), the indirect utility function, $V_j(t, b, \alpha, \beta, s)$, of voter j is given by

$$V_j(t, b, \alpha, \beta, s) = v_j - \frac{\alpha}{n-1} \sum_{k \neq j} \max\{0, v_k - v_j\} - \frac{\beta}{n-1} \sum_{i \neq j} \max\{0, v_j - v_i\}, \quad (6.29)$$

where v_j is defined in (6.28). In the light of Lemmas 6.7(bi) and 6.7(bii), (6.29) becomes

$$V_j(t, b, \alpha, \beta, s) = v_j - \frac{\alpha}{n-1} \sum_{k > j} [v_k - v_j] - \frac{\beta}{n-1} \sum_{i < j} [v_j - v_i]. \quad (6.30)$$

We now introduce two further assumptions, A1 and A2, followed by the main result.

A1: $t \in [0, 1) \Rightarrow \frac{\partial^2 v}{\partial s \partial t}(t, b, s) < 0$, where v is defined in (6.28).

Recall, from Lemma 6.7(cii), that $t \in [0, 1) \Rightarrow \frac{\partial v}{\partial t} < 0$. Hence, $\frac{\partial}{\partial s} \left(t \frac{\partial v}{\partial t} \right) = t \frac{\partial^2 v}{\partial s \partial t} < 0$ can be interpreted as saying that an extra 1% on the redistributive tax rate hurts a poor person less than a rich person. Thus Assumption A1 roughly says that redistributive taxes hurt the poor less than the rich. This is the basic foundation of the modern welfare state.¹⁸

A2: $\frac{\partial V_j}{\partial t}(t, b, \alpha, \beta, s) \leq 0$.

Since $\frac{\partial v}{\partial t} < 0$, for $t < 1$ (Lemma 6.7(cii)), an increase in tax (benefit, b , remaining fixed), is undesirable for a self-regarding-voter, which is entirely reasonable. Assumption A2 extends this to fair-voters as well. It implies that envy is not so great as to make a fair-voter prefer an increase in tax, even if it has no gain for anyone in terms of an increase in the benefits, b (b is held fixed in computing $\frac{\partial V_j}{\partial t}$ in A2).

Thus, conditions A1 and A2 bear an intuitive interpretation. Dhimi and al-Nowaihi (2010a) show that the class of utility functions that satisfy assumptions A1 and A2 is very large. They also discuss the interpretation of assumptions A1, A2 in terms of a voter's own-utility $\tilde{u}_j(c_j, 1 - l_j)$ but there are no obvious insights to be gained from this.

Proposition 6.14 (*Dhimi and al-Nowaihi, 2010a*): *Under assumptions A1 and A2 a majority of the other-regarding voters prefer the tax rate that is optimal for the median-skill voter.*

¹⁸ Assumption A1 is satisfied, for instance, in the important case of quasi-linear preferences, which is widely used in this literature.

Proposition 6.14 gives the conditions for the existence of a Condorcet winner when voters have social preferences. The modern literature on political economy when voters are self-regarding really took off after the publication of the conditions for the existence of a Condorcet winner. Proposition 6.14 gives the corresponding results for the case of other-regarding voters.

So far, we have assumed that all voters have social preferences. However, the evidence typically shows up a mixture of self-regarding and other-regarding individuals. The next section considers the implications of such a mixture for optimal redistribution. In order to prepare the ground for the next section we give some intermediate results.

Substituting labor supply, $l(t, b, s_j)$, into $y_j = s_j l_j$ gives before-tax income $y_j(t, b, s_j) = s_j l(t, b, s_j)$. Substituting $b(t, s)$, given by Lemma 6.6(g), into the indirect own-utility function (6.28), gives

$$w_j(t, s) = v(t, b(t, s), s_j). \quad (6.31)$$

Let

$$W_j(t, \alpha, \beta, s) = V_j(t, b(t, s), \alpha, \beta, s), \quad (6.32)$$

where $b(t, s)$ is given by Lemma 6.6(g). Then (10.18) can be written as

$$W_j(t, \alpha, \beta, s) = w_j(t, s) - \frac{\alpha}{n-1} \sum_{k>j} [w_k(t, s) - w_j(t, s)] - \frac{\beta}{n-1} \sum_{i<j} [w_j(t, s) - w_i(t, s)], \quad (6.33)$$

where w_j is defined in (10.22). This gives the Fehr–Schmidt utility of an individual with skill level s_j that depends only on the redistributive tax rate, t .

6.5.2 Heterogeneity in voter preferences and redistribution

We now examine some of the insights from Dhami and al-Nowaihi (2010b) who consider the implications for societal redistribution arising from a mixture of other-regarding and self-regarding voters. Consider the model in Section 6.5.1 but assume, for pedagogical ease, that voters belong to one of three categories: poor, middle class, and rich, whose skills are ordered as $s_1 < s_2 < s_3$. We also assume that voters have identical α, β parameters.¹⁹ Each type of voter can have either self-regarding preferences ($\alpha = \beta = 0$) or other-regarding preferences ($\alpha, \beta \neq 0$). One can assume either that there is a large number of voters who are uniformly distributed over the three skill levels or just three voters, one of each type. We use the latter interpretation below.

We assume that the own-utility function is quasi linear, with constant elasticity of labor supply, which is the most commonly used functional form in various applications of the median voter theorems.

$$\tilde{u}(c, 1-l) = c - \frac{\epsilon}{1+\epsilon} l^{\frac{1+\epsilon}{\epsilon}}, \quad (6.34)$$

¹⁹ For the case where the fairness parameters of voters can differ, so that the fairness parameters of voter $j = 1, 2, 3$ are summarized α_j, β_j , see Dhami and al-Nowaihi (2010b).

where ϵ is the constant elasticity of labor supply, assumed positive.²⁰ One can check that the more general case considered in Lemmas 6.6 and 6.7 continues to hold. Using (6.33), (6.34), and Lemmas 6.6 and 6.7, we can prove the next proposition.

Proposition 6.15 (Dhami and al-Nowaihi, 2010b) (Existence of optimal tax rates): Consider $W_j(t, \alpha, \beta, s)$ defined in (6.33).

- (a) Given α, β and s , $W_j(t, \alpha, \beta, s)$ attains a maximum at some $t_j \in [0, 1)$.
- (b) Whenever there is an interior solution to the tax rate, the tax rate, t_j , preferred by voter j , is unique.
- (c) $W_j(t, \alpha, \beta, s)$ is strictly increasing on $[0, t_j)$ and strictly decreasing on $(t_j, 1]$.
- (d) t_j is non-decreasing in α, β .

The final result in Proposition 6.15(d) deserves to be commented upon. The intuition is that an increase in α_j increases disutility arising from disadvantageous inequity. By increasing the redistributive tax rate, the voter reduces, relatively, the utility of anyone who is richer, hence, reducing disadvantageous inequity. On the other hand, an increase in β_j increases disutility arising from advantageous inequity. An increase in the redistributive tax benefits everyone poorer than the voter relatively more, thus, reducing advantageous inequity.

For the three-voter model, poor, middle class, and rich, there are $2^3 = 8$ possible combinations of the preferences of voters. Denoting by S and F , respectively, a self-regarding and a fair, or other-regarding voter, the eight possible combinations of the voters, each combination arranged in order of increasing skill level from left to right, are: $SSS, SSF, SFS, SFF, FSS, FSF, FFS, FFF$. For instance, SFF denotes an economy in which the lowest skill voter is self-regarding and the middle and high skill voters are both fair. Since the experimental evidence is that 1/3 to 2/3 of the participants are self-regarding, the most important cases are $SSF, SFS, SFF, FSS, FSF, FFS$.

Proposition 6.15 tells us about the features of the most preferred tax rate by any voter. Does a Condorcet winner exist in this economy? We cannot directly apply the results of Proposition 6.14 because we now have a mixture of self-regarding and other-regarding voters. The main result is summarized in Proposition 6.16.

Proposition 6.16 (Dhami and al-Nowaihi, 2010b): Let

$$\theta_1 = \frac{s_2^{1+\epsilon} - s_1^{1+\epsilon}}{s_3^{1+\epsilon} - s_2^{1+\epsilon}}; \theta_2 = \frac{2}{2 + \theta_1},$$

then,²¹ for the three-voter model:

- (a) The median-skill voter with skill s_2 is the Condorcet winner. Let $t_j, j = 1, 2, 3$ be the most preferred tax rate of voter j . Then the most preferred tax rates are ordered by magnitude as $t_3 < t_2 < t_1$, in the following cases:
 - (i) SSS, FSS, FFS , and FFF ,
 - (ii) SFS and SFF , if $\frac{\alpha}{2-\beta} < \theta_1$,
 - (iii) SSF and FSF , if $\beta < \theta_2$,

²⁰ The case $\epsilon = 1$ has special significance in the literature. In this case, $\tilde{u}(c, 1-l) = c - \frac{1}{2}l^2$.

²¹ It can be proved that the constant θ_1 is, for the three-voter case, directly proportional to the ratio of advantageous to disadvantageous inequality for voter 2; see Dhami and al-Nowaihi (2010b). θ_2 depends inversely on θ_1 .

- (b) *The low-skill voter with skill s_1 is the Condorcet winner, and $t_3 < t_1 < t_2$, in cases SFS and SFF, if $\theta_1 < \frac{\alpha}{2-\beta}$,*
- (c) *The high-skill voter with skill s_3 is the Condorcet winner, and $t_2 < t_3 < t_1$, in cases SSF and FSF, if $\theta_2 < \beta$.*

We now offer a discussion of Proposition 6.16.

In cases SSS, FSS, FFS, and FFF, the median-skill voter is decisive in the redistributive tax choice (Proposition 6.16a(i)). Note that in the cases SSS, FSS, the median-skill voter is self-regarding, while in cases FFS and FFF the median-skill voter is other-regarding. Hence, in these four cases, the redistributive outcome in the case of a mixture of voter types is identical to a hypothetical economy in which all voters are of the same type as the median-skill voter. So, for instance, the redistributive outcome in the FSS economy is the same as that in a SSS economy, while the outcome in the FFS economy is identical to the FFF economy.

The same result is also true for the other four cases SFS, SFF, SSF, and FSF provided that the relevant upper bounds on α and/or β are satisfied (Proposition 6.16a(ii) and a(iii)). In each of these eight cases, the tax rate implemented is the tax rate, t_2 , preferred by the median-skill voter.

If the upper bounds in Proposition 6.16a(ii), a(iii) are not satisfied, then the median-skill voter is no more decisive. From Proposition 6.16b, in cases SFS and SFF, the low-skill (and self-regarding) voter becomes decisive, and the implemented tax rate is t_1 . From Proposition 6.16c, in cases SSF and FSF, the high-skill (and other-regarding) voter becomes decisive, and the implemented tax rate is t_3 .

Note that in all such cases, *the implemented tax rate is the median tax rate and not, necessarily, the tax rate preferred by the median-skill voter.*

Consider the four striking cases in the following corollary to Proposition 6.16.

Corollary 6.1

- (a) *For SFS, the majority of voters are self-regarding yet, if $\frac{\alpha}{2-\beta} < \theta_1$, then a majority votes for the tax rate preferred by the median-skill other-regarding voter (Proposition 6.16a(ii)).*
- (b) *For SFF, the majority of voters are fair yet, if $\theta_1 < \frac{\alpha}{2-\beta}$, then a majority votes for the tax rate preferred by the low-skill self-regarding voter (Proposition 6.16b).*
- (c) *For SSF, the majority of voters are self-regarding yet, if $\theta_2 < \beta$, then a majority votes for the tax rate preferred by the high-skill other-regarding voter (Proposition 6.16c).*
- (d) *For FSF, the majority of voters are fair yet, if $\theta_2 < \beta$, then a majority votes for the tax rate preferred by the median-skill self-regarding voter (Proposition 6.16a(iii)).*

Denote by t_j^S and t_j^F to be the most preferred tax rates of voter j if he is, respectively, self-regarding and fair or other-regarding. From Proposition 6.16a(i), in an SSS economy, the median-skill voter is decisive, so $t_3^S < t_2^S < t_1^S$ because richer self-regarding voters prefer a lower redistributive tax. This is shown in Figure 6.1 by the curve labeled *abc*. Now suppose that we replace the *self-regarding* median-skill voter in an SSS economy by an other-regarding voter to generate the SFS economy. There are two cases:

- (a) If the inequality $\theta_1 < \frac{\alpha}{2-\beta}$ holds, then from Proposition 6.16b, for the SFS economy, we get the ranking of most preferred tax rates to be $t_3^S < t_1^S < t_2^F$. This is shown in Figure 6.1 by the curve *adc*. The tax rate of the low-skill self-regarding voter, t_1^S , is now able to defeat any of the other two tax rates in a pairwise contest (either of the other two classes of voters find it optimal to align with the low-skill voter against the tax proposal of the third voter). The optimal tax rate

Figure 6.1 The SSS and SFS economies.

of the lowest-skill voter becomes the decisive redistributive choice. Hence, in moving from the SSS to the SFS economy, there is a jump in the tax rate from point b to point a (or from t_2^S to t_1^S).

(b) If the restriction $\frac{\alpha}{2-\beta} < \theta_1$ holds, then we get the case in Proposition 6.16a(ii). In this case, the ranking of tax rates, for the SFS economy, is $t_3^S < t_2^F < t_1^S$, so the median skill voter is also the decisive median voter. In Figure 6.1, this ranking of tax rates is shown by the curve aec . In this case, as we transit from the economy SSS to the economy SFS, there is a smaller upward jump from point b to point e .

In Proposition 6.16b, the crucial inequality is $\theta_1 < \frac{\alpha}{2-\beta}$; for the SFS economy, the relevant curve is adc in Figure 6.1. To see why this inequality is important, suppose that there is pairwise voting between the two tax rates, t_1^S, t_2^F . For the high-skill voter (whose skill level is s_3) to prefer the tax rate of the low-skill voter, t_1^S , the optimal tax rate of the middle-skill voter, t_2^F , should be “too high” in the sense that $t_1^S < t_2^F$. In this case, a majority (the rich and the poor) will prefer the tax rate t_1^S to t_2^F . The following factors help to satisfy the inequality $\theta_1 < \frac{\alpha}{2-\beta}$, and, hence, are conducive to t_2^F being “too high.”

(a) High inequity aversion, as captured by the magnitudes of α, β : From Proposition 6.15d, higher magnitudes of the inequity aversion parameters, α, β , increase the optimal tax rate for other-regarding voters, so increase t_2^F .

(b) High skill inequality at the upper end of the skill distribution ($s_3 - s_2$) and low inequality at the lower end of the income distribution ($s_2 - s_1$) reduce θ_1 and increase t_2^F : To see this, suppose that $s_3 - s_2$ increases because of an increase in s_3 . This leads to an increase in disadvantageous inequity faced by a voter of skill level s_2 . Self-regarding voters would like to redistribute more when the rich get richer because average incomes increase, so the lump-sum available for redistribution is higher. Other-regarding voters have an additional motive to redistribute more, namely, that it reduces disadvantageous inequity. This facilitates an increase in t_2^F .

For self-regarding voters, a decrease in the low-skill level reduces the redistributive tax rate. The intuition is that reduction in low-skill income reduces average income available for redistribution, hence, reducing the marginal benefits of increasing the tax rate. For other-regarding voters, however, the results can go either way. The reason is that on the one hand, the other-regarding voter is influenced by very similar considerations to the self-regarding voter (because the other-regarding voter also cares about “own” payoff). However, on the other hand, the empathy/concern for poorer voters, on account of the disutility arising from advantageous inequity induces the other-regarding voter in the opposite direction, i.e., greater redistribution. The interplay between these two opposing factors determines if the other-regarding voter will respond,

Figure 6.2 The SSS, SSF, and FSF economies.

unlike the self-regarding voter, by redistributing more in response to poverty. The restriction $\theta_1 < \frac{\alpha}{2-\beta}$ ensures that overall, one gets the ranking $t_3^S < t_1^S < t_2^F$ for the optimal tax rates of the three voting classes.

In Figure 6.2, we illustrate the second generic case when $\beta > \theta_2$ (see Proposition 6.16c). For the benchmark SSS economy, we know from Proposition 6.16a(i), that the median-skill voter, of skill s_2 , is decisive, so $t_3^S < t_2^S < t_1^S$. Thus, the SSS economy is represented by the line abc . Now replace the highest-skill self-regarding voter by an other-regarding voter to generate the economy SSF. Under the restriction specified in Proposition 6.16c ($\beta > \theta_2$), the economy SSF is shown in Figure 6.2 by the curve abe and one gets the ordering of tax rates to be $t_2^S < t_3^F < t_1^S$. In this case, the rich but other-regarding voter is decisive because the proposed tax rate, t_3^F , can defeat any of the other two proposed tax rates in a pairwise contest. Under the restriction $\beta > \theta_2$, the FSF economy is also shown in Figure 6.2, by the curve dbc . The decisive median voter is again the rich other-regarding voter, who is not the median-skill voter.

Why does the restriction $\beta > \theta_2$ not involve α ? The reason is that for the cases in Figure 6.2 to arise, we need the most preferred tax rate of the rich other-regarding voter to be high enough, in the sense that $t_2^S < t_3^F$. The rich other-regarding voter faces no disadvantageous inequality, which explains the absence of the parameter α . However, if β is high enough, then the rich other-regarding voter suffers sufficiently highly from advantageous inequality with respect to the other two class of voters. In particular, if $\beta > \theta_2$, then $t_2^S < t_3^F$, which leads to the surprising outcome in Proposition 6.16c.

6.6 Fairness, general equilibrium, and welfare

In the presence of other-regarding preferences, can we invoke the standard machinery of general equilibrium and welfare economics? For instance, we know from undergraduate microeconomics that in the presence of consumption externalities, the fundamental welfare theorems need not hold. Such consumption externalities are also reflected in social preferences; see, for instance, the Fehr–Schmidt preferences in (6.1). The relevant issues are addressed by Dufwenberg et al. (2011). In this section we give readers a flavor of their results.²²

Consider a production economy with goods (inputs and outputs) indexed by $l \in \{1, 2, \dots, L\}$, profit maximizing firms indexed by $j \in \{1, 2, \dots, J\}$, and utility maximizing consumers indexed

²² We omit the proofs. However, the proofs use standard arguments used in graduate texts in microeconomics.

by $i \in \{1, 2, \dots, I\}$. The price of good l is $p_l \geq 0$, and the price vector of all goods is given by p . The production set of firm j , $Y_j \subseteq \mathbb{R}^L$, is closed and bounded; negative and positive entries in the production set are, respectively, inputs and outputs. The profit function of firm j is given by $\pi_j(p)$; its existence for all p is guaranteed by the assumptions. The set of all possible production profiles is given by $Y = \prod_{j=1}^I Y_j$, and the typical element is denoted by y . Consumer i has an initial endowment of $e_i \in \mathbb{R}_+^L$, and consumption vector given by $x_i \in \mathbb{R}_+^L$. The consumption vector of all I consumers is $x \in \mathbb{R}_+^{LI}$. All firms are owned by consumers. The share of consumer i in firm j is θ_{ij} , hence, the income of the consumer is $w_i = pe_i + \sum_{j=1}^I \theta_{ij} \pi_j(p)$.

Denote by $B_i = \{x_i \in \mathbb{R}_+^L : px_i \leq w_i\} \subseteq \mathbb{R}_+^L$, the non-empty and compact budget set of consumer i . Let $B = (B_1, B_2, \dots, B_I)$ be a profile of budget sets of all consumers and $\mathcal{B}$ be the set of all budget profiles. Other-regarding preferences are captured by defining, for any consumer i , a binary preference relation, $\succsim_i$, over objects in the set $\mathbb{R}_+^L \times \mathcal{B}$; each object (x, B) is a pair of the consumption profile of all consumers and of the budget sets of all consumers. It will sometimes be convenient to write (x, B) as (x_i, x_{-i}, B) where x_{-i} is the consumption profile of all consumers other than consumer i .

Definition 6.13 *The preferences of the individuals satisfy the following properties:*

- (a) *Strictly monotone in own consumption: Fix x_{-i}, B and let $x_i \geq x'_i$ but $x_i \neq x'_i$. Then strict monotonicity requires $(x_i, x_{-i}, B) \succ_i (x'_i, x_{-i}, B)$, where $\succ_i$ is the strict preference relation.*
- (b) *Continuous: Fix any x', B . The set $P = \{(x, B) : (x, B) \succsim_i (x', B)\}$ is closed.*
- (c) *Strictly convex over own consumption: Fix x_{-i}, B . Let $x_i \neq x'_i$ and $(x_i, x_{-i}, B) \succsim_i (x'_i, x_{-i}, B)$. Then strict convexity requires that for $\alpha \in (0, 1)$, $(\alpha x_i + (1 - \alpha)x'_i, x_{-i}, B) \succ_i (x'_i, x_{-i}, B)$.*

Under these assumptions, suppose that each preference relation, $\succsim_i$, can be represented by a continuous utility function $U(x, B) : \mathbb{R}_+^{LI} \times \mathcal{B} \rightarrow \mathbb{R}$. Clearly, this utility function is more general than the standard one because utility also depends on the budget sets. For instance, an individual may be envious of another who has the ability to buy a larger basket of goods.

Definition 6.14 *(Economy): An economy $\mathcal{E}$ is described by the vector $(I, e, \{U_i\}, J, Y, \theta)$, i.e., the set of players, their endowments, their utility functions, the set of firms, their production sets, and the shares of consumers in each firm.*

We have assumed that the budget set is compact, the utility function of each consumer is continuous, and preferences are strictly convex, so the demand function exists and for consumer i it is given by $d_i(x_{-i}, B) \in \arg \max_{x_i \in B_i} U_i(x_i, x_{-i}, B)$. Thus, the optimal demand of any consumer, d_i , depends not only on the consumption levels but also the budget sets of others. This contrasts with the neoclassical case of self-regarding preferences in which these effects of the consumption and budget sets of others are absent. Can one impose conditions on $U_i(x_i, x_{-i}, B)$ such that these effects are also absent when we allow for other-regarding preferences? If so (see below), consumer i is said to behave as-if-classical.

Definition 6.15 *(As-if-classical consumers): Consumer i behaves as-if-classical if d_i does not depend on x_{-i}, B_{-i} , where B_{-i} gives the profile of budget sets of all consumers other than i .²³*

²³ The actions of others do determine prices, p , hence, also w_i . These factors also determine d_i , hence, even as-if-classical consumers are "indirectly" influenced by the actions of others.

The actions of others do determine prices, p , hence, also w_i . These factors also determine d_i , hence, even as-if-classical consumers are “indirectly” influenced by the actions of others.

The demand functions of consumer i , $d_i(x_{-i}, B)$, for the L goods can be written as $d_i(x_{-i}, B_i, B_{-i})$. Substituting the optimal demands in the definition of the budget sets we can write $B_i = B_i(p, w_i)$. Hence, we may write the demand functions of consumer i as $d_i(p, w_i, x_{-i}, B_{-i})$.

The next definition is helpful to determine the conditions on preferences that ensure consumer i behaves as-if-classical.

Definition 6.16 (*Separable preferences*): Given any two consumption profiles, x, x' , and two budgets sets, B, B' , the preferences of consumer i are said to be separable if

$$(x_i, x_{-i}, B) \succeq_i (x'_i, x_{-i}, B) \Leftrightarrow (x_i, x'_{-i}, B') \succeq_i (x'_i, x'_{-i}, B').$$

In Definition 6.16, preferences over own consumption bundles are independent of the consumption bundles and budget sets of others.

Proposition 6.17 (*Dufwenberg et al., 2011*): Separable preferences have a utility representation given by $V_i(m(x_i), x_{-i}, B)$, where (i) V_i is increasing in m , and (ii) the function $m: \mathbb{R}_+^L \rightarrow \mathbb{R}$, known as the consumer’s “internal utility function,” is continuous, strictly monotone, and strictly quasi-concave.

The importance of separable preferences is shown in the next proposition.

Proposition 6.18 (*Dufwenberg et al., 2011*):

- (i) If the preferences of consumers can be written as $V_i(m(x_i), x_{-i}, B)$ (Proposition 6.17), then the consumer behaves as-if-classical (Definition 6.15).
- (ii) If $d_i(p, w_i, x_{-i}, B_{-i})$ is continuously differentiable in (p, w_i) , then consumers behave as-if-classical if the utility function can be represented as $V_i(m(x_i), x_{-i}, B)$ (Proposition 6.17).

The conditions in Proposition 6.18 hold for Fehr–Schmidt preferences, as we now show in the next example.

Example 6.5 (*Weighted utilitarian preferences; Dhami and al-Nowaihi, 2010a,b*) Consider the Fehr–Schmidt preferences given in 6.1. Define the sets A_i and D_i as the set of consumers with respect to whom consumer i has respectively, advantageous and disadvantageous inequity. So

$$A_i = \{j : i \neq j \text{ and } x_j \leq x_i\}, \quad (6.35)$$

$$D_i = \{k : k \neq i \text{ and } x_k > x_i\}. \quad (6.36)$$

Denote the respective cardinalities of these sets by $|A_i|$ and $|D_i|$. Then FS-utility can be written in a way that is reminiscent of the weighted utilitarian form:

$$U_i = \omega_{ii}x_i + \sum_{j \neq i}^I \omega_{ij}x_j, \quad (6.37)$$

where,

$$\begin{aligned} j \in A_i &\Rightarrow \omega_{ij} = \frac{\beta}{n-1} > 0, \\ i = j &\Rightarrow \omega_{ii} = 1 - \frac{|A_i|\beta}{n-1} + \frac{|D_i|\alpha}{n-1} > 0, \\ k \in D_i &\Rightarrow \omega_{ik} = -\frac{\alpha}{n-1} < 0. \end{aligned} \quad (6.38)$$

Furthermore, the weights sum up to one, i.e., $\sum_{j=1}^I \omega_{ij} = 1$. For self-regarding consumers, $\omega_{ii} = 1$ and $\omega_{ij} = 0$ ($i \neq j$). Clearly (6.37) is of the same form as V_i (Proposition 6.17), hence, the consumer must behave as-if-classical.

We are now interested in exploring the link between the Walrasian equilibrium of an economy with other-regarding preferences, and the Walrasian equilibrium with self-regarding consumers.

Definition 6.17 A Walrasian equilibrium is given by a triple of prices, consumption profiles, and production plans of firms, i.e., (p^*, x^*, y^*) , such that: (i) Each x_i^* maximizes the utility of the consumer U_i , subject to the budget constraint B_i , (ii) Each y_j^* maximizes the profit function of the firm, π_j , subject to the production set Y_j . (iii) All markets for the L goods clear.

Definition 6.18 Consider any economy $\mathcal{E} = (I, e, \{U_i\}, J, Y, \theta)$ (Definition 6.14). The corresponding ‘internal economy’ is defined by $\mathcal{E}^{Int} = (I, e, \{m_i\}, J, Y, \theta)$, where m_i is defined in Proposition 6.17.

In Definition 6.18, the only difference between an economy and its internal economy is that in the latter, all consumers are self-regarding. The next proposition gives the link between the Walrasian equilibria of the two economies.

Proposition 6.19 (Dufwenberg et al., 2011): Suppose that the preferences of all consumers are separable (Definition 6.16) and strictly monotone in own-consumption. Then the set of Walrasian equilibria of the two economies, $\mathcal{E}$ and $\mathcal{E}^{Int}$ are identical.

Example 6.6 (Dhami and al-Nowaihi, 2010a,b): Section 6.5, above, gives a behavioral political economy application in a simple general equilibrium model of endogenous labor supply. Lemma 6.6 shows that there is a unique labor supply for voter j , $l_j = l(t, b, s_j)$, that maximizes own-utility $u(l_j; t, b, s_j)$ despite the fact that voter j has other-regarding preferences. In other words, the voter behaves as-if-classical. The same individual with Fehr–Schmidt preferences behaves as if he had self-regarding preferences when he chooses labor supply but other-regarding preferences when he chooses the redistributive tax rate. This result was puzzling to the authors and they used it to argue that preferences may be context dependent.²⁴ The second stage general equilibrium outcome in this model is identical for voters who have self-regarding or other-regarding preferences. This result was given before the more general insights of Dufwenberg et al. (2011) were known, albeit in the specific context of voting.²⁵

We now consider issues of welfare economics. Here, the analysis requires a more restricted version of $V_i(m(x_i), x_{-i}, B)$.

Definition 6.19 (Well-being externalities): Well-being externalities arise if the utility function of any consumer i is given by $W_i(m_i, m_{-i})$, where m_i is given in Proposition 6.17. W_i is increasing in each argument and $m_k(x_k)$ is increasing for each k .

Example 6.7 Consider two examples of well-being externalities. The first one is due to Edgeworth (see citation in Dufwenberg et al. 2011).

²⁴ The authors argued that: “For example, individuals, when making a private consumption decision might act so as to maximize their selfish interest. But in a separate role as part of the government, as a school governor or as a voter, could act so as to maximize some notion of public well being. Individuals might, for instance, send their own children to private schools (self interest) but could at the same time vote for more funding to government run schools in local or national elections (public interest).”

²⁵ The original results were presented in the Public Economics Weekend, held at Leicester in 2006.

$$W_i(m_i, m_{-i}) = m_i + \frac{\eta_i}{I-1} \left(\sum_{k \neq i} m_k \right),$$

where $\eta_i > 0$ captures altruism, while $\eta_i < 0$ captures spite. The second example is a version of the Bolton–Ockenfels ERC model.

$$W_i(m_i, m_{-i}) = m_i - \eta_i \left| m_i - \frac{\sum_k m_k}{I} \right|; 0 \leq \eta_i < 1.$$

Definition 6.20 (Feasibility and Pareto optimality): An allocation $x = (x_1, x_2, \dots, x_I)$ is feasible if there exists some production plan $y = (y_1, y_2, \dots, y_J) \in Y$ such that $\sum_{i=1}^I x_i \leq \sum_{i=1}^I e_i + \sum_{j=1}^J y_j$. A feasible allocation, x , is Pareto optimal if there does not exist another feasible allocation x' such that at least one consumer is better off and no consumer is worse off.

We first show by an example that the second fundamental welfare theorem need not hold.

Example 6.8 The object of this example is to show that Pareto efficient allocations need not be Walrasian equilibria in the presence of other-regarding preferences. Suppose that there are two consumers ($I = 2$), two goods ($L = 2$), and the (identical) utility functions of the consumers are given by

$$W_i = m_i - 2m_k, i \neq k \text{ and } m_i(x_i) = h(x_{i1}) + h(x_{i2}), h' > 0, h'' < 0. \quad (6.39)$$

The aggregate endowment of each of the two goods is 1. The allocation $((0, 0), (0, 0))$ is not a Walrasian equilibrium of the internal economy' $\mathcal{E}^{Int}$ (Definition 6.18) because preferences are strictly monotone, yet no consumer consumes anything. However, given (6.39), $((0, 0), (0, 0))$ is Pareto optimal.

Example 6.8 indicates that additional restrictions on preferences are required for the standard welfare theorems to hold in the presence of other-regarding preferences. In particular, we would like to rule out the pathological case of Example 6.8.

Definition 6.21 (Social monotonicity): Consider an allocation, x . Then there exists another allocation z such that $z \geq 0$ and²⁶

$$W_i(m_i(x_i + z_i), m_{-i}(x_{-i} + z_{-i})) > W_i(m_i(x_i), m_{-i}(x_{-i})),$$

where $\sum_{k=1}^I z_k = z$ and at least one element of the vector z is strictly positive.

Definition 6.18 requires that redistributing an extra amount of resources to all consumers increases everyone's utility. This rules out the extreme case of spite in Example 6.8.

Proposition 6.20 (Dufwenberg et al., 2011): Suppose that the utility function exhibits well-being externalities (Definition 6.19) and the social monotonicity condition (Definition 6.21) holds.

- (i) The set of Pareto optimal allocations of the economy $\mathcal{E}$ is a subset of the Pareto optimal allocations of the economy $\mathcal{E}^{Int}$.
- (ii) Every Pareto optimal allocation of the economy $\mathcal{E}$ can be obtained as a Walrasian equilibrium if lump-sum transfers are allowed.

Proposition 6.20(i) shows the relation between the Pareto optimal equilibria of economies with other-regarding and self-regarding preferences. Proposition 6.20(ii) is the analogue of the second

²⁶ We use here the notation $\geq$, which applies the *greater than or equal to* operation to elements of vectors.

welfare theorem but for other-regarding preferences. The social monotonicity condition by itself does not ensure that Pareto efficient equilibria can be implemented as a Walrasian equilibrium unless lump-sum transfers are allowed; the next example discusses this point.

Example 6.9 *Suppose that there are three consumers and one good. The endowment of consumer 1 and consumer 3 is one unit each of the good, while consumer 2 has zero units (so $e = (1, 0, 1)$). Consumer 2 has purely self-regarding preferences. The utility of consumer 1 is $W_1 = x_1 + \frac{2}{3}x_2$ and the utility of consumer 3 is $W_3 = x_3 + \frac{2}{3}x_2$. Suppose that we allow for voluntary lump-sum transfers of goods between the three consumers and the social monotonicity condition (Definition 6.21) holds. Consumers 1 and 3 do not want to transfer any of the good to consumer 2 because giving up a unit costs 1 but gives a marginal benefit $\frac{2}{3} < 1$. Hence, the economy is stuck with the initial allocation $e = (1, 0, 1)$, yet it is Pareto dominated by the allocation $(0, 2, 0)$. Thus, no Walrasian equilibrium can implement the Pareto optimal allocation $(0, 2, 0)$.*

6.7 Evidence on models of social preference and reciprocity

In this section we consider first the evidence on models of social preferences (Section 6.7.1) followed by the evidence on the role intentions (Section 6.7.2).

6.7.1 The evidence on models of social preferences

One criticism of the inequity aversion models is that they do not specify the reference group over which an individual compares his payoff (Sobel, 2005). However, the reference group can be elicited from subjects in experiments and alternative assumptions on the reference group can be experimentally tested. Given individual heterogeneity, it may be undesirable for the theory to specify a reference group. Some individuals may simply compare their consumption with those on the street that they live in, others with colleagues in the workplace, still others with the population of subjects in similar professions, and so on.

Some models introduce the possibility that individuals care for the total economic surplus (Charness and Rabin, 2002). A natural way to test the relative concerns for surplus maximization and inequity aversion is to construct experiments that set these two opposing concerns against each other.²⁷ The main result of these papers is that in dictator games, a non-negligible fraction of proposers are willing to take an action that increases the total surplus, even at a cost in terms of personal payoff, and even if this increases disadvantageous inequity for them.

Andreoni and Miller (2002), and Andreoni and Vesterlund (2001) vary the price at which the proposer can transfer a unit of money to the responder in dictator games. Normally, in dictator games, by giving up a unit of money, the dictator can transfer a unit of money to the receiver (the 1:1 case). In the 1:1 case, experimental evidence shows that the dictator never proposes to transfer more than half the amount. Now suppose that we reduce the price of giving by using other ratios such as 1:2 (i.e., for every unit given up by the dictator, 2 units are transferred to the responder), and 1:3. In these cases, Andreoni and Miller (2002) and Andreoni and Vesterlund (2001) find that in a non-negligible fraction of cases, the dictators end up with less money relative to the

²⁷ See, for instance, Andreoni and Miller (2002), Andreoni and Vesterlund (2001), Bolle and Kritikos (1998), Charness and Rabin (2002), Cox (2000).

Table 6.2 Payoffs of three players in three different allocations.

Allocation	A	B	C
Person 1	9	8	11
Person 2	8	8	10
Person 3	4	8	9
Total	21	24	30

Source: Engelman and Strobel (2004).

receiver, but the total surplus between the two parties is higher. Such results are not consistent with models of inequity aversion models such as the ERC model, the Fehr–Schmidt model, and the composite model of Falk and Fischbacher (2006). There is substantial heterogeneity at the level of the individual. Andreoni and Vesterlund find that 44% of the subjects are completely self-regarding, 35% seem to have egalitarian preferences (they try to equalize payoffs), and only 21% are surplus maximizers.

Charness and Rabin (2002) consider the following two payoff-pairs in a dictator game: (400, 400) and (400, 750), where the first figure represents the dictator's payoff, while the second figure is the responder's payoff. Of the subjects 31% are found to be egalitarian, which is similar to the finding in Andreoni and Vesterlund (2001). To check for the presence of individuals who might not be willing to make the surplus maximizing choice at a cost to their own payoff, consider another choice condition: (400, 400) and (375, 750). In this case, only 49% make the surplus maximizing choice, because it reduces own-payoff by 25. When income disparities are increased further, e.g., in the choices (400, 400) and (400, 2000), then 62% make the egalitarian choice in preference to the surplus maximizing choice.

Iriberry and Rey-Biel (2013) find that in dictator games, there is heterogeneity in preference types (self-regarding, social welfare maximizing, inequity averse, and competitive); almost half the subjects are self-regarding. We have noted above, reservations about the use of the dictator game results to draw robust conclusions about social preferences (Fehr and Schmidt, 2006). However, an interesting element of the results in this paper is that people alter their preference types depending on the available social information (e.g., about the actions of others); this is suggestive of interdependent preferences. There is also substantial heterogeneity in beliefs about others that is dependent on one's preference type.

Engelmann and Strobel (2004) present the following example that illustrates concerns for efficiency and inequity aversion. There are three individuals and three possible allocations, A, B, and C; Table 6.2 shows the payoffs of the three players in the three different allocations. Suppose that individual 2 is asked to choose between allocations A and B, which give the individual an identical payoff of 8. Inequity aversion theories predict that individual 2 will choose allocation B over A because it has a more equitable payoff. However, there is another potential explanation. Allocation B is more efficient as compared to A (joint surplus being 24 rather than 21). So it might well be the case that what seems to be a choice based on inequity aversion is really a concern for efficiency. This is an extremely stringent test for inequity aversion theories because the more equitable allocation is also the surplus maximizing one.

Now suppose that individual 2 has a choice between all three allocations, A, B, and C. Suppose that allocation C is chosen. This will provide support for selfishness (2's payoff is highest

in allocation C), efficiency (joint surplus is highest in allocation C), inequity aversion,²⁸ and maximin preferences (the poorest individual is best off in allocation C). Engelmann and Strobel (2004) perform experiments to disentangle these three effects, namely, efficiency, inequity aversion, and maximin preferences. They conclude that a concern for efficiency and Rawlsian preferences, jointly, is more important, relative to a concern for inequity aversion. This result supports the Charness and Rabin (2002) model (see Section 6.8), over models of inequity aversion.

Preferences for efficiency and Rawlsian maximin, relative to inequity aversion were discussed in a series of papers in the December 2006 issue of the *American Economic Review*. Bolton and Ockenfels (2006) report fresh experiments to show that twice as many individuals sacrifice an outcome where they get a higher payoff for an equitable outcome as compared to an efficient one. Engelmann and Strobel (2006) argue that a potential confounding factor in these experiments is that the gains from efficiency are lower than the gains from equity.

Fehr et al. (2006), however, show that the results of Engelmann and Strobel (2004) are driven by the presence of economics students who learn about the importance of economic efficiency in their first year. After replicating several experiments in Engelmann and Strobel, they find that the dominance of the efficiency motive holds true only for economics and business administration students. Non-economist subjects find inequity aversion more attractive relative to efficiency.

The evidence on the surplus maximizing motive comes largely from dictator games in which only one player has a non-trivial action. There are several issues with using the dictator game for detecting the presence of a surplus maximization motive (Fehr and Schmidt, 2006). First, other than charitable donations, the dictator game is not a particularly important analogy for most other real-world economic situations. Second, as we have seen above, the results of the dictator games, unlike those of the ultimatum games, are not very robust, hence, this may not be a particularly suitable game to test surplus maximization. Third, there are end game effects (as in Andreoni and Miller, 2002), where the predictions of a surplus maximization preference are not borne out in the final periods of the experiment. These final period effects can be accounted for by models of inequity aversion and intention-based reciprocity. Fourth, what if we introduced the possibility of an element of strategic consideration in which more than one player has a non-trivial choice? Is there a reduction in the surplus maximizing choice in this case? The experiments of Fehr et al. (1993, 1998) that we consider next are important in this regard.

Fehr et al. (1993, 1998) embed a gift exchange game in a strategic environment. A proposer (firm) makes a wage offer that is observed by the responder (worker) who then chooses a non-binding effort level. Since the effort level is non-binding, the responder has a non-trivial choice that can affect the total surplus in the relation. An increase in the effort level by the responder increases the total surplus by five units on average. If surplus maximization is the overriding objective, certainly more important than outcome inequality and reciprocity, then we should observe the responder putting in the maximum possible effort level. Furthermore, we should not observe any correlation between wages and effort levels. Both these implications are rejected by the evidence. In no more than 2% of the cases does the responder undertake an effort level such that the proposer's payoff is relatively greater. There is also a clear correlation between the wage offered and the effort level undertaken. The actual effort level undertaken by the responder is significantly below the maximum feasible effort level.

When subjects punish others in public goods games in the lab, there are two possible motives. First, subjects may wish to act in a *reciprocal manner*. For instance, contributors may punish

²⁸ The reader can easily check that, for person 2, the Fehr-Schmidt utility is higher for distribution C as compared to distribution A.

non-contributors. A second motive may be to equalize payoffs. In a nice experimental design, Dawes et al. (2007) offer a way of separating the two motives. They replace the first (cooperation) stage in a Fehr–Gächter type cooperation and punishment game with a random allocation of incomes to the players that mimics the income distribution in Fehr and Gächter (2002) after the first stage. Then they give the players in stage 2, a possibility to reward or punish others in the group by assigning reward or punishment tokens to them. Interestingly, players with below-average incomes are often rewarded while players with above-average incomes often get punished. In this set up, reciprocity can play no role at all but FS or ERC-type inequity aversion can. However, ERC cannot explain this pattern of targeting rewards and punishments. This result suggests powerfully that inequity aversion (apart from reciprocity) as in the Fehr and Schmidt (2007) model is a powerful force in sanctioning behavior in public goods games.

6.7.2 *The evidence on intentions and reciprocity*

The *state of mind* of the accused and his/her *intentions* are of crucial importance in most legal systems when dealing with murder. The law, in most countries, defines *murder* as the *intentional* killing of another human being with full premeditation. On the other hand, the killing of a human carried out under some form of *diminished responsibility* that reflects *less than full intentionality* is treated differently.²⁹ In particular, the killing of a human where there is a clear lack of *intent* to kill is termed as *manslaughter* and it carries a different penalty from premeditated murder.

Murder and manslaughter are two extreme categories with several others in between. For instance, in the Canadian legal system, murder is further classified into first and second degrees based on *intent* of the perpetrator. First degree murder is the intentional killing of a human being with premeditation, while second degree murder does not involve premeditation, e.g., killing in the heat of the moment, but nevertheless, with intent to kill, which distinguishes it from manslaughter.³⁰

The *inequity aversion* models of Fehr and Schmidt (1999) and Bolton and Ockenfels (2000) are purely outcome oriented, and ignore the role played by intentions. In many contexts, one's behavior is determined by beliefs about the intentions of others. For instance, charitable giving in which one does not know the identity of the receiver of a gift might well be motivated by issues of inequity aversion. On the other hand, a firm contemplating a wage cut might be concerned that workers may form negative inferences about its intentions and may respond with negative reciprocity in the form of low effort.

An early experiment that considered the role of intentions in the ultimatum game was conducted by Blount (1995). In ultimatum games, if the initial offer is made by a computer generated random number (random offer condition) or a third party (third party condition), then the offer does not reveal any information about the intentions of the proposer. Hence, if intentions-based motives are the only explanation behind the results of the ultimatum game, we should observe no rejections in these two cases. Relative to the benchmark case, where a human proposer makes an offer, Blount (1995) finds that the rejection rates of responders decline significantly in the random offer condition. However, there is no significant change in the third party condition. The first result provides support for intentions-based models. But the second result (no significant

²⁹ Several factors may indicate diminished responsibility. These include, insanity, depression, side effects of certain medications, and even post-natal depression (in the case of murder of a child by the mother), etc.

³⁰ Intentions can also be transferrable, within the law, in the following sense. In English law, transferred malice occurs when an individual, say A, is attacked with an intention to kill but in fact another individual, say B, is killed. The perpetrator, say individual C, can be charged with the murder of individual B.

Figure 6.3 Modified ultimatum game.

Source: "On the nature of fair behavior," Falk, A., Fehr, E., and Fischbacher, U., *Economic Inquiry*, 41(1): 20–26. Copyright © 2007, John Wiley and Sons.

change in the third party condition) contradicts intentions-based explanations and is consistent with models of inequity aversion.³¹ Using the ultimatum game, Offerman (2002) finds that intentional low offers are 67% more likely to be followed by actions of opponents that are payoff reducing. Kagel et al. (1996) also find that the rejection rates in ultimatum games are higher when intentionally unequal proposals are made.

Falk et al. (2003) consider the modified ultimatum game in Figure 6.3 to isolate the role of intentions. The proposer, labeled by P, has two choices, 1 and 2, in offering a split of 10 dollars. The responder, labeled by R, has a choice to either accept (action a) or reject (action r). The payoffs are shown at each end node. Two variations of the game are considered. In the first variant, game-A, the payoffs from the strategy pair (2, a) are (5, 5), while in the second variant, game-B, the payoffs from the strategy pair (2, a) are (10, 0). In all other respects, the payoffs from the two games are identical.

Consider game-A and let the proposer choose strategy 1. In the absence of reciprocity, and based purely on self-interest, the best response of player 2 is to accept, resulting in the payoff pair (8, 2). However, in the presence of reciprocity and intentions, while deciding to accept or reject the offer, the responder brings into consideration the fact that the proposer has not chosen strategy 2, a relatively fairer strategy, which would have ensured payoffs of (5, 5). This reveals to the responder that the proposer's intentions *could have been fairer*.

Now consider game-B. If the proposer chooses strategy 1 over strategy 2, the responder knows that the proposer gave up a likely payoff of 10 and chose a payoff of 8 instead. This reveals to the responder that the intentions of the proposer *could have been less fair*. Hence, if intentions are important, then the responders in game-B should be more likely to accept the proposer's offer of an 8–2 split, despite the fact that the outcome (8, 2) is identical in both games. The essential feature of reciprocity is not necessarily to alter the distribution of payoffs but to respond to kindness and unkindness with like behavior.

Falk et al. (2003) find that the 8–2 split is rejected in 44.4% of the cases in game-A but it is rejected in only 8.9% of the cases in game-B. This runs counter to the predictions of the inequity

³¹ There were some peculiarities in these experiments that may or may not account for these conflicting results. For instance, in two out of the three treatments, subjects made decisions in the roles of proposers and responders but the payment they received was for one of these two roles, which was only subsequently revealed to them. Furthermore, in one treatment, deception was involved—subjects thought they were making the decisions as proposers but, in fact, the experimenter made the proposals.

aversion theories, which would predict that the rejection rates should not be different in the two games because the outcome (8, 2) is identical in both. However, the fact that there should be any rejection rate at all for game-B suggests that the reciprocity approach based on intentions does not provide a full explanation either. Clearly more empirical work in this area will provide a fuller picture.

One possible implication of intentions driven behavior for public goods games is the following. The extent of punishment meted out by cooperators to non-cooperators should depend on the difference in their contributions, which reveals the extent of unkindness of non-cooperators. Fehr and Gächter (2002) found this to be the case in their public goods experiments. They found that the single most important predictor of the punishment meted by contributors to non-contributors was the difference in contributions between the two players. Furthermore, 75% of all punishments were carried out by contributors whose contributions were above average.

In order to isolate the role of intentions, Falk et al. (2008) use the moonlighting game, which is due to Abbink et al. (2000). There were 112 subjects in the experiment. The moonlighting game allows one player, say *A*, to be kind or unkind in the first stage and then, in the second stage, allows another player, say *B*, to reciprocate with rewards or punishments. In particular, each of the players starts with an initial endowment of 12 monetary units of experimental money (MU). Player *A* chooses some action $a \in \{-6, -5, \dots, 0, \dots, 5, 6\}$ in the first stage. The interpretation of *A*'s action is that if $a > 0$, then player *B* receives a tokens (kind intentions), while if $a < 0$, then player *B* must surrender a tokens to *A* (unkind intentions). In the second stage, conditional on *A*'s action, player *B* takes some action $b \in \{-6, -5, \dots, 17, 18\}$. If *B* chooses $b > 0$, then *B* gives an amount b to *A* (reward) and if $b < 0$, then *B* loses b , while *A* loses $3b$ (punishment).

The experiment allows for two treatments. In the *intentions treatment* (I-treatment), players choose their actions freely, so intentions can be inferred from actions. In the *no-intentions treatment* (NI-treatment), a random device is used to choose *A*'s action, so intentions cannot be inferred. The ex-ante predictions are as follows.

1. If both *A* and *B* have self-regarding preferences, then the solution, using backward induction, is simple. In the second stage, when it is *B*'s turn to move, bygones are bygones. *B* maximizes her payoff by choosing $b = 0$. Anticipating *B*'s actions, *A* takes maximum advantage by choosing $a = -6$.
2. Suppose individuals care only about outcomes and ignore intentions, as in the inequity aversion models of Fehr and Schmidt (1999) and Bolton and Ockenfels (2000). Then, a higher action by player *A*, reduces *A*'s payoff. Since player *B* dislikes inequality, she should respond by contributing more. Thus b should be increasing in a . In particular, when $a = 0$, then $b = 0$. However, since there is no role for intentions, we do not expect any difference among the I-treatment and the NI-treatment.
3. Suppose now that only intentions (but not outcomes) matter.³² One can construct plausible equilibria such that a larger contribution, a , by player *A*, signals better intentions. In this case, in the I-treatment, we expect player *B* to reciprocate *A*'s action, so b is predicted to be increasing in a . In the NI-treatment, however, intentions cannot be inferred, so the model predicts $b = 0$ for all actions taken by player *A*. Finally, in models that take account of both intentions and outcomes, e.g., Falk and Fischbacher (2006), one expects b to be increasing in a . However, when intentions are revealed, as in the I-treatment, then we expect b to respond even more strongly to a on account of reciprocity. The predictions are summarized in Table 6.3.

³² Dufwenberg and Kirchsteiger (2004) and Falk and Fischbacher (2006) consider the role of intentions and outcomes; see the material on psychological game theory in Part 4 of the book.

Table 6.3 Summary of predictions for player B.

Model	I-treatment	NI-treatment
Standard prediction	$b = 0, \forall a$	$b = 0, \forall a$
Only payoff consequences matter (Fehr–Schmidt and Bolton–Ockenfels)	b increases in a	exactly the same behavior as in I-treatment
Only fairness intentions matter (Dufwenberg–Kirchsteiger)	b increases in a^0	$b = 0, \forall a$
Payoff consequences and fairness intentions matter (Falk–Fischbacher)	b increases in a	b increases in a but less than in the I-treatment

The experimental results are shown in Figure 6.4. The horizontal axis is player A’s action, a , while the vertical axis is player B’s action, b , in response to A’s action. In the I-treatment, average and median rewards by player B are increasing in the action of player A. This contradicts the prediction of self-regarding preferences, $b = 0$ for all a . The median response in the NI-treatment is exactly in line with the prediction of the self-regarding preferences ($a = b = 0$). The difference in the intentions and the no-intentions treatment is statistically significant and intentions matter

in the domain of both positive and negative reciprocity (recall that a can be negative or positive). Thus, the results also reject the “outcomes only” models.

Regression results also show that reciprocity is not completely wiped out in the NI-treatment. This is seen by running a regression of b on a constant term, α_0 , the action a of player A, a dummy variable d that equals 1 for the I-treatment and zero otherwise, and, finally, the interaction term, $a \times d$. The sum of the coefficients on the constant term and on the action “ a ,” give the additional amount of b that is elicited in the NI-treatment. This is positive and statistically significant, which is not consistent with the prediction in Dufwenberg and Kirchsteiger (2004). In conclusion, the aggregate evidence is that outcomes and intentions are both important, hence, more general models such as the one by Falk and Fischbacher (2006) have a better chance of succeeding.

The experiment also generated data at the disaggregated level, i.e., on individual choices. The percentage of subjects in the role of player B whose behavior corresponds to self-regarding preferences ($b = 0$ for all a), increases from 0 to 30 as one goes from the NI to the I treatments. Hence, a substantial part of the behavior is explained by fairness intentions. The percentage of subjects who exhibit positive or negatively reciprocal behavior, reduces from 76 to 30 as one moves from the I to the NI treatment. But importantly, reciprocity is not completely wiped out even in the NI treatment. About 40% of the subjects continue to exhibit reciprocal behavior. This supports the assertion that intentions alone do not drive human behavior; the concern for fair outcomes also plays an important role.

One set of experiments finds little evidence that fairness intentions play an important role in the domain of positively reciprocal behavior (Bolton et al., 1998; Cox, 2000; Charness, 2004), while another set of results suggests that intentions are important in the domain of negatively reciprocal behavior (Blount, 1995; Offerman, 2002). By contrast, the experimental results of Falk et al. (2008), described above, find clear evidence that reciprocal intentions are important in the domain of positively and negatively reciprocal behavior. What accounts for the differences in results?

Falk et al. (2008) raise four main concerns about earlier experimental work in explaining the differences from their results. First, in some of the experiments, a significant number of the subjects had an efficiency motive in the sense that they were willing to tolerate a reduction in their own payoffs to increase the total size of the cake. This may have confounded the reciprocity motive. Second, in some experiments, the repeated trials could have introduced noise and spillovers across the periods, making it difficult to isolate intentions. Third, in some experiments, the fairness or unfairness of actions is not salient enough to signal intentions of subjects. Fourth, the intentions and the no-intentions treatments in some of the experiments might not have been well differentiated.

Cox (2004) considers variants of the trust game. In treatment 1, which is similar to the moonlighting game above, Player A is given \$10 to pass on to player B, via the experimenter. The experimenter triples the amount that A has offered, before passing it on to B. Player B can then return any amount to player A. In treatment 2, Player B does not have the opportunity to return any money to player A. Finally in treatment 3, player A does not move, but the experimenter makes a move on behalf of player A, passing on the same amount as in treatment 1. The main difference between treatments 1 and 3 is that player A’s intentions can be inferred in treatment 1 but not from treatment 3. So, if players were purely inequity averse, then one should not observe any difference between the results of the two treatments. The experimental results show that player B returns more money in treatment 1 and, in particular, returns more when player A offers more money, hence, demonstrating the role of intentions and reciprocity.

Bartling and Fischbacher (2012) consider a four-player dictator game. There are two possible dictators, players A and B, and two possible receivers, players C and D. There are only two possible allocations. The *fair allocation* in which each player gets a payoff of 5, and the *unfair allocation* in which players A and B get a payoff of 9 each and players C and D get a payoff of 1 each. In the no-delegation treatment, player A has to directly choose among the fair and the unfair allocations. In the delegation treatment, player A delegates player B to make the allocation decision (player B cannot refuse). In the *punishment option*, player C observes the chosen allocation and can then engage in punishing players A and B. In the *no-punishment option*, player C cannot punish.

Under pure inequity aversion, the choice of delegation by A should not matter to the punishment decision of player C. However, the choice of allocation and the choice of delegation both convey important information about the intentions of each of the players A and B. While such intentions can be difficult to pin down, the paper makes progress in this direction. For instance, in one treatment, called *asymmetric*, A can either choose the fair allocation (but not the unfair allocation), or delegate the choice to B, who can then choose among the fair and the unfair allocations. In this case, delegation by A clearly reveals unkind intentions because there is some likelihood that B may choose the unfair allocation, so player A gets 9 instead of 5, while players C and D get the low payoff of 1 each.

The main findings are as follows. When the fair option is chosen by either A or B there is no punishment. The dictator (A or B) who chooses an unfair allocation is punished more and there is very little punishment of the other player. Thus, one observes more delegation by player A to player B when the punishment option by player C is available. Thus, by delegating to B, player A also shifts most of the punishment to B if an unfair allocation is chosen.

When player A delegates to player B who then chooses an unfair offer then player A is punished relatively more as compared to the case when he directly chooses the unfair allocation. In this case, C may believe that A could have chosen the fair allocation but chose instead to delegate to B who chose an unfair allocation, hence, revealing possibly unkind intentions on the part of A. As compared to the symmetric case (where A can choose among the fair and unfair allocations), punishment of player A by player C is significantly higher in the asymmetric treatment if B chooses the unfair allocation. The reason is that this clearly reveals, to player C, the unkind intentions of player A.

INTENTIONS, INEQUITY AVERSION, AND FAIRNESS REFERENCE POINTS

Most people would concede the importance of the *intentions motive* in influencing the actions of players. However, the relative importance of the *intentions motive* (the *attribution hypothesis*) and other-regarding preferences (the *distribution hypothesis*) has been an area of some conflicting views; see Bolton et al. (2008). See also the comments by Falk et al. (2008) on the possible reasons for the differences in results between the early and the later work.

The early literature found it difficult to produce evidence on the sole importance of the attribution hypothesis. The evidence is probably better described by a combination of the attribution hypothesis and the distribution hypothesis. However, in this section, we shall see that some of the evidence begs for the introduction of even newer theoretical considerations such as a *procedural approach to fairness* and/or a better understanding of a *fairness reference point*.

We have considered issues of a fairness reference point in relation to the work of Gneezy and List (2006) and Fehr et al. (2009), elsewhere in this chapter. Bolton et al. (2005) consider experimental evidence based on the ultimatum game that may form the basis of theoretical work on a procedural approach to fairness. The main idea of these experiments is that individuals are willing to accept an unfair outcome, provided it is the outcome of a procedure that is agreed to be fair. The authors give two insightful examples of the importance of their approach.

Example 6.10 In a court case in 1842 (*US v. Holmes*), crew members of a ship were found guilty of throwing 14 non-crewmen overboard from a leaky and crowded lifeboat. However, the guilty verdict centered not on throwing the 14 non-crewmen overboard (perhaps this was unavoidable) but rather on the unfairness of the “procedure” that excluded everyone from the crew to be thrown overboard. The judge ruled that the victims should have been chosen by a fair lottery that included both crew and non-crew members.

Example 6.11 A consortium of eight US states (the Southeast Compact) choose North Carolina as a destination for a radioactive waste management facility, using a lottery method. The North Carolina legislature accepted the decision on the grounds that they were chosen based on a fair procedure.

Existing theories of social preferences and intentions are neutral towards the perceived fairness of procedures that govern outcomes. Rather, their interest centers around the fairness of outcomes and the kindness of intentions. Clearly, if the outcomes are sensitive to the perceived fairness of the procedure, then we need a broader model; the experimental evidence in Bolton et al. (2005) makes such a case.

Recall that Blount (1995) produced mixed evidence for the role of intentions—rejection rates in ultimatum games were very similar in the baseline and the third party treatments, which actually contradict the intentions motive. Another set of experiments, conducted around the mid 1990s and reported in Charness (2004), applied Blount’s idea to a gift exchange game.³³ Consistent with the attribution hypothesis, he found a positive correlation between the actions of two players (gift exchange). However, when the first mover’s action are allocated to a third party or chosen randomly, so intentions are impossible to infer, the contributions by the second player are even higher. This contradicts the attribution hypothesis.

Similar difficulties in finding support for the intentions hypothesis were encountered by Bolton et al. (1998), which is an early, published, experimental contribution. They consider a two-player sequential game; players observe a 3×6 normal form game (see Figure 6.5). However, as explained below, they actually play a 2×6 normal form game in three different treatments. The row player always has the choice of the middle row (m), in each treatment. But in three different treatments, he can choose one additional row from among the top (t) or bottom (b) rows. The choice of the additional row reveals important information about the intentions of the row player. The column player chooses between columns, c1 to c6, and has a dominant action, c1, irrespective of the choice of the row player. However, by successively choosing actions c2, c3, . . . , c6 he can, at some personal cost to his payoffs, increase the payoff of the row player, such that the total surplus

	c1	c2	c3	c4	c5	c6
t	800, 2050	1000, 2000	1200, 1950	1400, 1900	1600, 1850	1800, 1800
m	900, 1650	1100, 1600	1300, 1550	1500, 1500	1700, 1450	1900, 1400
b	1000, 1250	1200, 1200	1400, 1150	1600, 1100	1800, 1050	2000, 1000

³³ Earlier versions of these results circulated in a working paper, circa 1996.

increases (social dilemma game). Once each player chooses his actions, payoffs are determined as in Figure 6.5.

In the baseline treatment, treatment II, the row player picks his second row to be *m*, thus, the choice by the row player is irrelevant. This is the *no free choice treatment* because the intentions of the row player cannot be inferred.

In treatment I, the row player picks his second row to be *b*. This is the *positively reciprocal treatment* because by choosing *m* over *b*, the row player can improve the payoff of the column player, should the latter play his dominant action, *c1*. The column player can now, if he wishes, reward the kind intentions of the row player by a choice that is different from *c1*. The higher the chosen column number, the greater is the reward for kind intentions; we shall refer to this as the degree of *cooperative behavior* of the column player; this is the horizontal axis in Figure 6.6. One can then compare the results in treatments I and II, say, when player 1 chooses *m*, to determine the extra contribution of intentions to the outcome. Finally, in the *negatively reciprocal treatment*, treatment III, the row player chooses row *t* as his second row (so the choice is between the two rows *t* and *m*). In this case, by choosing *m*, the row player signals to the column player that he has unkind intentions. Again, one may compare the choices with treatment II to infer the marginal effect of intentions.

The results are shown in Figure 6.6 in terms of the cumulative frequencies of the cooperative choices of the column player in each treatment. Thus, a higher graph indicates a less cooperative choice (this just follows from first order stochastic dominance). The choices by the column player, particularly departures from action *c1*, can be used to infer reciprocal behavior in both reciprocity treatments, I and III. Notice, from Figure 6.6, that in the no free choice treatment (treatment II), about half the column players choose an action higher than *c1*. Thus, there is a significant element of other-regarding preferences that can be noiselessly isolated from any reciprocity considerations. However, when the three distributions in Figure 6.6 are compared using the relevant statistical tests, one cannot reject the null hypothesis that the contributions of the column player belong to the same underlying distributions. Nor can we reject similar null hypotheses when the contributions under any two treatments are compared in a pairwise manner. The authors conclude (p. 213): “Hence our statistical tests imply that all of the observed reciprocal action is attributable to the distribution hypothesis.”

Bolton and Ockenfels (2005) observe variations in the results from ultimatum games, say, the probability of responder rejections, as one alters the parameters in the game; they refer to this as

Figure 6.6 Cumulative distribution of the second player's cooperative decision (*c1* to *c6*).

stress testing the results. The two variations are shown in their multiplicative and additive forms, respectively, in the left and right panels of Figure 6.7. A proposer has a cake of size \$4 that he can split with the responder. The proposer has two actions; action *l* is the more equitable choice, while action *r* is less equitable. The responder observes the action chosen by the proposer, then chooses to accept, *a*, or reject, *r*.

Consider first the multiplicative game in the left panel of Figure 6.7. In this game, stress testing involves varying the values of $x = 0.2, 0.6, 1$ and 1.2 ; each of these games is known as UG^*x . The payoffs of both players are not required to sum up to \$4. When $x = 1$ this is a standard ultimatum game. Notice, in particular, that the parameter x does not influence the payoff of the responder.

Under self-regarding preferences, the subgame perfect outcome of any UG^*x game is (r, a) . Given the *kindness functions* used by the authors,³⁴ purely intentions driven models predict that the size of x should not influence the rejection rates of the responder. However, the magnitude of x does influence the relative payoffs of the two players, hence, models of other-regarding preferences predict variability of rejection rates with respect to x .

The results on the rejection rates of responders in the UG^*x game are shown in Figure 6.8. There are no rejections when the proposer plays the strategy *l*. However, when the proposer plays the strategy *r*, rejection rates rise sharply from zero in the $UG^*0.2$ game to 43% in the $UG^*0.6$ game but, thereafter, these rates stabilize. This is inconsistent with the attribution hypothesis.

What explains the sharp rise in rejections between the $UG^*0.2$ game and the $UG^*0.6$ game? Consider the following explanation. When $x = 0.2$, both players get an equal payoff of 0.6 when the proposer chooses *r*. However, when $x > 0.2$, we get highly unequal payoffs from the action profile (r, a) in any UG^*x game. The responder gets 23% of the cake in $UG^*0.6$ and 13% in $UG^*1.2$. One may conjecture that starting from a 50% share of the cake in $UG^*0.2$, a 23% share of the cake appears highly unattractive, hence, rejections increase dramatically between $UG^*0.2$ and $UG^*0.6$. However, the difference between a 23% and 13% share of the cake is less dramatic, hence, it elicits a smaller difference in rejection rates between $UG^*0.6$ and $UG^*1.2$.

In the UG^*x game we varied *distributive measure of fairness* and held the *kindness measure* fixed. We now flip these roles in the UG^*+y game in the right panel of Figure 6.7, where $y \in$

³⁴ For a fuller discussion, see the discussion on psychological game theory in Part 4.

$\{-1.6, 0, 0.8, 1.6\}$. The subgame perfect outcome is (r, a) . Since the payoffs following the choice of r by the proposer are independent of y , the distribution hypothesis predicts that the rejection rates must be identical in any UG^*+y game. The rejection rates following a choice of l by the proposer are predicted to fall between the games $UG^*-1.6$ and UG^*+0 . However, the distribution hypothesis cannot predict the rejection rates following a choice of l by the proposer as y increases beyond zero. The reason is that the absolute payoff increases but the relative payoff falls (think, e.g., of the Fehr–Schmidt model).

By contrast, the intentions-based hypothesis (attribution hypothesis) predicts that as y increases, the rejection rates following a choice of r by the proposer should increase. The reason is that the proposer leaves only 0.6 for the responder by playing r when he could have left a lot more by playing l . This is the sense in which the *kindness measure* is varied in the UG^*+y game.

The average rejection rates are shown in Figure 6.9. As predicted by the distribution hypothesis, the rejection rates following a choice of l by the proposer fall sharply between the games $UG^*-1.6$

and UG^*+0 . However, the rejection rates following the choice of r by the proposer are different in the various UG^*+y games. Hence, there is mixed support for the distributional hypothesis. Following a choice of r by the proposer, as y increases from -1.6 to 0 , the rejection rates increase; this supports the attribution hypothesis. However, as y increases beyond 0 , the rejection rates fall, contradicting the attribution hypothesis. In a strict sense, these results reject both distribution-only and attribution-only hypotheses.

What accounts for the rejection rates in the UG^*+y game? One plausible conjecture is that the responder's notion of what is *fair* depends on y . When $y = 0$, the payoffs from the strategy pair (l, a) are $(2, 2)$, which may possibly serve as a *reference point for fairness*. In this case, the rejections following a choice of r by the proposer that give rise to unequal payoffs are maximal (Figure 6.9). As y increases, the payoffs from the strategy pair (l, a) , given by $(2 - y, 2 + y)$, become increasingly unequal. Thus, the new reference point for fairness may have become more unequal, prompting a greater acceptance rate following the choice of r by the proposer. Indeed, when $y = -1.6$, the rejection rate following a choice of r by the proposer is the lowest. This suggests an alternative approach to the distributional and the attribution hypotheses in which there is an explicit consideration of the reference point for fairness.

6.8 A discussion of other promising models

In this section, we consider other models of fairness and reciprocity such as the hybrid model of Charness and Rabin (2002), and models of interdependent preferences. We describe the relevant theory and also pit the models against the evidence.

6.8.1 The Charness and Rabin (2002) hybrid model

Charness and Rabin (2002) argue that experiments that test for social preferences have been unduly restrictive in the sense of giving too few options to the subjects in experiments. For instance, in the context of experiments in the ultimatum game, they argue that (1) a responder only has the option to accept or reject, which rules out other interesting choices such as “social objectives,” and (2) the structure of the game ensures that the only retaliatory instrument (rejection of the responder's offer) reduces inequality between the two players. They design experiments that allow for a larger range of choices for subjects in experiments. One of their main findings is that very few subjects are willing to sacrifice their own money in order to reduce inequality by lowering the payoffs of others. Half of the subjects are willing to reduce their own payoffs in order to make inequality-increasing sacrifices.

This does, however, run counter to the experimental results from public goods games with punishments as well as those from experiments conducted in a voting context (see Section 6.5 above). Charness and Rabin (2002) write (p. 5): “Indeed, while our analysis stresses that our data contradict difference-aversion models, we do not think we have conclusively disproved these models. Fehr and Schmidt [1999], for instance, have argued that only 40 percent of subjects need be difference-averse to explain the phenomena they explain. This is arguably consistent with our data.”

Charness and Rabin (2002) present two versions of a theoretical model. The models combine inequity aversion and the role of intentions, hence, they may be termed as *hybrid models*. The first version is a model of social preferences. Suppose that the set of individuals is $N = \{1, 2, \dots, n\}$,

and individuals are given respective allocations or consumption levels, $x_1, x_2, \dots, x_n$. The social welfare function is defined as

$$W = \delta \min \{x_1, x_2, \dots, x_n\} + (1 - \delta) (x_1 + x_2 + \dots + x_n); \delta \in (0, 1). \quad (6.40)$$

Social welfare is a convex combination of a Rawlsian maximin criterion, reflecting Rawlsian inequity aversion, (first term) and the sum of individual payoffs reflecting altruism and/or efficiency (second term). The utility of any individual $i \in N$ is defined as follows,

$$U_i = \lambda x_i + (1 - \lambda) W,$$

where $\lambda \in (0, 1)$ and W is defined in (6.40). When $n = 2$, denoting the two players by A, B , and $A \neq B$, the utility function for player A is given by:

$$U_A = \begin{cases} x_A + (1 - \lambda)(1 - \delta)x_B & \text{if } x_A < x_B \\ (1 - \delta + \lambda\delta)x_A + (1 - \lambda)x_B & \text{if } x_A \geq x_B \end{cases}. \quad (6.41)$$

For the preferences given in (6.41), the indifference curves in (x_A, x_B) space are kinked and downward sloping. To see this, we can use (6.41) to calculate the marginal rates of substitution (MRS) in each of the two outcome domains:

$$\frac{dx_B}{dx_A} = \begin{cases} MRS_{AB}^- = \frac{-1}{(1-\lambda)(1-\delta)} & \text{if } x_A < x_B \\ MRS_{AB}^+ = \frac{-(1-\delta+\lambda\delta)}{(1-\lambda)} & \text{if } x_A \geq x_B \end{cases}.$$

The absolute value of the slope is relatively greater below the 45° line ($|MRS_{AB}^-| > |MRS_{AB}^+|$). Hence, when $x_A < x_B$, the opportunity cost of a unit of x_i for player i , expressed in terms of x_j is relatively higher. Thus, individuals are more reluctant to accept a reduction in their payoffs when they are behind others as compared to the case where they are ahead of others.

This model is able to explain why proposers in dictator games give a strictly positive amount to responders and why trustees in trust games return a strictly positive amount to the investor. However, it is not able to explain why subjects in experiments retaliate and reduce the material payoffs of others at a cost to themselves as, for instance, in public goods games with punishments.

For this reason, Charness and Rabin propose a second version of their model, in which players are affected by outcome differences as well as the intentions of other players. Like models of interdependent preferences that we consider below, this model ignores the more rigorous framework of psychological game theory in which beliefs are modeled endogenously; see Part 4 of the book. By contrast, the Charness and Rabin (2002) and Levine (1998) models opt for a reduced-form framework that may be more tractable.

Suppose that there are two individuals, A and B , with respective material payoffs, x_A and x_B . Then, the preferences of player B are represented by the following utility function (the utility function of player A is analogously written by swapping the indices A and B).

$$U_B(x_A, x_B) = \begin{cases} (1 - \rho - \theta q)x_B + (\rho + \theta q)x_A & \text{if } x_A \leq x_B \\ (1 - \sigma - \theta q)x_B + (\sigma + \theta q)x_A & \text{if } x_A > x_B \end{cases}. \quad (6.42)$$

The payoff of any player is a weighted average of one's own payoff and the payoff of the other player. The weights depend on one's relative payoff with respect to the other player and also the intentions of the other player. In (6.42), $q = -1$ if player A has revealed negative intentions and $q = 0$ otherwise. The parameters of social preference are ρ, σ, θ . The first two, ρ, σ , relate to inequity aversion, while θ captures the role of intentions.

Suppose first that $\theta = 0$, so ignore the role of intentions for the time being.

1. An individual is said to have *competitive preferences* if $\sigma \leq \rho \leq 0$. In this case

$$U_B(x_A, x_B) = \begin{cases} x_B + |\rho|(x_B - x_A) & \text{if } x_A \leq x_B \\ x_B - |\sigma|(x_A - x_B) & \text{if } x_A > x_B \end{cases}.$$

Hence, player B derives utility from a higher material payoff and disutility from a lower payoff. Furthermore, since $|\sigma| > |\rho|$, player B exhibits a form of loss aversion; it is more painful to fall behind in material payoffs. Similar comments apply to player A .

2. The *difference aversion* (or *inequity aversion*) models of Bolton and Ockenfels (2000), Fehr and Schmidt (1999), and Loewenstein et al. (1989) can be represented by $\sigma < 0 < \rho < 1$. In this case, using (6.42) and continuing to assume that $\theta = 0$, we get

$$U_B(x_A, x_B) = \begin{cases} x_B - \rho(x_B - x_A) & \text{if } x_A \leq x_B \quad (\text{Altruism}) \\ x_B - |\sigma|(x_A - x_B) & \text{if } x_A > x_B \quad (\text{Envy}) \end{cases}.$$

Difference aversion and reciprocity can be combined, as in Falk and Fischbacher (2006), but without the apparatus of psychological games, by allowing $\theta \neq 0$. Suppose now that $\theta > 0$. Let $q = -1$, i.e., player B believes that player A has revealed negative intentions. Then, from (6.42), player B reduces the weight that she places on the payoff of player A , relative to her own payoff. This is quantitatively similar to a reduction in σ or ρ .

Charness and Rabin then define a *reciprocal fairness equilibrium* (RFE). The RFE is defined in the context of a richer model in which there are n players and there is a *demerit profile* $\rho = (\rho_1, \rho_2, \dots, \rho_n)$. The i th element of the demerit profile, $\rho_i \in [0, 1]$, indicates how much player i "deserves" in the view of the other players. The weight placed on player i 's payoff in the utility function of other players is decreasing in ρ_i . The demerit of any player is unanimously agreed upon by all other players by comparing the strategy of player i to some selfless standard of behavior. One can extend (6.40) to write the preferences of player i in this case as

$$U_i = (1 - \lambda)x_i + \lambda \left(\delta \min \left\{ x_i, \min_{j \neq i} (x_j + d\rho_j) \right\} \right) + \lambda(1 - \delta) \left(x_i + \sum_{j \neq i} \max \{1 - k\rho_j, 0\} x_j - f \sum_{j \neq i} \rho_j x_j \right). \quad (6.43)$$

where $d, k, f \geq 0$ are the model parameters. When $d = k = f = 0$, then (6.40), (6.43) are identical. Player i places less weight on the payoff of player j when d, k are large. When f is large, and ρ_j is large, then player i might derive utility from a reduction in the payoff of player j .

An RFE is a profile of strategies and a demerit profile such that (1) each player maximizes his payoff given in (6.43), and (2) the demerit profile is consistent with the profile of strategies. It is difficult to use the RFE concept except for simple games and the large number of parameters creates difficulties in testing the model. The demerit profile is defined only in equilibrium, which

makes it a difficult concept to use in the presence of multiple equilibria—a problem that is not uncommon in many models in economics.

Does the experimental data reveal that subjects have maximin preferences? The results of Engelmann and Strobel (2004), reviewed above in Section 6.7.1, reveal some support for such preferences but also persuasive evidence to the contrary. In the three player ultimatum game, the experimental evidence is that the passive receiver typically gets nothing (Riedl and Vyrastekova, 2002). This is clearly evidence against maximin preferences. Frechette et al. (2003) also find evidence against maximin preferences. In a group of five players, they ask one player to make a proposal to allocate a fixed sum of money among the five players. The support of at least three players (majority rule) is needed to implement the proposal. In 65% of the cases, the winning proposal made no allocation to two of the five players. Hence, all gains are mopped up by the winning coalition.

Okada and Riedl (2005) perform another experiment with a strategic element. There is one proposer and two responders. The proposer allocates a given amount to himself and the other two players; denote this allocation by (x_1, x_2, x_3) . If the proposer decides to form a three-person coalition, the total amount to be allocated is 3000. If he decides to form a two-person coalition, the total amount available is an element of the set $\{1200, 2100, 2500, 2800\}$. For the proposer's offer to be successful, both responders must accept the offer in the three-person coalition and the single responder must accept the offer in the two-person coalition. The prediction of maximin preferences is that the proposer chooses a three-player coalition and $x_1 = x_2 = x_3$. When the amounts available for the two-player coalition are high enough (2500, 2800), then 90% of the players choose the two-player coalition. The three-player coalition is chosen by most proposers only when the amount available to the two-player coalition shrinks sufficiently, i.e., to 1200.

These results suggest that in strategic situations, the maximin motive does not seem to be always salient. On the other hand, in dictator games, there is a strictly positive level of giving to the responder that is consistent with the presence of such a motive. It is conceivable that the maximin motive is probably more important in non-strategic settings such as charity, or in the context of anonymous voting for national referenda. The reader may also wonder if these results negate models of inequity aversion, such as the Fehr–Schmidt model. The answer depends on what is the appropriate reference group. From models of social identity (see Chapter 7), we know that individuals treat *ingroup* and *outgroup* members differently, and passive outsiders, in the experiments reported above, may be perceived as outgroup members. In this case, there is no violation of models of inequity aversion. Indeed, using these ideas one might better endogenize the issue of reference groups in models of inequity aversion.

6.8.2 *Models of interdependent preferences*

In models of *interdependent preferences*, actions taken by a player depend on the perceived type of the other player. For instance, altruistic players may wish to be kind to other altruistic players but not to other non-altruistic players. Let us consider the model of interdependent preferences in Levine (1998).³⁵

Suppose that there are n players and the game has an extensive form representation. At any end node, player $i = 1, 2, \dots, n$ has *direct utility* u_i . Each player has a type that is characterized by some altruism coefficient, $a_i \in (-1, 1)$. We say that the individual is spiteful if $a_i < 0$, self-regarding

³⁵ For the Ellingsen and Johannesson (2008) model of type-based reciprocity, see Section 8.5.2.

if $a_i = 0$, and altruistic if $a_i > 0$. A higher value of $a_i > 0$ denotes a more altruistic player. The altruism-adjusted or composite utility of player i is

$$v_i = u_i + \sum_{j \neq i} \beta_j u_j; \beta_j = \frac{a_i + \lambda a_j}{1 + \lambda}; \lambda \in [0, 1]. \quad (6.44)$$

In the special case $\lambda = 0$, we have $v_i = u_i + \sum_{j \neq i} a_i u_j$. So, depending on the sign of a_i , we have a model of *pure altruism* or *pure spite*, as in Ledyard (1995). When $a_i = 0$ and $\lambda = 0$ for all i , then we get the self-regarding case, $v_i = u_i$.

Players' concern for fairness is captured in the following manner.

1. If $\lambda > 0$ and $a_i > 0$, $a_j > 0$, then $\beta_j > 0$, so the payoff of altruistic players is increasing in the payoff of other altruistic players. If $\lambda > 0$, then β_j is increasing in a_j , i.e., the weight put on player j 's payoff is increasing in the altruism of player j .
2. When $\lambda > 0$ and $a_i > 0$, $a_j < 0$ such that $\frac{a_i}{\lambda} < |a_j|$ we have $\beta_j < 0$. In this case, the utility of an altruistic player i is decreasing in the spiteful player j 's payoff. So essentially, individuals want to be nice with altruistic individuals and spiteful with spiteful ones.

Population heterogeneity is introduced by assuming that a_i is drawn from some cumulative distribution function, $F(a)$, that is common knowledge to the players. However, a_i is privately known to player i only. Hence, the underlying game is one of private information about the types of others, where a type is the degree of altruism of a player. Players, through their actions, can reveal their private information about their altruistic coefficient, a_i . As in the Fehr-Schmidt model, the payoffs of other players are taken into account, but in addition, the types of the other players are also taken into account. An objective of the model is to explain the results of small stake experiments, so, typically $u_i(x_i) = x_i$.

The data from the ultimatum game is used to estimate the value of λ and to calibrate the distribution $F(a)$. Using these parameters, the model is able to explain why some individuals contribute in public goods games or why strictly positive offers are rejected in ultimatum games. However, it cannot explain why there is positive giving in the dictator game. Another potential issue, common with other signaling games, is that there might be a multiplicity of equilibria.

Rotemberg (2008) proposes another model of interdependent preferences to account for the results of the ultimatum and dictator games. One of the motivations of this paper is that the model by Levine (1998) is unable to explain the results of the modified dictator game of Charness and Rabin (2002); it predicts far too much spite relative to what is observed. In an ultimatum game, the responder's utility in Rotemberg's model is given by

$$U_R = x_R + (a_R - f(a_p^e, a_{\min})) x_P,$$

where x_R and x_P are the respective payoffs of the responder and the proposer, a_R is the responder's altruism, a_p^e is an estimate made by the responder of the proposer's altruism, $a_{\min}$ is some minimum level of altruism, and f is a function such that

$$f = \begin{cases} 0 & \text{if } a_p^e > a_{\min} \\ 1 + a_R & \text{if } a_p^e \leq a_{\min} \end{cases}.$$

Thus, if the perceived altruism of the proposer falls below a certain level ($a_p^e \leq a_{\min}$), then U_R is decreasing in the proposer's payoff. As a_p^e changes and $a_p^e - a_{\min}$ alters signs, we are likely to observe discontinuous jumps in the actions of the responder from acceptance to rejection; this is consistent with the experimental findings. The responder's decision to accept or reject makes the proposer's payoff risky. This is incorporated by specifying the proposer's utility function to be

$$U_P = E[x_P + a_R x_R]^\gamma,$$

where $\gamma > 0$ captures the degree of risk aversion of the proposer. In order to explain the data, it is assumed that the proposer is risk loving, i.e., $\gamma > 1$. Under the assumptions made above, the model explains well the data from the ultimatum game. However, it is not clear how well the model explains results from other experimental games on human sociality.

6.8.3 The model of Cox, Friedman, and Gjerstad (2007)

Cox, Friedman, and Gjerstad (2007) propose a flexible utility function with interdependent preferences that applies to sequential two-person games of perfect information. The utility function of player i is

$$U_i = \begin{cases} \frac{1}{\alpha} (x_i^\alpha + \beta x_j^\alpha) & \text{if } \alpha \neq 0 \\ (x_i x_j)^\beta & \text{if } \alpha = 0 \end{cases}, \quad (6.45)$$

where $\alpha \in (-\infty, 1]$ captures the ease of substituting x_j for x_i , and $\beta \neq 0$ is the *emotional state* of the player. In (x_i, x_j) space, the slope of an indifference curve for the preferences given in (6.45) is

$$MRS_{i,j} = \beta^{-1} \left(\frac{x_j}{x_i} \right)^{1-\alpha}, \quad (6.46)$$

where $\frac{x_j}{x_i}$ gives the relative payoffs of the two players. When $\alpha = 1$, $MRS_{i,j} = \beta^{-1}$, i.e., the allocations of the two individuals are substitutes. For $\alpha < 1$, one recovers the standard case of convex indifference curves. When $\alpha = 0$, $MRS_{i,j}$ is constant along any ray from the origin, so we get homothetic preferences. Leontief preferences correspond to $\alpha \rightarrow -\infty$.

Let $\pi_i^{\max}(s_j)$ be the maximum payoff that player i can get, conditional on the strategy, s_j , of player j and let $\bar{\pi}_i$ be some reference payoff of player i . The *reciprocity motive* of player j , denoted by ρ_j , is defined as $\rho_j = \pi_i^{\max}(s_j) - \bar{\pi}_i$.

The parameter β depends positively on the reciprocity motive, i.e., $\beta = \beta(\rho_j)$, which is an increasing function.³⁶ If $\rho_j < 0$, then player j is believed to have unkind intentions towards player i . In this case, $\beta(\rho_j) < 0$, so U_i is decreasing in x_j . Hence, player i would want to be unkind to player j .

The authors estimate the parameters of their model using data from ultimatum games and the Stackelberg duopoly game in Huck et al. (2001). The model fits well the data from these games. It remains to see if it also fits the data from other experimental games on human sociality.

³⁶ In the more general model $\beta = \beta(\rho_j, \phi)$, where ϕ is a variable that measures status. β is assumed to be increasing in both arguments.

6.8.4 A brief note on axiomatic foundations

We have considered three main kinds of theoretical models above. Models of social preferences (e.g., Fehr and Schmidt, 1999), models of interdependent preferences (e.g., Levine, 1998), and models of intentions-based reciprocity (e.g., Charness and Rabin, 2002).³⁷ The aim of these models is to propose psychologically plausible utility functions that can explain a range of experimental results. It is not clear, however, what restrictions on preferences are required for these utility functions.

Segal and Sobel (2007) make progress on this issue. We give a purely heuristic outline of the relevant conditions. They ask: what axioms need to be imposed in order to generate preferences for fairness and reciprocity? Segal and Sobel specify preferences directly over the profile of mixed strategies. Suppose that the generic mixed strategies of two players i, j in a two-player game are denoted by σ_i and σ_j , respectively. They define a preference relation for the i th player as $\succeq_{i\sigma_j}$ that is defined directly over the mixed strategies of player i , but conditional on the mixed strategy followed by player j , σ_j . More generally, the preference relation can depend on the entire mixed strategy profile of the players, which the authors call the *context* of the game.

Suppose that the following conditions hold: (1) Preferences over outcomes satisfy the axioms of expected utility. (2) Preferences over mixed strategies, $\succeq_{i\sigma_j}$, satisfy the continuity and the independence axioms. These two axioms are as stated under expected utility (see Part 1), but the objects over which they are stated are mixed strategies. (3) The self-interest axiom holds in the sense that if all other players are indifferent between two mixed strategies, then one chooses the mixed strategy that gives a higher own-payoff. Under these conditions, Segal and Sobel show that the preferences $\succeq_{i\sigma_j}$ can be represented by a utility function of the following form.

$$U_i = v_i(\sigma_i, \sigma_j) + \alpha_{i,\sigma_j} v_j(\sigma_i, \sigma_j), \quad (6.47)$$

where $v_i(\sigma_i, \sigma_j)$ is the utility of the i th player from material payoffs that arise from the strategy profile (σ_i, σ_j) . The parameter α_{i,σ_j} , which can be either positive or negative, depends on the strategy of the opponent. Although the authors do not use these terms, the sign of the parameter α_{i,σ_j} captures strategy-dependent altruism ($\alpha_{i,\sigma_j} > 0$), or strategy-dependent spite ($\alpha_{i,\sigma_j} < 0$). Several models that are discussed in Part 2, on altruism, spite, and inequity aversion, are special cases of (6.47), although in these models, altruism/spite are not dependent on the strategy of the opponent.

The following example demonstrates the implications of the preferences in (6.47).

	AM	PM
AM	$10(1 + i\alpha), 10$	$0, 0$
PM	$0, 0$	$10(1 + i\alpha), 10$
ALL	$7 + 10i\alpha, 10$	$7 + 10i\alpha, 10$

The column player is a plumber and the row player is a homeowner who has a leaky faucet. The plumber can either come in the morning (AM), or in the evening (PM). The homeowner needs

³⁷ For a formal consideration of models of intentions-based reciprocity, based on the more satisfactory framework of psychological game theory, see Part 4 of the book.

to take time off from work to facilitate the plumber's access to the faucet. If the homeowner takes time off in one session (either AM or PM), then it is not as damaging to his material payoff as taking the whole day off (the strategy, ALL). The plumber has purely self-regarding preferences, while the homeowner has social preferences. The homeowner places a weight $\alpha > 0$ on the payoff of the plumber. In this sense the homeowner is altruistic.

The joint payoffs are obviously maximized if the plumber and the homeowner can coordinate on the time (AM or PM); the parameter i , in the payoff matrix, captures feelings of reciprocity of the homeowner towards the plumber. Suppose that the plumber plays the two strategies, AM and PM, with respective probabilities $p, 1 - p$. If the plumber plays a pure strategy, i.e., $p = 0$ or $p = 1$, then the homeowner assigns "kind" intentions to the plumber because the latter is viewed as someone who likes to coordinate. In this case, $i = 1$, which implies positive reciprocity from the homeowner. However, if the plumber plays a purely mixed strategy, i.e., $p > 0$, then the plumber does not seem interested in coordinating and may cause the homeowner to take a full day off. The homeowner then assigns unkind intentions, $i = -1$, i.e., the homeowner places a negative weight on the payoffs of the plumber (negative reciprocity).

1. Suppose first that the plumber plays a pure strategy (so $p = 0$ or $p = 1$). If $p = 1$, then AM is strictly dominant for the homeowner, and if $p = 0$, then PM is strictly dominant for the homeowner. Hence, the two pure strategy Nash equilibria are (AM, AM) and (PM, PM).
2. Suppose that the homeowner has purely inequity averse preferences and does not care about intentions, so that $i = 1$ for all values of x . In this case, it is easy to check that (AM, AM) and (PM, PM) are still the Nash equilibria of the game.
3. Now suppose that intentions too matter, so $i = -1$ if the plumber plays a strictly mixed strategy, and $i = 1$ if he plays a pure strategy. We want to show that, in this case, the strategy ALL might be a part of the Nash equilibrium strategy profile. Define $g(\alpha) = \frac{0.7-\alpha}{1-\alpha}$. For ALL to dominate AM we require that $g(\alpha) > p$ and for ALL to dominate PM we require that $p > 1 - g(\alpha)$. Hence, the following is a mixed strategy Nash equilibrium. The homeowner plays ALL and the plumber plays AM with a probability p such that $g(\alpha) > p > 1 - g(\alpha)$. For instance, if $\alpha = 0.1$, then $g(0.1) = 2/3$. Hence, any p such that $\frac{2}{3} > p > 1/3$ is sufficient to induce the homeowner to play ALL in the Nash equilibrium.

Neilson (2006) provides axiomatic foundations for the Fehr and Schmidt (1999) preferences. The key axiom is *self-referent separability* that we consider heuristically. Suppose that we have three players. Consider ordered tuples of the allocations of the three players (x_1, x_2, x_3) , where x_i is the allocation of player $i = 1, 2, 3$. Suppose that the first player reveals the preference

$$(60, 60, 60) \succeq (60, 80, 40). \quad (6.48)$$

The payoff of the first player is common to both choices. The standard separability axiom requires that for any x_1 , it must be the case that $(x_1, 60, 60) \succeq (x_1, 80, 40)$. In particular, it must be the case that $(50, 60, 60) \succeq (50, 80, 40)$. But this has the implication that player 1 prefers an allocation in which he is ranked third in the income distribution rather than second. In other words, the separability axiom is not sensitive to one's rank in the income distribution.

The main thrust of a modified separability axiom, the *self-referent separability axiom*, is to take account of the rank of players making choices. Suppose that the set of feasible allocations of players belong to some set X . The following two conditions are required for this axiom to be satisfied in the context of this three person game.

1. Starting from any symmetric allocation, if a player prefers to add $y \in X$ to his allocation rather than $y' \in X$, then he should do so for any other symmetric allocation also. Formally, for any $x, y, z, y' \in X$,

$$\text{if } (x + y, x, x) \succeq (x + y', x, x), \text{ then } (z + y, z, z) \succeq (z + y', z, z).$$

2. Starting from any two symmetric allocations, if a player prefers adding some amount $y \in X$ to the outcomes of the other players for one allocation, he should also prefer to do so for any other amount $y' \in X$. Formally, for any $x, y, z, y' \in X$,

$$\text{if } (x, x + y, x + y) \succeq (z, z + y, z + y), \text{ then } (x, x + y', x + y') \succeq (z, z + y', z + y').$$

Proposition 6.21 (Neilson, 2006): Suppose that there are $n \geq 2$ players. Consider any allocation $x = (x_1, x_2, \dots, x_n)$ of payoffs to the n players. The preference ordering satisfies self-referent separability if and only if there exist functions $u_1, \dots, u_n$ such that preferences can be represented by a function U of the form

$$U(x) = u_1(x_1) + \sum_{i=2}^n u_i(x_i - x_1). \quad (6.49)$$

Several inequity averse utility functions, for instance, the Fehr–Schmidt (1999) utility function, are of the same form as (6.49). In (6.49), one's own consumption bundle is the reference point against which the consumption bundles of others are compared. As the reader may have guessed, one can also get a representation for prospect theory type preferences using similar axioms; see Neilson (2006).

CHAPTER 7

Human Morality and Social Identity

7.1 Introduction

In neoclassical economics, there is no explicit role for *character virtues*, such as the desire to be honest, to keep promises, to avoid deception and lies, and to be fair to one's fellow human beings. Neoclassical economics assumes that people are disposed to tell *selfish black lies* (Erat and Gneezy, 2012), i.e., lies that benefit the individual but also typically harm others. By contrast, we do observe individuals whose behavior accords well with “good” character virtues. The explanation for such behavior in neoclassical economics is *instrumental* because individuals are *consequentialists*. In this view, individuals strategically exhibit the relevant character virtues, based on a cost–benefit analysis. Neoclassical economics, thus, takes a fairly dim view of human nature, relative to many of the other social sciences in which humans *intrinsically* display character virtues.

The purpose of the first part of this chapter (Section 7.2) is to give experimental evidence on the source of human character virtues—instrumental, or intrinsic. Furthermore, we wish to apply these concepts to a theoretical model of promises and threats. We begin, in Section 7.2.1, with some of the relevant evidence. The evidence shows that character virtues may directly provide utility to humans, say, on account of enhanced self-esteem. Such character virtues are likely to dominate behavior, particularly when the gains from non-virtuous behavior are small. Humans are not likely to lie for small gains, but as the gains become large, the morality of a fraction of the subjects is loosened (Gneezy, 2005; Gneezy et al., 2013; Gibson et al., 2013). Character virtues may also depend on the prevalence of such character virtues in the population. For instance, bribing a traffic policeman, or evading taxes may be considered less non-virtuous in societies where such activity is already prevalent.

In an interesting experiment, Fischbacher and Föllmi-Heusi (2013) asked subjects to privately roll a six-sided dice, observe and then self-report the outcome. The distribution of self-reported outcomes can now be compared with the predicted statistical distribution where each of the six outcomes, 1 to 6, occur with probability 1/6. Roughly 40% of the subjects are *completely honest*, even when lying could have improved their payoffs. A significant fraction of the subjects tell *partial lies*, even when they could have lied more strongly (see also Gneezy et al., 2013). About 22% behave in a manner that is consistent with the selfish black liars assumed in neoclassical economics. We also report the results of a similar elicitation by Pruckner and Sausgruber (2013), who examine non-conclusive evidence on gender differences in lying, as well as the importance of many non-economic factors in the lying decision.

In neoclassical economic theory, *promises* and *threats* are simply cheap talk. By contrast, a significant fraction of subjects in experiments honor their promises (Ellingsen and Johannesson, 2004; Charness and Dufwenberg, 2006; and Vanberg, 2008). We consider some of the relevant evidence in Section 7.2.2. We also consider here, a theoretical model of promises and threats in a buyer–seller problem in which there is the possibility of the hold up of the seller’s investment (Ellingsen and Johannesson, 2004). When the buyer and the seller have other-regarding preferences, and there is a cost of breaking a promise, or not carrying out a threat, two things happen. First, promises and threats become effective, and alter the eventual outcome; this is confirmed by the experimental results. Second, the effect of other-regarding preferences can magnify the cost of breaking a promise and the cost of not carrying out a threat.

One may also carry out promises and threats for reasons other than the costs of lying. For instance, promises may induce others to form certain beliefs. If one believes this to be the case, then one may suffer from *guilt* by breaking the original promise (Charness and Dufwenberg, 2006). Issues of guilt and the relevant empirical evidence is considered in Part 4 of the book. However, the results of Vanberg (2008) support the *cost of lying* explanation of breaking promises.

Section 7.3 considers the topic of *social identity*, which traditionally is a part of the subject matter of social psychology. Our focus, however, is on exploring the recent advances from the rapidly expanding literature in economics. In *social identity theory*, one’s *social identity* refers to the *social category* one belongs to, such as black or white, blue collar worker or white collar worker, and soldier or civilian. Different identities may be triggered by different social contexts. For instance, a national identity may apply to a football supporter when his country plays against another, and a club identity when his preferred club plays against another. Once the social identity of a group is taken on, group members prefer to conform to the group norm.

In most classic experiments on social identity, individuals are *primed* for a group identity. There is evidence that even a *minimal group identity*, based on even trivial characterizations, say, blue and red groups, may alter the behavior of group members. The typical finding is that one favors one’s own group members, or the *ingroup*, relative to non-group members, or the *outgroup* (Billig and Tajfel, 1973; Tajfel and Turner, 1986).

In Section 7.3.1, we consider the evidence from recent experiments in economics on social identity. The Asian American identity is associated with the norms of hard work and patience. When Asian Americans are primed for their identity, they make more patient choices than whites. By contrast, in the unprimed condition, their choices are more impatient than whites (Benjamin et al., 2010). Altruism and envy are found to be stronger towards ingroup members and players are more likely to forgive unfavorable behavior by an ingroup member relative to an outgroup member (Chen and Li, 2009).

Charness et al. (2007) play a two-player battle of sexes (BOS) game and a two-player prisoner’s dilemma (PD) game. They find that subjects make more aggressive choices (e.g., defect in the PD game) when group membership is highly salient (e.g., choices are made in front of other group members who observe the outcomes immediately). When a player observes that the opponent is making choices under highly salient group membership, he responds by making more accommodating choices (e.g., cooperate in the PD game). When group membership is less salient, the percentage of aggressive choices drops significantly.

Goette et al. (2012) argue that real-life social groups (SG) exhibit far more social ties and friendships between group members relative to the minimal groups (MG) in experiments. Based on field studies on Swiss army trainees, they find that there are qualitative and quantitative differences between the behavior of SG and MG group members that can be used to reconcile existing results. There is significantly greater cooperation between SG members and they punish defecting

ingroup members as much as defecting outgroup members. However, while MG members punish defecting outgroup members as much as SG members do, they punish ingroup members far less.

Since ingroup members engage in unfavorable behavior towards outgroup members, one might wonder if the existence of groups reduces overall welfare. Hargreaves Heap and Zizzo (2009) argue and empirically show that group membership confers private hedonic benefits. Taking account of these hedonic benefits produces an overall positive effect of group formation.

Section 7.3.2 considers a simple principal–agent model of the interaction between identity and incentives (Akerlof and Kranton, 2000, 2005, 2008). The principal has the choice of appointing a supervisor to monitor the non-contractible effort level of the agent. However, the very act of appointing the supervisor alters the identity of the agent, who now considers himself an outsider. When the principal has the option of appointing a supervisor, yet does not appoint one, then the agent feels trusted, and dons the identity of an insider.

Once the agent considers himself as an insider he internalizes a *higher effort norm*. Thus, choosing not to appoint a supervisor has a cost and a benefit for the principal. The cost is the inability to engage in ex-post punishments, such as fines, if the agent shirks; this reduces deterrence. The benefit is that since the agent internalizes a higher effort norm, the individual rationality constraint of the agent can be satisfied at a lower expected wage cost. These sorts of trade-offs then determine the optimal organizational design.

7.2 Human virtues

We separate the discussion in this section into two parts. In the first part, we discuss the empirical evidence on *lying behavior*. In the second part, we consider formal models of *promises* and *threats*.

7.2.1 Evidence on human virtues

While the interest in human attitudes to lying in economics is a relatively recent and growing phenomenon, psychologists have been interested in these issues for much longer (Vrij, 2000, 2008). In neoclassical economics, one takes a fairly dim view of human nature. Using the terminology of Erat and Gneezy (2012), neoclassical economics assumes that humans feel no remorse in telling *selfish black lies*. Typically, such lies benefit the person telling the lie but harm the other party. In particular, an individual telling selfish black lies suffers no decrease in utility on account of the lies. Neoclassical economics then proceeds to determine incentive compatible mechanisms that induce truth-telling, purely in response to the underlying economic incentives. The dismal nature of this view of human nature is not a reason to reject it. Our interest, below, is in empirically pitting this view against alternative views of human nature.

In contrast to selfish black lies, *white lies* do not harm the other party, and may indeed contribute to increasing the utility of others. Erat and Gneezy (2012) give two insightful examples. Consider a supervisor giving feedback to a failing employee. If the feedback is entirely truthful, it may seriously undermine the employee's confidence in undertaking future tasks. Shading the truth may be efficacious in meeting longer-term objectives. In other contexts, doctors may sometimes give placebos to patients when they fully know that the placebo has no pharmacological effect.

Two further categories of white lies have also been used in empirical work. A player who tells *altruistic white lies* may be harmed by the lies, but the intention is to increase the payoff of the other party. A player tells *Pareto white lies* when such lies improve the payoffs of both players.

Table 7.1 Payoffs of the players in each treatment in Gneezy (2005).

Treatment	Option	Payoff of	
		Player 1	Player 2
1	A	5	6
	B	6	5
2	A	5	15
	B	6	5
3	A	5	15
	B	15	5

It is also useful to consider the following terminology in Gneezy (2005). Suppose that action A involves a lie but action B does not, yet both actions lead to the same monetary payoff for a player. If the player is indifferent between the actions A and B, we say that the player takes a *consequentialistic approach*. Players in neoclassical economics are consequentialists. Otherwise, if there is a preference for one action over the other, the player takes a *non-consequentialistic approach*. The bulk of the empirical evidence indicates that the actions of players are non-consequentialistic.

In cheap talk games, unlike signaling games, the messages sent by players do not affect the payoffs of players. Rather, the messages influence the beliefs of the other player about the state of the world, hence, they indirectly influence payoffs through their effect on actions. Gneezy (2005) considers cheap talk games between two players; the three treatments in his experiments are shown in Table 7.1. In each treatment, player 1 (the sender) has two possible choices: A and B. Player 2 (the receiver) does not see the payoffs, however, player 1 can see the payoffs.

Player 1 sends one of two possible messages to player 2. Message A says: “Option A will earn you more money than option B.” Message B says: “Option B will earn you more money than option A.” Message B is a *lie* because for all three treatments, player 2 gets a lower payoff from option B. The sender always gets a higher payoff from option B. Player 2 observes the message and then chooses either option A or B. Player 2’s chosen option is then implemented. The structure of the game is not rich enough for a signaling equilibrium to be sustained; player 2 does not even know if the incentives of the two players are aligned.

Out of the 50 participants who were assigned the role of a sender, in an incentive compatible elicitation, 82% expected the receiver to follow their message. This was close to the actual percentage of receivers who did follow the messages, 78%. Thus, conditional on their messages being largely followed, if senders are assumed to tell selfish black lies, then they should always choose the option that maximizes their payoff (message B in all treatments).

Notice that the incentive to lie for player 1 (choosing message B) is different in each of the three treatments on two different counts. First, the gain in own-payoff is 1 for treatments 1 and 2 but it is 10 for treatment 3. Second, the loss to player 2 from being lied to is 1 in treatment 1 but 10 in treatments 2 and 3. The percentage of player 1s who lied in treatments 1, 2, and 3, respectively, is 36, 17, and 52 and these percentages are statistically different. In treatments 1 and 2, the personal gain from lying is 1, however, the loss to player 2 increases from 1 to 10. This reduces the fraction of player 1s who lie by more than half. However, in treatments 2 and 3, the loss to player 2 is 10 in each case but the personal gain to player 1 increases from 1 to 10. This significantly increases the

percentage of player 1s who lie to 52. This experiment shows that the extent of lying responds to the gain from lying and the cost to the other player. However, it cannot cleanly separate the *role of other-regarding preferences from aversion to lying*.

In a separate questionnaire, Gneezy (2005) asks a different set of players to judge the fairness of lies with different consequences. University of Chicago students are asked which of the following two lies is more unfair. In one case, the seller sells a car to a buyer without revealing that it will cost \$250 to fix a pump in the car. In another, the seller does not reveal that the brakes are faulty, which will also cost \$250 for the gullible buyer to fix. A significantly higher percentage of the respondents judged the second scenario (faulty brakes) to be the more unfair of the two lies, despite identical monetary costs of repair. Subjects are not merely consequentialists but they apparently care about the higher potential risk to the buyer in the second case. If the responses of these subjects are more generally representative of the population, then we can trust a car salesman to more accurately report the condition of the brakes as compared to the air-conditioner.

Hurkens and Kartik (2009) reconsider the results of Gneezy (2005) and show that they are unable to reject the hypothesis that the data comes from a population of players of two types. Type-I never lies whatever the cost (ethical types) and Type-II always lies (unethical type).¹ However, if the types are fixed, this evidence begs the question of why the extent of lying responds to the incentives to lie in so many diverse contexts.

Gibson et al. (2013) conduct a decision theoretic lab experiment in which the confounds of strategic considerations and other-regarding preferences are eliminated. In the truth-telling task, subjects, in their role as the CEO of a company, had to decide on two possible earnings announcements that affected their own payoffs. A higher announcement is a lie but also increases their payoff. In several different treatments, the payoff differences between truth-telling and lying are different. For instance, in one treatment, the choice was between announcing 31 cents/share and 35 cents/share and the higher announcement led to 5 times higher earnings for the CEO. The subjects are told that the lie is within the bounds of what could be defended on accounting grounds.

If the subjects were of only two types, ethical and unethical, then we should not get any variation in the levels of truthfulness as the incentive to lie varies. The ethical types should never lie and the unethical types should always lie. In contrast, the extent of lying was sensitive to the incentive to lie. The authors find that the most significant factor in the decision to lie is the intrinsic cost of lying, which ties in with the results of Gneezy (2005). Hence, people seem to have underlying preferences over how much they are willing to lie as incentives for lying vary.

Fischbacher and Föllmi-Heusi (2013) introduce a novel method of measuring the extent to which people lie, even when the individual responses cannot be checked for lying. Subjects in the experiment are asked to roll a dice and privately observe the outcome of the dice. To ensure anonymity, the experimenter is not present in the room when each participant privately rolls the die. For the numbers 1, 2, 3, 4, and 5, the payoff equals the self-reported number that subjects claim has appeared on the dice. If the claimed number is 6, then payoff is zero. The experimental design ensures that subjects can never be found out if they cheat. The distribution based on the claimed numbers is then compared to the predicted statistical distribution of outcomes in which each number comes up with a probability 1/6 or 16.7%. Several control treatments were used that varied the level of stakes, created a negative externality on another player from lying, and created even higher levels of anonymity.²

¹ For an early theoretical attempt at modeling two-type models of this sort, see Koford and Penno (1992).

² In this treatment, participants shredded any pieces of paper they had written on and directly took prize money from an envelope without the intervention of the experimenter.

Figure 7.1 Results for the baseline treatment.

Source: "Lies in disguise: an experimental study on cheating," Fischbacher, U. and Föllmi-Heusi, F. *Journal of the European Economic Association*, 11(3): 525–47. Copyright © 2013 by the European Economic Association.

The results of the baseline treatment for 389 participants are shown in Figure 7.1. On the horizontal axis are the payoffs of the player that simply correspond to the claimed number on the dice (recall that for a report of 6 on the dice, the payoff is zero). The vertical axis measures the percentage who report being in each category; the theoretical prediction of 16.7% is also shown. The stars denote the significance levels for a two-sided binomial test of the differences in observed percentage of players who self-report in each category from the theoretical prediction of 16.7%. The results are as follows.

1. A Kolmogorov–Smirnov test rejects the hypothesis that the observed distribution is identical to the predicted uniform distribution where each number occurs with a chance of 16.7%.
2. Numbers below 4 and the number 6 are underreported as they lie below the 16.7% line, while the numbers 4 and 5 are overreported. Since only 16.7% of the subjects are predicted to get a 6 and anybody who does not get a 6 is unlikely to report a 6, it is significant that 6.4% nevertheless report 6. This is contrary to the assumption of selfish black liars in neoclassical economics. Assuming that the proportion of intrinsically honest players is independent of the number arising on the throw of the dice, then, since $\frac{6.4}{16.7} = 0.383\ 23$, the proportion of intrinsically honest subjects is 38.3%.
3. The number 5 is payoff maximizing, yet 16.7% of the subjects would have got a 5 anyway, hence, the percentage of people who are unethical income maximizers is $\frac{6}{5} (35 - 16.7) = 21.96\%$.
4. More than 16.7% of the subjects report the number 4. Hence, there is a set of subjects who lie but do not lie maximally. These may be termed as partial liars. Such behavior could arise, for instance, if subjects wish to maintain a positive self-image.

A similar elicitation method is used by Prucker and Sausgruber (2013) using field data. They conducted their field experiments in two towns in Austria. Several tabloids operate under an *honor system* in which newspapers are sold on the street using a booth filled with newspapers. Customers pay into a padlocked cashbox. The payments are not monitored, so customers can pay an amount below the price of the newspaper or not pay at all. There is very little gain from

not paying and a very small probability of non-payments being discovered. The authors run two different treatments by posting a note on the booth.

In the treatment LEGAL, a note is posted on the booth, reminding customers of the legal norm of paying for the newspaper. In treatment MORAL, the posted note appeals to the honesty of the customers, so it primes them to follow a social norm. The newspaper costs 0.60 euros and only a third of the customers pay a strictly positive amount. Average payment in the LEGAL treatment is 0.061 euros and average payment in the MORAL treatment is 0.14 euros. Thus, the MORAL treatment is more effective. The authors conjecture that there is, in fact, a moral norm of payment and when subjects are primed to consider it, self-interest is reduced somewhat in favor of a social norm of honesty.

Abeler et al. (2014) conducted a field study in Germany. Participants were contacted by phone, asked to toss a coin that only they privately observe, and report the result on the phone. Subjects received a payoff of 15 euros if they report tails. Under self-regarding preferences and amoral preferences, all subjects should report tails. Using the method introduced by Fischbacher and Föllmi-Heusi, the reported distribution of tails is compared to the predicted theoretical distribution. Almost all subjects told the truth; indeed the percentage reporting tails is lower than 50%. The authors conclude that the results are consistent with a cost of lying and that lab experiments understate the costs of lying and overstate the extent of amoral preferences.

Mazar et al. (2008) used two different treatments. In the first treatment, the experimenter checked answers to 20 maths questions and students were paid according to the number of correct answers. This establishes a benchmark distribution of marks. In the second treatment, subjects could mark the questions themselves (based on an answer key provided by the experimenter), then shred their answers and self-report the number of correct answers to claim the payment. Students in treatment 2 reported solving 10% more questions as compared to treatment 1. If students did not feel any unease at telling selfish black lies, then all of them should have reported 100% correct answers, given that this would have maximized their payoffs, particularly when the probability of being caught was zero.

Gneezy et al. (2013) introduce a third method of measuring lying aversion. Two individuals A and B are paired to play a simple sequential sender–receiver game. Only player A observes a randomly determined state of the world $s \in S = \{1, 2, \dots, 6\}$; each of the states is equally likely. Player A then sends a message $r \in S$ to player B. The message is truthful if $r = s$, otherwise it is a lie. Player B observes the message and then chooses an action $a \in S$. The payoff of player A, π_A , is linearly increasing in r but it does not depend on the state, s , or the action, $a \in S$, of player B. The payoff of player B, π_B , depends on his action a and the truthfulness of A. The exact payoffs are as follows.

$$\pi_A = 10 + 2r \text{ and } \pi_B = \begin{cases} 10 & \text{if } r = a \text{ and } r = s \\ 0 & \text{if } r = a \text{ and } r \neq s \\ 3 & \text{if } r \neq a \end{cases}.$$

Thus, player B gets the highest payoff when A sends a truthful message that is believed by player B. If player B chooses not to believe the message of player A (truthful or not), then he gets a fixed payoff of 3. If untruthful messages are believed, then B's payoff is zero. A player who is disposed to tell selfish black lies, as in neoclassical economics, would choose the message $r = 6$ in every state, s . The incremental payoff to player A from lying increases as s decreases.

The results with 72 subjects, who were rematched randomly over 24 rounds are as follows. The messages sent by player A in each state are shown in Figure 7.2. Each column corresponds to the

Figure 7.2 Messages sent by player A in each state.

Source: Reprinted from *Journal of Economic Behavior & Organization*, 93: 293–300. Gneezy, U., Rockenbach, B., and Serra-Garcia, A., “Measuring lying aversion.” Copyright © 2013, with permission from Elsevier.

percentage distribution of messages, $r \in S$, sent by player A for each state, $s \in S$. The sizes of the circles reflect the fraction of choices in each category. Along the diagonal, we get the percentage of truthful messages sent by A. Since the incentive to lie increases as s falls, it is not surprising that as s increases, messages are increasingly truthful.

Another indicator of this is the top row in Figure 7.2, which shows a message of $r = 6$ for each $s \in S$. As s increases from 1 to 5, the percentage of player As who lie maximally ($r = 6$) falls; these differences are statistically significant. These results are consistent with those of Gneezy (2005) reviewed above. As in Fischbacher and Föllmi-Heusi (2013), many players are partial liars but the percentages here are smaller; for instance, for states $s = 1, 2$, and 3 , there are 10% partial liars. There is also an element of other-regarding preferences in the results that is revealed over successive rounds of the experiment. Player As are less likely to lie in period t if their lie in period $t - 1$ reduced B's payoff.

As in many of the other results reported in this section, a very large fraction of player Bs choose to follow player A's message (i.e., $a = r$). For $r = 1, 2, \dots, 5$, in 85–89% of the cases we have $a = r$ but when $r = 6$ we have $a = r$ for only 46% of player Bs. There is evidence of learning over successive rounds; player Bs reduced their dependence on messages by A if they were lied to in the previous period. On the whole, excluding $r = 6$, player Bs significantly improved their payoffs from following the message of player A.

A developing theoretical literature introduces a cost of lying in the players' utility functions.³ Serra-Garcia et al. (2013) consider the efficacy of cheap talk in asymmetric information, sender-receiver, games. They consider two kinds of messages that can be sent by the sender—a message

³ See, for instance, Ellingsen and Johannesson (2004), Kartik et al. (2007), and Kartik (2009).

about the private information of the sender or a message about the action of the sender. In these kinds of games, there are two equilibria. In the *babbling equilibrium*, the receiver ignores the message sent by the sender. However, in the *influential equilibrium*, there is a separating equilibrium in which different types of senders send different messages and the receiver conditions his actions on the message of the sender. Under the *cost of lying assumption*, the only equilibrium that survives is the influential equilibrium.

There is a growing literature that examines the differential propensities of men and women to lie. For instance, Dreber and Johannesson (2008) find that men are more likely than women to tell a selfish black lie. Childs (2012) finds no gender differences in lying. However, when the stakes are reduced, in a similar game to Dreber and Johannesson, no gender differences are found by Gylfason et al. (2013). Erat and Gneezy (2012) show that men are more likely to tell a selfish black lie and a Pareto white lie. However, women are more likely to tell an altruistic white lie. This contributes to a developing literature that requires further replication and testing; for a survey on gender differences in preferences, see Croson and Gneezy (2009).

Conrads et al. (2013) find that individuals are more prone to lying under team incentives relative to piece rates. The reason is that under team incentives, players may be able to spread the consequences of lying among other team members. Cappelen et al. (2013) consider the non-economic correlates of lying. They find that the non-economic factors are as important as the economic ones. Participants who gave larger amounts in dictator games are also less likely to lie in sender–receiver games. They do not find a gender effect of lying, although females are slightly more prone to lie than males, a finding that is in contrast to earlier work. Other variables that correlated with lying were age, a measure of other-regarding preferences, and the nature of the lie, e.g., the incidence of lying falls when the message of the sender involves personal content.

7.2.2 A theoretical model of promises and threats

In neoclassical economics, promises or threats are not credible unless instrumentally rational self-regarding players respond to reputational concerns, or to third party enforcement. In the absence of these conditions, verbal commitments, in the form of *promises* or *threats*, are predicted to be ineffective. This is in contrast with the view taken in psychology and sociology, where such verbal communication can be efficacious; Part 4 of the book considers experimental evidence that supports this view. Ellingsen and Johannesson (2004), henceforth EJ, examine the predictions from these conflicting approaches in a classical hold up problem.

Consider a multi-stage, two-player, game between a seller (*S*) and a buyer (*B*). In stage I, the seller can, at a fixed cost, $F > 0$, make an investment decision $I \in \{0, 1\}$. $I = 0$ denotes foregoing the investment opportunity, and $I = 1$ denotes making the investment. The gains from trade in stage II are $g \in \{0, G\}$. If $I = 1$, then $g = G > F$, otherwise if $I = 0$, then $g = 0$.

If $I = 1$, then, in stage II, let x_S, x_B be, respectively, the seller's and buyer's shares of the gains from trade, G . Following, $I = 1$, the buyer proposes a split of G by making a proposal $x = \{x_S, x_B\}$ such that $x_S + x_B = G$. The seller makes the binary accept/reject decision $a(x) \in \{0, 1\}$. If the decision is to accept ($a = 1$), the proposal x is implemented, and if it is to reject ($a = 0$), both get zero. The outside option of the seller is zero. In the experiments, the unit of currency is Swedish Kroner (SEK), $F = 60$ and $G = 100$.

Let us first consider the theoretical predictions under the benchmark case of self-regarding preferences.

Proposition 7.22 *Suppose that the seller and the buyer have self-regarding preferences. Then, in the unique subgame perfect equilibrium of the game: $I = 0$, $x_B = G$, $x_S = 0$, and $a = 1$. Furthermore, any promises made by the buyer or the seller at any stage do not influence the outcome.*

Proof: In stage II, the seller will accept any non-negative offer because the outside option is zero, so $a = 1$. Knowing this, the buyer offers $x_S = 0$, so $x_B = G$. In stage I, the ex-ante utility of the seller from $I = 1$ is $-F < 0$ and from $I = 0$ it is 0. Thus, $I = 0$ is optimal. The reason that promises have no effect in the game is that players have self-regarding preferences and there is no cost of breaking a promise. ■

Let us now examine the experimental results to see if the predictions of the self-regarding model in Proposition 7.22 hold. EJ consider three treatments. In the first treatment, no communication is allowed. In the second treatment, the buyer sends a message to the seller before the seller makes the investment decision. In the third treatment, the seller sends a message to the buyer along with his investment decision $I \in \{0, 1\}$. Clearly, messages in the second treatment are of the nature of promises. For instance, the buyer might *promise* in his message to the seller that “I shall share the net gains from trade, $G - F$, equally with you.” Messages in the third treatment are of the nature of *threats*. For instance, in his message to the buyer, the seller might issue the threat that “If you make me a low offer, I will reject your offer and each of us will get zero.”

The experimental results reject the predictions of Proposition 7.22, and are as follows. In treatment 1, a third of the sellers choose $I = 1$ and the modal offer by buyers is to split the net gains from trade $G - F = 40$ equally, thus, the modal proposal is $x_S = 80$, $x_B = 20$. However, the mean offer in treatment 1 is $x_S = 48.57$ and mean profit of the seller, $x_S - F = -12.86 < 0$.

The presence of communication in treatments 2 and 3 increases the mean offer. The mean offer in treatment 2 (buyer communication) is the highest and it is significantly higher than in treatment 1; the mean profit of the seller in treatment 2 is 8.75. The two most frequent proposals made by the buyer in treatment 2 were $x_S = 60$ (so seller’s net profit, $x_S - F$, is zero), and $x_S = 80$ in which case the seller’s net profit is 20. Out of the 30 pairs of subjects, in three cases, sellers accepted an offer that made them a loss.

The mean offer in treatment 3 is lower but not statistically different from that under treatment 2. Nine out of the 21 messages in treatment 3 contained threats; however, these threats were not very credible and often ignored by the buyers. The vast majority of the seller messages (16 out of 21) suggested splitting the net gains from trade equally but in the majority of cases (9 out of 16), the buyers made lower offers to the seller. This is in keeping with the nature of the holdup problem; once the seller sinks the investment, the buyer can holdup the seller, ex-post.

The failure of the predictions of the model with self-regarding preferences is problematic because the hold up problem is of fundamental importance in industrial organization and in contract theory. EJ suggest that the explanation lies in other-regarding preferences, modified to take account of a cost of breaking the promise.

Suppose that the seller and the buyer in the EJ model have Fehr–Schmidt preferences as in (7.1), so that the Fehr–Schmidt utility of the seller is denoted by $U_S(x, I, a; \alpha_S, \beta_S)$, where α_S, β_S are the preference parameters of the seller. The buyer’s Fehr–Schmidt utility is denoted by $U_B(x; \alpha_B, \beta_B)$, where α_B, β_B are the preference parameters of the buyer and $x = \{x_S, x_B\}$. Suppose that there is mutual knowledge of the utility functions, U_S and U_B .

Proposition 7.23

- (a) *If $\beta_B > \frac{1}{2}$, then in the unique subgame perfect equilibrium of the model: $I = 1$, $x_B = \frac{G-F}{2}$, $x_S = \frac{G+F}{2}$ and $a = 1$.*

(b) If $\beta_B < \frac{1}{2}$, then in the unique subgame perfect equilibrium of the model, $I = 0$.

Proof: Consider a seller who, in stage II, is making his acceptance decision, having observed the buyer's proposal $x = \{x_S, x_B\}$, and conditional on having chosen $I = 1$ in stage I. The stage II payoffs of the seller and the buyer are, respectively, $x_S - F$ and x_B , where $x_S + x_B = G$. Suppose that the buyer does not make any overfair offers, so the buyer's payoff is relatively greater (we appeal to the ultimatum game for this sort of evidence⁴). Denote the utility of the seller from accepting ($a = 1$) and rejecting ($a = 0$) the proposal, respectively, by $U_S(x, 1, 1; \alpha_S, \beta_S)$ and $U_S(x, 1, 0; \alpha_S, \beta_S)$. Thus,

$$U_S(x, 1, 1; \alpha_S, \beta_S) = x_S - F - \alpha_S [x_B - (x_S - F)] \text{ and } U_S(x, 1, 0; \alpha_S, \beta_S) = -F - \alpha_S F. \quad (7.1)$$

Substituting $x_B = G - x_S$ in (7.1), the smallest offer x_S that the seller accepts such that $U_S(x, 1, 1; \alpha_S, \beta_S) > U_S(x, 1, 0; \alpha_S, \beta_S)$ is

$$\underline{x}_S = \frac{\alpha_S G}{1 + 2\alpha_S} > 0. \quad (7.2)$$

A rational buyer with mutual knowledge of Fehr-Schmidt preferences knows that any offer to the seller below $\underline{x}_S$ will be rejected (recall that under self-regarding preferences, buyers offered $x_S = 0$). Thus, the maximum monetary payoff of the buyer is $G - \underline{x}_S$.

In making his proposal, $x = \{x_S, x_B\}$, the buyer takes the subsequent behavior of the seller, in (7.2), as given. Suppose that we are interested in the case where the buyer demands more than half the net surplus, i.e., $x_B \geq \frac{G-F}{2}$, so that the buyer's payoff is relatively greater. Since $x_S = G - x_B$, the condition $x_B \geq \frac{G-F}{2} \Leftrightarrow x_S \leq \frac{G+F}{2}$. Also notice that $\frac{G+F}{2} > \underline{x}_S$. Thus, the buyer chooses x_B in order to maximize $U_B(x; \alpha_B, \beta_B) = x_B - \beta_B [x_B - (x_S - F)]$ subject to the constraints $x_S + x_B = G$ and $0 < \underline{x}_S \leq x_S \leq \frac{G+F}{2}$. This is equivalent to the problem of choosing x_B in order to maximize

$$U_B(x; \alpha_B, \beta_B) = x_B - \beta_B [x_B - (G - x_B - F)], \quad (7.3)$$

subject to $\frac{G-F}{2} \leq x_B \leq G - \underline{x}_S$. From (7.3) we have

$$\frac{dU_B}{dx_B} = 1 - 2\beta_B.$$

Suppose that $1 - 2\beta_B < 0 \Leftrightarrow \beta_B > \frac{1}{2}$, then the buyer chooses the lower limit $x_B = \frac{G-F}{2}$, so $x_S = G - x_B = \frac{G+F}{2}$. In this case, it is optimal in the first stage for the seller to choose $I = 1$.

When, $\beta_B < \frac{1}{2}$, $\frac{dU_B}{dx_B} > 0$, so the buyer chooses the upper limit $x_B = G - \underline{x}_S = G \left(\frac{1 + \alpha_S}{1 + 2\alpha_S} \right)$. The ex-ante utility of the seller from investing in this case is $U_S(\underline{x}_S, 1, 1; \alpha_S, \beta_S) = \underline{x}_S - F - \alpha_S [G - \underline{x}_S - (\underline{x}_S - F)] = -F - \alpha_S F < 0$, which is lower than the outside option of zero. Hence, $I = 0$. ■

The inequity aversion parameters of both players, α_S and β_B , determine the size of the offer and the investment decision. If the advantageous inequity parameter of the buyer, β_B , is high enough ($\beta_B > 1/2$), then the buyer offers to share equally in the gains from trade, inducing the seller to

⁴ This assumption comes with the caveat that in some cultures overfair offers are not unheard of; see Henrich et al. (2001).

make the investment in stage I. If $\beta_B < 1/2$, then the ex-post hold-up problem is serious enough for the seller to prevent any investment in stage I. From (7.2), we have that the seller's minimum acceptable share is increasing in the gains from trade, G , as well as the disadvantageous inequity parameter of the seller, α_S . The higher is α_S , the more likely the seller is to reject an offer by the buyer, eliciting higher offers for the seller in equilibrium.

Social preferences of the Fehr–Schmidt form are consistent with the experimental findings in EJ of strictly positive offers made by buyers and the investment choice, $I = 1$, of the sellers. However, these preferences still do not explain the role of communication in enhancing investment by sellers. In order to incorporate the role of communication, EJ introduce a cost of breaking a promise. This cost, l , is incurred only if a promise is broken.

Suppose that $\beta_B < \frac{1}{2}$, so that $1 - 2\beta_B > 0$. We know that, in this case, from Proposition 7.23, the seller is offered $\underline{x}_S$ but the seller does not find it worthwhile to invest ($I = 0$). Can the buyer *promise* to offer more to the seller, say, x_S^* , in order to induce first stage investment ($I = 1$)? Let us assume that the buyer does not make overfair offers, so he does not offer to share more than half the net gains from trade. Thus, the buyer promises to give a share, x_S^* , to the seller that satisfies

$$\underline{x}_S < x_S^* \leq \frac{G + F}{2}.$$

If the buyer keeps his promise, then the utility of the buyer is

$$U_B(x_S^*, \cdot) = G - x_S^* - \beta_B [G - x_S^* - (x_S^* - F)].$$

If the buyer does not keep his promise and reverts back to his ex-post optimal level of offer $\underline{x}_S$ then his utility is

$$U_B(\underline{x}_S, \cdot) = G - \underline{x}_S - l - \beta_B [G - \underline{x}_S - (\underline{x}_S - F)],$$

where l is the cost of breaking the promise. It is optimal for the buyer to keep his promise if $U_B(x_S^*, \cdot) \geq U_B(\underline{x}_S, \cdot)$, so the lowest promise of the seller's share is

$$x_S^* = \min \left\{ \frac{G + F}{2}, \underline{x}_S + \frac{l}{1 - 2\beta_B} \right\}.$$

Since we are considering the case $0 < 1 - 2\beta_B < 1$, we have $\frac{l}{1 - 2\beta_B} > l$. Thus, the presence of inequity aversion on the part of the players magnifies the effect of the costs of breaking the promise. If players had entirely self-regarding preferences, so $\beta_B = 0$, then the effect of promises does not get magnified.

Consider now the case of seller communication when there is a cost of not carrying out a threat. Suppose that the seller threatens to reject any unfair offers $x_S < F + \frac{G-F}{2} = \frac{G+F}{2}$. We are interested in the maximum offer $\hat{x}_S < \frac{G+F}{2}$ that the seller can credibly threaten to reject.

Using (7.1), we can find $\hat{x}_S$ from the following condition

$$\hat{x}_S - \alpha_S [G - \hat{x}_S - (\hat{x}_S - F)] - l = -\alpha_S F, \quad (7.4)$$

where l is the cost of not carrying out the threat by accepting any infinitesimal amount less than $\hat{x}_S$. Solving out for $\hat{x}_S$ from (7.4), and using the upper bound $\frac{G+F}{2}$ on $\hat{x}_S$ we get

$$\hat{x}_S = \min \left\{ \frac{l + \alpha_S G}{1 + 2\alpha_S}, \frac{G + F}{2} \right\}.$$

The seller will always get an ex-post offer of $x_S = \frac{\alpha_S G}{1 + 2\alpha_S}$ in (7.2). However, the cost of breaking threats, l , can give the seller an extra minimum payoff of $\frac{l}{1 + 2\alpha_S}$, which is decreasing in α_S . Thus, as the degree of disadvantageous inequity suffered by the seller, α_S , increases, the set of offers that he can credibly threaten to refuse, shrinks. This reduces the commitment value of threats. A simple application of L'Hopital's rule shows that $\lim_{\alpha_S \rightarrow \infty} \hat{x}_S = \frac{G}{2}$, thus, as $\alpha_S \rightarrow \infty$, the seller cannot threaten to reject even $\frac{G}{2}$, which splits the gross gains equally (i.e., not taking account of F). In this case, the ex-post monetary payoff of the seller is $\frac{G}{2} - F$, which for the EJ experiments ($F = 60$ and $G = 100$) is a negative number.

The experimental data in EJ does show that seller threats are not very potent, while buyer promises are far more effective; this qualitative feature is consistent with the proposed theoretical model. However, in order to explain the quantitative features of the data, one has to allow for a distribution of values for α and β (and possibly also of l) across the population.⁵

In contrast to EJ, Charness and Dufwenberg (2006) locate the explanation for the efficacy of promises in *guilt aversion*. Subjects who break a promise experience *guilt* when they let down the payoff expectations of others. An understanding of this mechanism requires the machinery of *psychological game theory* that is considered in Part 4 of the book. A priori, one possible objection to the explanation offered by EJ may be that they assume the very result they wish to prove, by including a cost of breaking a promise in their objective function. There are two responses. First, EJ make very precise predictions that differ between buyers and sellers, which can be tested. Second, one chooses among different explanations of the same phenomenon not by a-priori plausibility but by putting them to a stringent empirical test.

Vanberg (2008) pits the two competing explanations by EJ and Charness and Dufwenberg (2006) empirically against each other. He argues that the experiments by Charness and Dufwenberg are not able to distinguish between the two competing explanations. Thus, he designs experiments in which the predictions of the two explanations can be neatly distinguished. The main finding is that the results are consistent with a model in which people have a preference for keeping their promises, as in EJ.

7.3 Social identity

Individuals may “identify” themselves with certain *social categories*. *Social identity* refers to one's social category. For instance, an individual's identity could be manager or worker, blue collar or white collar worker, black or white, member of a club or a non-member, and soldier or civilian. Each social category is governed by a *norm* of behavior that specifies the *ideal behavior* of a member in each situation.⁶ Different social contexts may trigger different identities—a family identity—a regional identity, or a national identity (Turner et al., 1987).

Let us begin with an example. Akerlof and Kranton (2005, p. 9) describe the following initiation at the US West Point military academy. “On plebes' first day . . . they strip down to their

⁵ Indeed, Fehr and Schmidt (1997) use such a distribution from experimental data to explain their own findings. For instance, α takes the values 0, 0.5, 1, and 4 for, respectively, 30, 30, 30, and 10% of the players. The parameter β takes the values 0, 0.25, and 0.6 for, respectively, 30, 30, and 40% of the players.

⁶ For early developments in social identity theory, see Tajfel and Turner (1979).

underwear. Their hair is cut off. They are put in uniform. They then must address an older cadet, with the proper salute . . . must stand and salute and repeat, and stand and salute and repeat, until they get it exactly right, all the while being reprimanded for every tiny mistake.” How should an economist brought up on the theory of incentives and organizations make sense of this?

Akerlof and Kranton (2005, p. 9) offer an answer: “Economists’ current picture of organizations and work incentives has no place for the West Point program . . . The Army’s aim at West Point is to change cadets’ preferences. They wish to inculcate non-economic motives in the cadets, so that they have the same goals as the U.S. Army. Alternatively stated, the goal of West Point is to change the identity of the cadets, so they will think of themselves, above all else, as officers in the U.S. army. They will feel bad about themselves—they will lose utility—if they fall short of the ideals of such an officer.”

The effect of social identity has also been documented for some of the experimental games considered in Chapter 6. For instance, Ockenfels and Werner (2014) show that dictators transfer a higher amount to responders who are perceived to share a common group identity. Second order beliefs of the dictator are important too. When the dictator knows that the responder is unsure of the common group identity, he transfers a lower amount.

There are three main components of social identity theory. In the first, *categorization*, the individual players are classified into the relevant categories, say, gender, race, nationality, and profession. In the second, *identification*, individuals identify with the characteristics of the category in which they are categorized; perhaps individual identity imparts greater self-esteem. Other members of the same group are often called insiders or *ingroup members* and members of other groups are called outsiders or *outgroup members*. Identification might involve adopting the stereotypical behaviors of one’s group members. It also typically involves favoring the ingroup members over outgroups. In the third, *social comparison*, individuals compare their own group to other groups on some criteria, which is also possibly stereotypical.

Research in *social psychology* has typically employed the technique of inducing *artificial group identities* through a process of *priming* the individuals; see Tajfel et al. (1971) for the classic experiments. The typical experiment then observes the effect of such priming on the behavior of subjects towards ingroup and outgroup members. The experimental process involves finding the *minimal group* such that the weakest possible identification with the group produces discriminatory behavior towards ingroup and outgroup members.

An important finding of this research is that with most minimal groups, and even the most trivial categorization, say, into blue and red groups, there is relatively more favorable behavior towards ingroup members; for surveys, see Tajfel and Turner (1986) and McDermott (2009). Even when subjects know that the assignment to groups is random, they continue to discriminate in favor of insiders (Billig and Tajfel, 1973). These findings suggest that humans might be hardwired, perhaps for evolutionary reasons, to take on social identities that can create both socially harmful and socially helpful outcomes.⁷ Examples of socially harmful outcomes might be intolerance, discrimination, and prejudice, whereas socially helpful outcomes might arise from internalizing desirable norms of hard work and honesty; for instance, when Asians in the US are primed for their Asian identity, they achieve greater educational and professional success.

⁷ Henri Tajfel, one of the pioneers of social identity theory was a Polish Jew who suffered extreme hardships in Nazi concentration camps and lost his family. His interest in social identity theory was possibly fueled by the prejudice and discrimination that he personally experienced.

7.3.1 Evidence on social identity and other-regarding preferences

Benjamin et al. (2010) explain how priming of subjects to induce group identities can be used in experiments to explain the choices of subjects. Suppose that an individual belongs to some category C , and chooses some action, $x \in X$, where X is some finite set of actions; more generally, x could be a vector of actions. If the individual did not belong to any category, then his most preferred action would have been x_P . However, the target action (possibly a norm) for a member of category C is x_C . The individual must choose x in order to maximize his utility, given by

$$U = -w(s) (x - x_C)^2 - [1 - w(s)] (x - x_P)^2, \quad (7.5)$$

where $w(s)$ is the weight that the individual puts on conforming with his category norm, x_C . In (7.5), the individual derives disutility from a weighted combination of departures of his action, x , from the category norm, x_C , and his privately optimal choice, x_P . The variable s may be thought of as the strength of affiliation with one's category, and could reflect the extent of priming in the experiment. The restrictions on $w(s)$ are that $w(0) = 0$ and $w' > 0$, so greater priming induces a greater weight on conforming with group norm. The first order condition is sufficient and solving it we get the optimal choice

$$x^* = w(s)x_C + [1 - w(s)] x_P, \quad (7.6)$$

which is just a weighted average of the group norm and the privately optimal choice. Several conclusions can be drawn from (7.6). First, because $w' > 0$, as the strength of affiliation with one's category, s , increases, the optimal choice x^* becomes closer to the category norm, x_C . Suppose that starting from some level of strength, s , priming of subjects induces an extra affiliation, ε , to one's category, so that the final level of strength is $s + \varepsilon$. Then, expanding $x^*(s + \varepsilon)$ around $x^*(s)$ using a first order Taylor series approximation, and using (7.6),

$$x^*(s + \varepsilon) - x^*(s) \approx \varepsilon \frac{dx^*(s)}{ds} = \varepsilon w'(s) (x_C - x_P).$$

Since $w' > 0$, the effect of priming on optimal choices depends on whether $x_C \gtrless x_P$. Also, $\frac{d}{ds} \left(\frac{dx^*(s)}{ds} \right) = w''(s) (x_C - x_P)$, which depends on the sign of $w''(s)$ and whether $x_C \gtrless x_P$. Thus, a priori it is not necessarily the case that on the margin, priming is more effective for those individuals who identify more strongly with a category. These considerations could be important in understanding the behavior of individuals in social identity experiments.

Benjamin et al. (2010) consider the following stylized facts, using US data. First, Asian Americans accumulate more human capital and save more in tax-deferred savings accounts relative to white Americans. Controlling for observable demographic features, black Americans do relatively worse than white Americans on these counts. Second, women appear to take lower risks than men in financial investments, and also behave relatively more conservatively in the lab. Further, it has been advanced that the norms in each of these groups (by ethnicity and gender) may be responsible for these findings. For instance, it is believed that the Asian American identity is associated with the norm of patience, while the non-immigrant black identity with the opposite norm—impatience and risk taking. Similarly, the male identity may be associated with taking

more risks than the female identity.⁸ Clearly non-experimental data is fairly noisy in this respect because it includes many other confounds, such as peer pressure, income levels, and various socioeconomic aspects. Hence, the authors propose an experimental test.

After being primed for Asian, black, or gender identities, the risk preferences of the subjects and the time preferences are elicited. Priming took the form of background questionnaires in which the questions highlighted racial or gender identities. For instance, there were questions about languages spoken at home and how long the immigrant family had been in the US. In terms of the simple theoretical framework proposed above, x equals risk or time preferences and x_C are the relevant category norms. For instance, if $x_P = \theta_P$ is the discount rate of an unprimed Asian American, then $x_C = \theta_C < \theta_P$ is the discount rate of an Asian American who has been primed for his more patient Asian identity.

The results are as follows. Unprimed Asians are more risk-averse and more impatient than whites. However, when primed with their Asian identity, the impatient choices drop by 14%, which is significant at the 1% level. Primed Asians require much lower interest rates to defer payments from a current date to a future date.⁹ For a current amount of \$4 and payments deferred by a week, the elicited percentage interest rate falls by three-quarters when primed for the Asian identity.

The difference between the impatient choices of primed and unprimed whites and primed and unprimed immigrant blacks are not statistically significant. However, contrary to the received view, in terms of their time preference, primed native blacks respond in the same direction as primed Asians, i.e., become more patient. Individuals who are primed for gender do not make choices that are any different from the unprimed condition.¹⁰ Shih et al. (1999) find that when subjects are primed separately for Asian and gender identities, and given a maths test, they do best when primed for the Asian identity and worse when they are primed for the female identity.

Chen and Li (2009) consider the effect of social identity on other-regarding preferences. Each of their treatments has four stages. In the first stage, the subjects are categorized into groups. The groups are formed, based on the preferences of subjects for paintings by one artist over another artist.¹¹ In stages 2 and 3, the group identities are strengthened through two tasks. In the first task, subjects were quizzed about the names of artists for a set of paintings. Correct answers were rewarded with tokens that could be cashed for money from the experimenter. Subjects were allowed to consult their group members (but not the members of the other group) in searching for the correct answer. In the second task, subjects were given a set of tokens and had to decide, over five rounds, how to allocate them to other players. The identity of the other players was varied between ingroup and outgroup members. The players knew that one of the rounds would then be randomly picked and played for real money. Two further control groups were constructed in which the identity of the subjects towards their ingroup members was not primed in this manner.

⁸ We refer the reader to the large number of references on these claims in Benjamin et al. (2010).

⁹ Denote current income as Y_0 , next year's income as Y_1 , annual interest rate as r and the annual discount rate as θ . Then the elicited interest rate r^e makes the decision maker indifferent between the two choices: Y_0 and Y_1 . Thus, $Y_0 = \frac{Y_1(1+r^e)}{1+\theta}$, so a lower r^e reveals a lower θ , and a more patient individual.

¹⁰ This is consistent with the results of Cadsby and Maynes (1998) who also find that gender has little effect on contributions in public good experiments when subjects are primed for gender identities in a pregame questionnaire.

¹¹ The painters are two modern artists. Based on the names of the painters, the two groups are the "Klee" and "Kadinsky" groups. To control for possible salience effects of the names of the artists, two control groups—the Maize and Blue groups were also used.

Once group identity was induced and enhanced in this manner, in the final stage, stage 4 of the experiment, subjects played several two-person sequential move games from Charness and Rabin (2002). In these games, player 1 chooses between two actions, stay out or enter. If player 1 stays out, the game ends with exogenously given payoffs, and if player 1 enters, then player 2 chooses between two possible payoff allocations for the player. The strategy method is used to elicit the choices. Player 2 is asked to make a choice in each of the two cases, assuming that player 1 has stayed out and that player 1 has entered. The games are differentiated by the actions of both players. For instance, in making his choice, player 2 could choose an option where no sacrifice is involved in ensuring that player 1 gets a higher payoff, or where such a sacrifice is involved, or where the sacrifice actually reduces the payoff of player 1. The choices reveal the extent to which players appear to exhibit elements of other-regarding preferences towards others.

The results are as follows. For stage 2 of the treatment, players allocated significantly more tokens to ingroup members relative to outgroup members. This replicates the often found result that minimal groups favor ingroup members. From the choices made in stage 4 of the experiment, players exhibit altruism towards opponents if their payoff is greater and envy if it is lower. However, altruism and envy are relatively stronger towards ingroup members.

Other interesting results arise by observing the behavior of player 2 when the decision of player 1 (to enter or stay out) conveys information about intentions. In this case, results can be further sharpened by observing cases where player 2 sacrifices own-payoff to get player 1 a better payoff, and where the sacrifice in own-payoff leads to lower payoff for player 1. Here, the results, based on a logit specification, are as follows. Players are 18.6% likely to reward ingroup members more than outgroup members. Social preferences matter in the sense that player 2 is less likely to reward player 1 if player 2's payoff is relatively lower—so envy limits positive reciprocity.

For every 100 token disadvantageous gap, player 2 is less likely to reward player 1 by 7.8%. Since the strategy method is used to elicit the choices of player 2 for both possible choices of player 1 (stay or enter), we can determine if player 2 is likely to reward or punish unfavorable choices. It turns out that player 2 is more likely to reward favorable behavior by an ingroup player 1 and also more likely to forgive unfavorable behavior by an ingroup player 1. Finally both players are more likely to choose the joint payoff maximizing choice when they are ingroup members.

Cohn et al. (2013) conduct a field study of prison inmates from Switzerland's largest adult penitentiary. Their aim is to see if imprisonment fosters a criminal identity. In the baseline treatment, criminals were asked to report the number of heads in 10 tosses of a coin that they privately observed. The reported outcomes were then compared to the statistical average of 50% heads. Criminals misreported 20% of the times. When criminals were primed for their criminal identity (e.g., by asking what they were convicted for) they cheated even more—now they misreported 32% of the times. By contrast, in a placebo condition, subjects were recruited from the general population. In this case, when primed for a criminal identity (reading a short text profile describing a criminal or a non-criminal person), the percentage of misreported heads fell from 14% to 10%.

In Charness et al. (2007), subjects are assigned to one of two groups, row players (R) and column players (C), in the prisoner's dilemma game (PD) and the battle of sexes game (BOS). These games are shown in Figure 7.3.¹² The PD has a unique Nash equilibrium (B,B). The BOS game has two pure strategy Nash equilibria (A,A) and (B,B) and a mixed strategy Nash equilibrium in which each player plays his preferred strategy (A for row player and B for column player) with probability 0.75.

¹² Part 4 of the book considers the experimental results on these two class of games in detail.

Battle of sexes game			Prisoner's dilemma game		
	A	B		A	B
A	3, 1	0, 0	A	5, 5	1, 7
B	0, 0	1, 3	B	7, 1	2, 2

Figure 7.3 The battle of sexes (BOS) game and the prisoner's dilemma game (PD).

Source: Charness et al. (2007) with permission from the American Economic Association.

Players in the PD game are said to be *aggressive* if they play B and *accommodating* if they play A. In the BOS game, aggressive players play their preferred strategy, and accommodating players play the opponent's preferred strategy. Players are randomly assigned as row players (category label R) and column players (category label C). Once the category labels (R and C) are assigned to the players, they go to their respective rooms labeled R and C. If a game is played in room R, then the row player is termed as the host and the column player is termed as the guest. Similarly, in room C, the column player is the host and the row player is the guest.

The treatments exploit two dimensions. In the *audience treatment*, the other group members sit in a semi circle behind the player when he makes the decision, but do not otherwise interfere in actual choices made. This is intended to induce greater salience of group membership. In the *no-audience treatment*, other group members do not watch. In the second dimension, the *feedback treatment*, all people in the room immediately learn the outcome, while in the *no-feedback treatment*, the payoffs are revealed only at the end of the session. The payoffs of any player are made up of two components—their own-payoffs in games when they make active decisions and a one third stake in the payoffs of one's ingroup members when others in the ingroup play the games.

When group membership is more salient (audience treatment) subjects are more likely to choose the action that maximizes their own payoff. For the row player, these actions are B in the PD game, and A in the BOS game. However, when this salience is reduced (no-audience treatment) these aggressive choices are reduced. In the audience treatment, in the BOS, hosts are aggressive in 84% of the cases and guests accommodate in 65% of the cases. By contrast, in the no-audience treatment, these numbers are significantly lower at 60% and 38% respectively. Thus, hosts are more aggressive when they play in front of an audience of their ingroup members. Guests seem to anticipate this behavior and are more accommodating. Similarly, the feedback treatment makes group membership more salient and creates effects similar to those in the audience treatment. When group membership is most salient, in the treatment with audience effects and feedback effects, almost all hosts are aggressive (95%) and this is again well anticipated by the guests who accommodate even more.

In the PD game, hosts accommodate in 62% of the cases when there is no audience and feedback. However, when group membership is most salient (audience plus feedback) hosts only accommodate in 28% of the cases. The effect of group membership is smaller but still significant for guests. In the case of no audience and feedback, guests accommodate in 45% of the cases but this reduces to 34% in the audience and feedback treatment.

Goette et al. (2012) consider the external validity of minimal groups (MG) created in the lab in which ingroup members may have limited interaction with each other. They argue that real-world groups are, instead, characterized by strong interactions among ingroup members. These members have social ties and friendships between each other, which may generate empathy and prosocial behavior within the group. Denote the treatment with real social groups by SG treatment.

The main research objective is to examine the behavior of subjects in minimal and real social groups. In each of the MG and SG treatments, members of groups are randomly assigned, rather than endogenously assigned. Individuals only knew whether the player they interacted with is an ingroup or outgroup member but not the identity of the player; this rules out strategic, reputation building, motives.

The subjects in the experiment were Swiss army trainees who stayed in the same platoon once they joined the Joint Officer Training Program (JOTP). The subjects had performed a range of joint tasks together, possibly enhancing their group identity. The random assignment of the trainees to a platoon (each platoon has 21 members) comprises one *real* social group (SG). Assignment to a platoon enhances social identity among platoon members as they do a variety of joint tasks during a three week period. In contrast, the minimal group, MG, is formed simply on the basis of random choice, using the social security numbers of the army trainees. This is a minimal group because all members are part of the JOTP, yet, unlike the SG, may belong to different platoons, so have not necessarily interacted over the three weeks of platoon training. In the experiments, subjects are simply told of the ID number of the platoon of the opponent as a method of identifying ingroup and outgroup members.

The subjects played a modified trust game, akin to a simultaneous move prisoner's dilemma. Two players, A1 and A2, were given 20 points. They simultaneously decide to send up to 20 points to the other player. The experimenter doubled the points that were passed to the other player. Sending 0 points may be considered to be the *defection decision* and sending all 20 points may be considered to be the *cooperative decision*. In the ingroup condition, the opponent was a member of the same platoon, while in the outgroup condition, he was a member of another platoon.

In experiment 1, players simply choose the number of points to send to the other player. In experiment 2, the possibility of third party punishment was allowed with the introduction of players B1 and B2, each of whom was allocated 70 points. Having observed the actions of player A_j, $j = 1, 2$, player B_j could punish player A_j. Punishment took the form of each player B_j being allowed to spend up to 10 deduction points aimed at player A_j. For each point surrendered by player B_j, player A_j lost 3 points. This allows one to test for altruistic norm enforcement. Players B1 and A1 form an ingroup and players B2 and A2 form another ingroup. The payoffs (one point equalled 0.25 CHF) were mailed to the home addresses of the trainees, 10 days after the end of the course, on completion of the JOTP.

Figure 7.4 Cooperation rates and beliefs in the modified trust game. Bars represent standard errors of the means.

Source: Goette et al. (2012) with permission from the American Economic Association.

Panel A in Figure 7.4 shows the cooperation rates in the MG and the SG treatments. In Figures 7.4, 7.5 we use the convention that other A players are all referred to as A2 players and all players that a player B can punish are called A1 players. In both treatments, MG and SG, there is significant, positive, ingroup bias in cooperation rates. Averaged across both treatments, the cooperation rate with ingroup members is 65%, while that with outgroup members is 50%. The difference in cooperation rates towards ingroup and outgroup members in the MG treatment is 10%, but it is 20% in the SG treatment. Thus, there is a significant quantitative difference in the two treatments. The actual differences in cooperation rates are also evident in the beliefs of the players (Panel B); ingroup members are believed to be significantly more cooperative.

Figure 7.5 shows that the behavior in treatments MG and SG is qualitatively different. In the MG treatment (Panel B), when player A1 defects, the punishment is smaller for ingroup members relative to outgroup members. But when A1 cooperates, punishment of ingroup members and outgroup members is similar in both MG and the SG treatments; some punishment still takes place because players do not fully cooperate. In the SG treatment (Panel A), punishment of outgroup members for defection is nearly identical to ingroup members. Another interesting finding is that defection against ingroup members is punished relatively more highly in the SG treatment (see Figure 4 in Goette et al., 2012). By contrast, there is no such difference in the MG treatment. Thus, third party norm enforcement is stronger when the group identity is stronger (SG treatment).

These qualitative and quantitative differences between the SG and MG treatments can potentially reconcile the differences in existing results between minimal and real groups. For instance, for real groups (akin to the SG treatment) Bernhard et al. (2006) find that tribes in Papua New

Figure 7.5 Group membership and punishment. Bars represent standard errors of the means.

Source: Goette et al. (2012) with permission from the American Economic Association.

Guinea punish ingroup and outgroup members equally for defection. However, Chen and Li (2009) using minimal groups (akin to the MG treatment) find that ingroup members are punished less than outgroup members.

Yamagishi and Kiyonari (2000) find that the effects on cooperation rates are different in a simultaneous and sequential move prisoner's dilemma game. The argument is that in the sequential game, non-cooperative behavior is punished anyway by the second mover, removing the need for group identity to sustain cooperative behavior. Guala et al. (2013) show that common knowledge of group affiliation enhances cooperation rates in a prisoner's dilemma game.

Chen and Chen (2011) consider *minimum effort games* that are considered, in detail, in Part 4 of the book. In such games, the payoffs of players are decreasing in their own action, but increasing in the minimum action of the group. There are several possible symmetric Nash equilibria in which all players choose the same action. In the Pareto efficient Nash equilibrium, all group members choose the highest possible action. The authors show that when subjects are not primed for any identity, they choose an inefficient action. However, once individuals are primed for group identity (e.g., by undertaking group tasks), and learning is allowed, then individuals choose the efficient equilibrium.

Hargreaves Heap and Zizzo (2009) consider a trust game played by players from two groups of players. They verify the usual finding of more cooperative behavior towards ingroup members relative to outgroup members. They argue that while this clearly improves the welfare of ingroup members, it reduces the welfare of outgroup members. On net, the outcome may reduce aggregate welfare, which is a potentially negative outcome of group affiliation. What accounts for the psychological benefits from joining a group? In order to elicit the value that people place on belonging to a group, they run artificial markets in which participants can trade in their group membership for a price. The elicited prices suggest that people derive psychological benefits that exceed the material benefit of belonging to the group. When one adds these psychological benefits to the net welfare computed above, the overall social welfare of group formation is non-negative.

7.3.2 Identity and economic incentives

Identity economics is the study of identity, norms, and ideal behavior. It offers a radically different view of incentives, one that is not new to sociologists but would be to many economists. Several decades of experiments in social psychology show that it might be optimal for organizations to alter the identity of its members, so that they internalize the mission and objectives of the organization and think of themselves as *insiders* in the organization. Clearly, if this can be done successfully, then identity may substitute, perhaps partly, for the monetary costs of incentives to ensure that members work to fulfill the objectives of the organization that they work for. We draw on Akerlof and Kranton (2000, 2005, 2008) in our discussion of the relevant issues in this section.

Consider a prototype principal-agent model in which the agent can choose among two possible actions, high and low, H, L , which give rise, respectively, to the effort levels, $e_H > e_L$. The profits of the principal can either be high, π_H , or low, π_L , $\pi_H > \pi_L$. The actions of the agent induce a probability distribution over profits. Under action H , the profits π_H, π_L are equally likely, while under action L , the profit level π_L occurs with probability 1. The principal cannot observe the effort level but can condition wage payments to the agent, w , on the profit levels, π_L, π_H . For any wage-effort pair, (w, e) , define

$$u(w, e) = \ln w - e. \quad (7.7)$$

We shall enrich this prototype model below.

Denote the identity of the agent by $I_c \in \mathbb{R}$, where c indexes the identity of the agent. We distinguish between two identities. In the first, the agent identifies himself as part of the group that he works with; we call this the *insider identity* or *group identity* ($c = G$). In the second, the agent considers himself to be an outsider; we call this the *outsider identity* ($c = O$). Identity $c \in \{O, G\}$ is associated with the norm of an ideal effort level, e_c . The norm of effort for insiders is likely to be higher than for outsiders, so $e_G > e_O$. Thus, it is cheaper to elicit higher effort from insiders. The utility of the agent when his identity is c , is given by

$$U(w, e; c) = u(w, e) + I_c - \mu_c |e_c - e|, \quad (7.8)$$

where u is defined in (7.7), and $\mu_c > 0$ is a scaling parameter. In standard textbook economics models, the utility of the agent is given by $u(w, e)$. By contrast, in models of identity, the agent additionally derives direct utility from his identity, I_c , and disutility from deviations of effort from the norm for the identity group (last term in (7.8)).

Since $e_G > e_O$, the principal needs to offer relatively lower wage differentials (across the two effort levels, high and low) to insiders, for eliciting high effort. In other words, when there are two effort levels, then, under an insider identity one would expect to observe flatter wage profiles. This result need not hold under more than two effort levels, because an insider identity may also induce the principal to elicit an even higher effort level. Thus, incentives and identity are complements when there are two effort levels but may become substitutes when there are more than two effort levels.

The firm may consider altering the worker's identity from an outsider to an insider if the cost of doing so is low enough. The benefits are two fold. First, the incentive cost of eliciting the same effort level is lower. Second, a lower variation in wage is preferred by the risk averse insider, reducing the incentive costs of the firm. We now consider some of these issues in a model of optimal hierarchical organizational design (Akerlof and Kranton, 2008).

Suppose that a risk-neutral principal hires an agent with the preferences given in (7.8). The principal can either hire a supervisor or not. The supervisor obtains hard evidence of action L with probability $p > 0$, but cannot obtain verifiable evidence of action H . In the event that the supervisor reports hard evidence of a low level of effort, e_L , the principal levies a fine $f > 0$ on the agent.

The presence or the absence of the supervisor alters the identity of the agent and this is borne out by evidence from social psychology experiments (Jex and Britt, 2008). In the presence of the supervisor, the agent feels as an outsider (identity $c = O$) and in the absence of the supervisor, the agent feels trusted, so he has an insider or group identity (identity $c = G$). The principal understands, correctly, the agent's identity under various regimes.

The assumptions on the ideal effort levels are as follows: (1) The ideal effort level of an outsider is $e_O = e_L$. (2) The ideal effort level of an insider is the effort level $e_G = e_M$, corresponding to some action M on the part of the agent such that $e_L < e_M < e_H$. Under action M , the probability of getting high profits, π_H , is $\frac{\theta}{2}$ and the probability of getting low profits π_L , is $1 - \frac{\theta}{2}$, where $0 \leq \theta \leq 1$. The outside option of the agent is given by $\bar{u}$.

The principal offers a profit-contingent wage to the agent, (w_H^c, w_L^c) , where w_j^c is the contracted wage when the observed profit is π_j , $j = L, H$, and the identity of the agent is $c \in \{O, G\}$. Effort

is non-contractible. The expected profit of the principal from inducing the high effort level, e_H , when the agent's identity is c is given by

$$\Pi(c) = \frac{1}{2} (\pi_H - w_H^c) + \frac{1}{2} (\pi_L - w_L^c).$$

The expected profit, if other effort levels are to be induced can be found analogously.

PRINCIPAL APPOINTS A SUPERVISOR (REGIME-I)

When the principal appoints a supervisor (Regime-I), the agent takes the identity of an outsider, so $e_O = e_L$. Suppose that the principal wishes to induce the effort e_H . The expected profit of the principal is

$$\Pi(O) = \frac{1}{2} (\pi_H - w_H^O) + \frac{1}{2} (\pi_L - w_L^O).$$

The individual rationality constraint (IR), ensures that the agent receives at least as much as the outside option.

$$\frac{1}{2} \ln w_H^O + \frac{1}{2} \ln w_L^O - e_H + I_O - \mu_O |e_L - e_H| \geq \bar{u}. \text{ (IR)}$$

The incentive compatibility constraint (IC) of the agent ensures that action H is preferred to action L . Note that the identity of the agent stays the same under both actions and depends only on the organizational structure (supervisor or no supervisor). If the agent chooses action L , the outcome π_L obtains with probability 1. An audit by the supervisor reveals, with probability p , that the agent chose L in which case the agent is fined an amount f . Hence, the IC is given by

$$\frac{1}{2} \ln w_H^O + \frac{1}{2} \ln w_L^O - e_H - \mu_O |e_L - e_H| \geq (1 - p) \ln w_L^O + p \ln(w_L^O - f) - e_L. \text{ (IC)}$$

Finally, there is a limited liability constraint (LLC), which ensures that the agent's payoff after paying a fine cannot be driven below $l > 0$.

$$0 < l \leq w_L^O - f. \text{ (LLC)}$$

The IR binds in equilibrium. If not, then the principal can increase profits by reducing the incentive payments w_H^O and w_L^O . The IC also binds in equilibrium. If not then the principal can increase his profits by reducing w_H^O . The RHS of the IC is decreasing with respect to p , hence, the payoff of the agent from taking the action L is lower under better supervision. However, since the IC must bind, there are two ways of restoring the binding IC after an increase in p : Either w_H^O goes down or w_L^O goes up or a bit of both. We collect these results in the next lemma.

Lemma 7.8 *When the principal appoints a supervisor, then more effective supervision associated with a higher probability of detection, p , induces a flatter optimal wage profile (the gap between w_H^O and w_L^O is lower). This also reduces the expected cost of the incentive payment to the principal.*

THE PRINCIPAL DOES NOT APPOINT A SUPERVISOR (REGIME-II)

When the principal does not appoint the supervisor (Regime-II), he chooses not to monitor the agent, so the agent has an insider or group identity, $c = G$. The norm-driven ideal effort level of the agent is $e_G = e_M$. Suppose, initially, that the principal wishes to induce the high action, H . The expected profit of the principal is

$$\Pi(G) = \frac{1}{2} (\pi_H - w_H^G) + \frac{1}{2} (\pi_L - w_L^G).$$

The individual rationality constraint of the agent is

$$\frac{1}{2} \ln w_H^G + \frac{1}{2} \ln w_L^G - e_H + I_G - \mu_G |e_M - e_H| \geq \bar{u}. \text{ (IR)}$$

There are two incentive compatibility constraints, IC1 and IC2. The principal needs to ensure that the agent prefers the effort level e_H to e_M (IC1) and the effort level e_H to e_L (IC2). Recall that the probability of outcome π_H under the action e_M is $\frac{\theta}{2}$.

$$\frac{1}{2} \ln w_H^G + \frac{1}{2} \ln w_L^G - e_H - \mu_G |e_M - e_H| \geq \frac{\theta}{2} \ln w_H^G + \left(1 - \frac{\theta}{2}\right) \ln w_L^G - e_M \text{ (IC1)}$$

$$\frac{1}{2} \ln w_H^G + \frac{1}{2} \ln w_L^G - e_H - \mu_G |e_M - e_H| \geq \ln w_L^G - e_L - \mu_G |e_M - e_L|. \text{ (IC2)}$$

As in Regime-I, there is also a limited liability constraint in Regime-II. Note in IC1 and IC2 that the identity of the agent stays the same under different effort levels in this regime. The lack of supervision has costs and benefits. The cost is that, ex-post, the agent is not punished for exerting a low effort level. The benefit is that with a group identity, the ideal effort level of the agent is higher, $e_M > e_L$. Since $e_L < e_M < e_H$, it follows that $|e_M - e_H| < |e_L - e_H|$, thus, the individual rationality constraint is easier to satisfy in Regime-II relative to Regime-I. So, the wage costs are also relatively lower in Regime-II.

When might the principal not wish to induce the high effort level, e_H , in Regime-II and settle for the intermediate effort, e_M ? To answer this question, rewrite IC1 as follows

$$\frac{(1-\theta)}{2} (\ln w_H^G - \ln w_L^G) - (1 + \mu_G) (e_H - e_M) \geq 0. \text{ (IC1)}$$

As $\theta \rightarrow 1$, it becomes prohibitively expensive to elicit the effort level, e_H ; in this case one would need an extremely steep wage profile for IC1 to hold. The reason is that, as $\theta \rightarrow 1$, an agent with identity G finds that he gets only marginally higher wage payments by exerting the higher effort level, e_H , but substantially greater disutility from having to compromise on the ideal effort level, e_M . Under such identity concerns, the principal may find it optimal to induce the ideal effort level of the agent, e_M . In this case, the relevant incentive compatibility constraint, which ensures that the agent chooses the effort level e_M rather than e_L is given by IC3:

$$\frac{\theta}{2} \ln w_H^G + \left(1 - \frac{\theta}{2}\right) \ln w_L^G - e_M \geq \ln w_L^G - e_L - \mu_G |e_M - e_L|. \text{ (IC3)}$$

Or,

$$\frac{\theta}{2} (\ln w_H^G - \ln w_L^G) \geq (1 - \mu_G) (e_M - e_L). \text{ (IC3)}$$

The factors that make it easier for IC3 to hold and, hence, more likely that the principal will successfully induce e_M , are (1) $\theta \rightarrow 1$, $\mu_G \rightarrow 1$, and (2) the gap between e_M and e_L is small.¹³

¹³ For a richer and more encompassing model of identity, see Bénabou and Tirole (2011). Benjamin et al. (2010) consider the effect of ethnic, racial, and gender identity norms on risk and time preference.

CHAPTER 8

Incentives and Other-Regarding Preferences

8.1 Introduction

Traditional economic theory extolls the virtues of incentives, typically high-powered, in models where individuals have self-regarding preferences. By contrast, real-world incentives are typically low-powered. Consider the quote from the empirical study by Lemieux et al. (2009): “in the United States only 37 percent of individuals have some kind of pay-for-performance component to their compensation and that among those who do the median magnitude of these incentives is only 3.5 percent of their base wage.”

Models of *multitask agency* have already shown that high-powered incentives may be counter-productive. For instance, in the presence of high rewards on easily observed tasks, agents may put disproportionately less effort into tasks that are valuable for the principal, yet are hard to observe and reward formally. However, the experimental results show that even when agents have a single task, the optimal incentives may be low powered. This does not mean, of course, that incentives are unproductive. For instance, recall that the evidence in Chapter 5 shows that punishments (negative incentives) are efficacious in public goods games. However, the evidence from behavioral economics shows that the effect of incentives on human behavior is far more nuanced than can be accounted for by models of self-regarding preferences.

In Section 8.2, we consider the effects of other-regarding preferences on incentives in the presence of *moral hazard*. The agent’s effort is either not observable or is observable but not verifiable, hence, wage contracts can be conditioned only on the observable and verifiable outcomes, such as output levels.

Section 8.2.1 considers the effect of inequity aversion on optimal wage schemes when a principal observes a noisy signal of the agent’s effort level. Following Itoh (2004), consider two effort levels, two output levels, and a self-regarding principal. The agent is other-regarding (in the Fehr–Schmidt sense) and suffers inequity aversion with respect to the principal. The presence of moral hazard gives rise to rents for the worker, as in models of self-regarding preferences. However, the principal needs to offer even higher rents to an inequity averse agent to compensate for the agent’s disadvantageous inequity, relative to the principal.

Suppose that there are several agents who suffer from inequity aversion with respect to each other but not with respect to the principal. Each agent works on an independent project, but inequity aversion creates interlinkages between the outcomes on the projects. In this case, the choice among alternative forms of compensation schemes such as *team incentives*, *relative*

performance evaluation, and *independent contracts*, depends on the degree of advantageous and disadvantageous inequity suffered by the agents. For instance, if the advantageous inequity of the winning agent is too high, then relative performance evaluation creates higher disutility to the winning agent. Hence, to ensure satisfaction of the incentive compatibility constraint, the principal needs to offer a higher level of rents. By contrast, team incentives do not create inequality aversion, so they may be preferred to relative performance evaluation.

Inequity aversion reduces a player's utility when, relative to another player, his payoff is greater (altruism) or lower (envy). By contrast, *reciprocity* induces players to reciprocate kind actions of others by kindness and unkind actions by unkindness. Section 8.2.2 considers the implications of reciprocity for optimal contracts in a principal–agent problem with moral hazard. Ideally, one would wish to use the machinery of psychological game theory (see Part 4 of the book) to model issues of reciprocity. This allows for the endogenous determination of beliefs about others. However, here we follow Englmaier and Leider (2012) in modeling reciprocity in a simpler, reduced-form, manner.

Suppose that the outside option of the agent is zero. If the principal leaves positive rents to the agent, the agent perceives this to be a kind action and may reciprocate by aiding the principal in increasing profits. The implications for optimal contracts under moral hazard are profound, even in this reduced-form model. For instance, it has been a puzzle why real-world contracts are so low-powered relative to the predictions of agency models of moral hazard with self-regarding preferences. In the presence of reciprocity, however, it can be shown that even a *flat wage schedule* can implement high levels of effort, provided that the principal leaves sufficiently high rents with the agent. The reason is that the reciprocity induced by these rents elicits high effort level from the agent, as in gift exchange games.

Section 8.3 considers a principal–agent problem with non-verifiable effort and other-regarding preferences of the Fehr–Schmidt form (Fehr et al., 2007). The principal is uncertain whether the preferences of the agent are self-regarding or other-regarding. In addition to the standard *incentive contract*, we consider here a *trust contract* and a *bonus contract*. In the incentive contract, the principal can invest in a costly monitoring technology that gathers hard evidence of the shirking of the agent with some probability. In the event that shirking is discovered, the principal can levy a fine. Clearly, if the detection technology is effective and the level of fines is high enough, the agent will never shirk under an incentive contract. In a trust contract and a bonus contract, by contrast, the principal foregoes investing in the monitoring technology, even when such a choice is available. This is interpreted by the agent as *kind intentions* on the part of the principal. By contrast, the offering of an incentive contract is interpreted as unkind intentions.¹ Thus, other-regarding agents behave as if they were self-regarding in the presence of incentive contracts but other-regarding in the presence of trust and bonus contracts.

In a trust contract, the principal offers a fixed, contractible, wage despite not having the ability to monitor the agent. Clearly, the success of such a contract relies on the reciprocity of agents, as in gift exchange experiments. In a bonus contract, by contrast, the principal promises a bonus at the end of the game, after having observed the outcome. If the agents believe in the principal's reciprocity, then they know that if they work hard, they will be rewarded ex-post; this is true both for self-regarding and other-regarding agents. The incentive contract is least incomplete (effort can always be enforced with high enough detection probability and fines), the trust contract is more incomplete (effort can never be enforced), and the bonus contract is the most incomplete (effort and the bonus level are unenforceable).

¹ This is consistent with the empirical results that are reviewed below.

The benefit of the incentive contract is that it allows for the monitoring and punishment of shirking agents, while the cost is that such contracts cannot tap into the reciprocity of the other-regarding agents. Hence, they suffer on account of lower effort levels and output levels. The advantage of the trust and the bonus contracts is that they can tap into agents' reciprocity, but the disadvantage is that they cannot dissuade purely self-regarding agents from shirking. The eventual outcome depends on these competing trade-offs. The greater the probability that the agent is self-regarding, the more successful will an incentive contract be. The other-regarding principal suffers from disadvantageous inequity when he encounters a self-regarding agent. But if the disadvantageous inequity parameter of the principal is low, the costs of offering a trust and a bonus contract are low relative to the positive reciprocity obtained from the other-regarding agent.

The empirical evidence on contractual choice in the presence of such contractual incompleteness issues is considered in Section 8.3.3 (Fehr et al., 2007; Fehr and Schmidt, 2007). It turns out that the bonus contract is empirically the most widely chosen contractual form. The effort levels and the profits of the principal are also the highest under a bonus contract. By contrast, if the principal and the agent were purely self-regarding, the incentive contract always dominates the bonus contract.

We also examine the empirical choice of organizational forms in the presence of the classical hold-up problem between two parties (Fehr et al., 2008). The prediction of the model with self-regarding preferences is that residual control rights should be given to the party that makes the investment. Joint-ownership, by contrast, is predicted to stifle investment because it creates the problem of ex-post holdup. However, the empirical evidence shows that when given a choice, most players choose joint ownership because it is more conducive to reciprocal behavior.

In Section 8.4, we introduce the possibility of *two-sided asymmetric information* and *long-term contracts* in a principal–agent relationship (Brown et al., 2004, 2012). Our aim is to characterize the perfect Bayesian equilibrium in the model. The firm (principal) and the worker (agent) both have asymmetric information about each other's type; types can be either self-regarding or other-regarding. In a model with a finite number of periods, we allow firms to either hire workers in a spot market condition, or choose to endogenously maintain long-term relations with them.

When workers have other-regarding preferences, in the last period, they will not choose their effort opportunistically. Their inequity aversion induces an effort level higher than the minimum effort level that would be chosen by a purely self-regarding agent. Analogously, other-regarding principals will wish to offer rents in the last period. In the penultimate period, workers with self-regarding preferences may not wish to shirk because if they are revealed to be shirkers they will be fired from their job and forgo rents in the final period. One can work this logic backwards and ensure that workers get rents in equilibrium and, irrespective of their type, put in an effort level greater than the purely self-regarding one. The evidence supports the predictions of this model. One observes the endogenous formation of long-term relations. Effort levels, profits, and rents are higher in long-term relations, relative to spot-market or short-term relations. The formation of social ties in the relation induces even greater cooperation in long-term relations (Van Dijk et al. 2002).

Section 8.4.4 addresses the ambitious question of why firms exist. Or, under what conditions will an employer choose an *employment contract* over a *sales contract*? An employment contract gives greater ex-post flexibility to the employer, but also opens up the possibility that the employer may exercise his residual control rights in a manner that is disadvantageous to the employee. By contrast, a sales contract prevents the possibility of ex-post abuse of the contract by the employer but suffers from the absence of the ex-post flexibility of an employment contract. It turns out that the presence of other-regarding preferences and long-term endogenous contracts play a key

role in identifying a new set of transaction costs that explain the existence of vertical integration (Bartling et al., 2013). We shall consider the relevant theoretical framework, but particularly the empirical evidence, in some detail.

In contract theories with self-regarding preferences, cleverly designed incentives typically have a positive impact on effort, output, and profits. However, it is well known that even with self-regarding preferences, incentives may not always have the desired effects. First, incentives can be conditioned only on a limited number of variables that may be observable and verifiable, such as revenues or output. Second, under *multi-task agency*, where the agent simultaneously chooses effort levels on several distinct tasks, which are observed with error, incentives for more easily observable and verifiable tasks may shift attention away from other, valuable, but less-well observed tasks (Holmstrom and Milgrom, 1991). Third, when tournaments among workers are organized, they might sabotage each other or not cooperate with each other. A large amount of experimental and field evidence now demonstrates the presence of other-regarding preferences in worker–firm relations.² This creates further issues with the use of incentives in principal–agent problems.

An emerging literature explores the effectiveness of incentives, not only by using other-regarding preferences, but also by invoking additional features such as identity, reputational concerns, asymmetric information, self-signaling, and social signaling motives for one's actions.³ For instance, anonymous donations are rare, yet are considered to be very commendable, and boasting of one's charitable donations is looked down upon. Clearly, models that incorporate social signaling of one's intentions are a promising candidate to explain such phenomena. Models that explain monetary charitable giving as a signal of one's wealth cannot sometimes explain in-kind donations such as volunteering for social causes and donating blood. In taking such actions, the individual could be self-signaling respectable human qualities such as altruism or kindness.

In Section 8.5, we consider theoretical models of *intrinsic* and *extrinsic* motivation. Extrinsic motivation refers to human endeavor that arises purely as a response to external material incentives. Any remaining motivation that is independent of incentives offered by another party, is intrinsic. Section 8.5.1 considers first a principal–agent framework in which the agent has asymmetric information about the cost of the project (Bénabou and Tirole, 2003). The agent observes a private signal of the cost and the level of bonus offered by an informed principal. We show that in a perfect Bayesian equilibrium of the model, higher levels of bonus offered by the principal convey bad news to the agent about the cost. Hence, incentives may deter the effort of the agent. These sorts of models can potentially explain situations where one party to a formal or informal contract has private information (child rearing, education, monitoring of employees).

One needs a different theoretical framework to explain *prosocial decisions* such as blood donations, charitable giving, and voting (Bénabou and Tirole, 2006). In this case, incentives may signal to others that the individual's motivation is not intrinsic. Such incentives could, for instance, take the form of direct incentives for blood donations and tax-exempt charitable donations. Hence, there is a trade-off between appealing to an individual's extrinsic motivation and a cost in terms of the reputational payoffs that the individual perceives are being lost by responding to such incentives. These theoretical models do not, however, address the question of whether they can explain the experimental evidence from the dictator, ultimatum, trust, and public goods games.⁴

² See for instance, Fehr et al. (1997), Fehr and Schmidt (1999), Fehr and Gächter (2000), Bandiera et al. (2005), Falk et al. (2005), Fehr et al. (2007), DellaVigna (2009), Sloof and Sonnemans (2011).

³ See Bénabou and Tirole (2003, 2006, 2011) for an extensive discussion of these issues.

⁴ But also see Benabou and Tirole (2011), whose motivation is to explain experimental evidence that may be anomalous for some of the models of social preferences, such as reluctant altruism in dictator games.

Section 8.6 considers the empirical evidence on extrinsic and intrinsic motivation. Section 8.6.1 shows that incentives may signal a *hostile intent*. In gift exchange games, the effort level is higher when no incentives are used, relative to negative incentives (fines) and positive incentives (bonuses). Within the two incentive treatments, effort levels are higher under positive, as compared to negative incentives (Fehr and Gächter, 2001). In trust games, when a fine is available but not used, it produces the highest level of trustworthiness (Fehr and Rockenbach, 2003).

Section 8.6.2 shows that incentives may conflict with the desire of agents for *autonomy* and *independence* (Deci and Ryan, 1985; Deci et al., 1999). In trust games, when the trustor announces a target back-transfer from the trustee, the degree of trustworthiness falls (Falk and Kosfeld, 2006). Relatively high monetary incentives can arouse the agent excessively and the agent may be distracted by the high reward. It is possible that under these conditions, the agent *chokes* and produces a lower level of performance, as, for instance, in a penalty kick taken in a high pressure football game (Ariely et al., 2009a).

When employers are given an opportunity to screen the past history of the workers, relative to a base treatment where such screening is not allowed, one observes important implications for contract choice (Bartling et al., 2012). Employees who develop good reputations by putting in high effort levels in the past are rewarded with good jobs that have high wages and are subject to low levels of control. On the other hand, employees who do not develop such reputations are offered bad jobs (low wages, high control, and low surplus). The possibility of screening spurs workers to work harder in order to build a reputation. Even self-regarding workers mimic other-regarding workers to partake in this reputation building exercise in order to increase their payoffs.

Section 8.6.3 considers the possibility that economic agents may *switch off their ethicality* in the presence of incentives; a phenomenon that psychologists refer to as *moral disengagement*. The moral frame of the dictator game can be changed if it is framed as an exchange game, leading to lower transfers from the dictator (Hoffman et al., 2008). Similarly, when a *competitive environment* is introduced in ultimatum games, proposers make lower offers (Schotter et al., 1996). In field studies of common property resources, regulation produces less cooperative outcomes as compared to communal cooperative efforts (Cardenas et al., 2000).

Fines on parents for arriving late in day care centres in Haifa induced parents to arrive even later. In the absence of fines, a reciprocity relation between carers and parents ensured that they did not arrive as late (Gneezy and Rustichini, 2000a). When students were primed to collect money for a good cause, but not given incentives, they produced greater collections, relative to low incentives. Higher incentives increased collections relative to low incentives, but not relative to the case of no incentives and priming for a good cause (Gneezy and Rustichini, 2000b).

Section 8.6.4 shows that incentives may reduce the ability of people to signal their human virtues, hence reducing prosocial behavior. Titmuss (1971) argued that blood donations are likely to be higher on a voluntary basis as compared to incentivized blood donations. Swedish data on blood donations showed that while there is no crowding-out effect of incentives for men, there is a statistically significant crowding-out effect for women (Mellström and Johannesson, 2008). However, the emerging evidence points to an even more nuanced set of effects. Non-monetary incentives may actually improve blood donations (Lacetera et al., 2012; Goette and Stutzer, 2008). In contrast, several studies find no effect of incentives on blood donations (Reich et al., 2006; Goette et al., 2010).

Monetary incentives given to high school students, preparing for their Bagrut certification in Israel, are ineffective for boys but effective for girls whose predicted grades are higher than

the average (Angrist and Lavy, 2009). When charitable donations are publicly observed, then incentives reduce the signaling value of such donations, reducing the level of donations (Ariely et al., 2009b).

Section 8.6.5 considers the effect of the economic environment. For instance, the legal environment and the strength of law enforcement has an effect on the trustworthiness of agents in a principal–agent relation (Bohnet et al., 2001). *Moral suasion* may be effective in inducing contributions in public goods games, while regulation to contribute a certain minimum level may have a long-run detrimental effect (Reeson and Tisdell, 2008). Bicycle couriers who receive performance related pay are likely to cooperate less in sequential prisoner’s dilemma games. By contrast, those on a fixed hourly wage or members of cooperatives are more likely to cooperate (Burks et al., 2009). This also contributes towards establishing the external validity of lab experiments.

Section 8.6.6 considers situations in which there is synergy between incentives and prosocial behavior. Punishments in public goods games are less likely to be *antisocial punishments* (non-contributors punishing contributors) when punishments for non-cooperation elicit shame and guilt (Herrmann et al. 2008; Carpenter et al., 2009). When sanctions are imposed in public goods games to punish non-contributors, based on a referendum among players (rather than sanctions imposed by the experimenter), they are likely to be more effective. Such sanctions are also more likely to elicit feelings of shame and guilt (Tyran and Feld, 2006).

No significant link is found between intrinsic motivation and incentives in a field study conducted in US schools. However, while incentives for output (final grades) are ineffective, incentives for inputs, e.g., attendance and good behavior, are more effective (Fryer, 2011). The effects of short-term educational incentives are likely to be gender specific and age specific. Further, when incentives are given with delay they are less effective (Levitt et al., 2012). Incentives to exercise over a long term are more effective than short-term incentives (Charness and Gneezy, 2009).

8.2 Moral hazard and other-regarding preferences

In this section, we consider a traditional principal–agent framework in which there is moral hazard and only the agent has other-regarding preferences. We will, in turn, consider the effects of *inequity aversion* (Section 8.2.1) and *reciprocity* (Section 8.2.2) on optimal contracts. Here we restrict attention only to state-contingent wage contracts. The subsequent sections will consider a richer range of contracts such as trust and bonus contracts, as well as issues of asymmetric information.

8.2.1 *Inequity aversion and moral hazard*

Consider the following simple model, due to Itoh (2004), using the standard moral-hazard framework, that should be familiar to undergraduate students in economics. A risk-neutral principal hires a risk-neutral agent to engage in a project that has two possible observable and verifiable outcomes (outputs), $0 \leq y_L < y_H$. The agent can choose one of two unobservable (or observable but non-verifiable) actions $a_0 < a_1$. The cost of the actions is given by $c(a_i)$, $i = 0, 1$. Action a_i results in the outcome y_H with probability p_i , and $p_1 > p_0$. Thus, the higher action induces a higher probability of the higher outcome. The reservation utility of the agent is normalized to zero.

A contract (w_L, w_H) specifies a wage $w_j \geq 0, j = L, H$, contingent on the only observable and verifiable outcome, i.e., y_j . The constraint $w_j \geq 0$ reflects *limited liability*. We rule out renegotiation of contracts.

The principal has self-regarding preferences and his profit is given by

$$\pi_j = y_j - w_j, j = L, H. \quad (8.1)$$

The agent has other-regarding preferences with respect to the payoffs of the principal. His utility function is of the Fehr–Schmidt form and is given by

$$u(w_j, \pi_j, a_i) = \begin{cases} w_j - c(a_i) - \alpha\gamma v(w_j - \pi_j) & \text{if } w_j \geq \pi_j \\ w_j - c(a_i) - \alpha v(\pi_j - w_j) & \text{if } w_j \leq \pi_j \end{cases} ; j = L, H, i = 0, 1, \quad (8.2)$$

where $\alpha > 0, |\gamma| < 1$, and v is an increasing function. Typical, under Fehr–Schmidt preferences, $\beta = \alpha\gamma$ (see (6.1)). If $\gamma > 0$, then the agent suffers from advantageous inequity. But if $\gamma < 0$, then the agent derives satisfaction or pride in coming out ahead; see also the discussion on these issues in Section 6.4. When $w_j = \pi_j$, we have $u(w_j, \pi_j, a_i) = w_j - c(a_i)$, so there are no inequity concerns. Notice that in (8.2), the disutility of effort does not enter into the comparison of the agent's payoff with the principal's payoff; this assumption can be relaxed.

For pedagogical reasons, we make the following two simplifying assumptions.

- A1. The principal always wishes to induce the higher action, a_1 , from the agent (possibly because y_H is high enough).
- A2. The second assumption involves the following relatively innocuous normalization

$$c(a_0) = 0, c(a_1) = c > 0, y_L = 0. \quad (8.3)$$

Let us first consider the textbook case of self-regarding preferences ($\alpha = 0$). The results are summarized in the next proposition.

Proposition 8.24 *Suppose that the agent has self-regarding preferences ($\alpha = 0$).*

- (i) *Let the action of the agent be observable and verifiable. Any combination (w_L, w_H) such that $w_L + p_1(w_H - w_L) = c$, is able to implement the first best contract.*
- (ii) *Under moral hazard, the first best contract does not satisfy the incentive compatibility conditions of the agent.*
- (iii) *Under moral hazard, the unique optimal second best contract specifies $w_L = 0$ and $w_H = \frac{c}{p_1 - p_0}$.*
- (iv) *The outside option of the agent gives a payoff of zero, yet the agent earns positive rents in the second best contract.*

Proof: Define the following first differences.

$$\Delta w = w_H - w_L, \Delta p = p_1 - p_0. \quad (8.4)$$

The expected utility of the agent from the contract (w_L, w_H) , when the agent puts in effort a_1 is $(1 - p_1)w_L + p_1w_H - c$; this can be written as $w_L + p_1\Delta w - c$. The incentive compatibility (IC) constraint and the individual rationality (IR) constraint are given by

$$\begin{cases} IC: & w_L + p_1 \Delta w - c \geq w_L + p_0 \Delta w \\ IR: & w_L + p_1 \Delta w - c \geq 0 \end{cases}$$

Using the notation in (8.4) the IC and IR constraints can be written compactly as

$$\begin{cases} IC: & \Delta p \Delta w \geq c \\ IR: & w_L + p_1 \Delta w \geq c \end{cases}$$

(i) If the action of the agent is observable and verifiable, then the only relevant constraint for the principal is the IR constraint. The principal can directly specify an action and implement it. Leaving any rents to the agent, beyond the agent's outside option of zero, reduces the principal's profits, hence, the IR constraint binds. Thus, any combination (w_L, w_H) such that $w_L + p_1 (w_H - w_L) = c$, is able to implement the first best contract.

(ii) From (8.3), $y_L = 0$, hence, we pick the first best contract $(w_L, w_H) = \left(0, \frac{c}{p_1}\right)$ such that the IR constraint binds. Substitute into the LHS of the IC constraint, we get $\Delta p \Delta w = \Delta p w_H = c \left(1 - \frac{p_0}{p_1}\right) < c$, which violates the IC constraint.

(iii) The problem of the principal under moral hazard is to minimize expected cost, $EC = w_L + p_1 \Delta w$, subject to the IC, IR, and the limited liability constraints. Both IC and IR constraints cannot bind at the same time. For instance, using $(w_L, w_H) = \left(0, \frac{c}{p_1}\right)$, where the IR constraint binds, we get the contradiction in part (ii). In particular, the agent must get some rents under moral hazard from taking the higher action a_1 . Thus the IR constraint does not bind. The IC constraint must bind in equilibrium. If not, then the principal can reduce w_L, w_H by a small amount $\varepsilon > 0$. This does not alter the IC and for a sufficiently small ε , the IR constraint continues to hold. However, the principal's expected costs are reduced. Thus, IC must bind, so, $\Delta p (w_H - w_L) = c$. Thus, the principal's expected cost is $EC = w_L + c \frac{p_1}{\Delta p}$, which is minimized by choosing $w_L = 0$ and choosing $w_H = \frac{c}{\Delta p}$. Thus, the optimal contracts under moral hazard specify $(w_L, w_H) = \left(0, \frac{c}{\Delta p}\right)$.

(iv) Substituting the wage in (iii) contracts on the LHS of the IR constraint, we get $c \frac{p_1}{\Delta p} > c$. Thus, the agent gets strictly positive rents under the optimal contract. ■

Let us now consider optimal contracts when the agent has other-regarding preferences ($\alpha > 0$). We restrict attention to optimal contracts where $w_L = 0$. This restricts the class of optimal contracts, but under certain conditions it is without loss of generality.⁵

Using (8.1), (8.2) the assumptions in (8.3) imply that when $j = L$ we have $w_L = \pi_L = 0$. So, in this case, there are no inequity aversion issues to consider. Thus, inequity aversion has bite only when $j = H$. Using (8.1),

$$w_H \geq \pi_H \Leftrightarrow w_H \geq \frac{y_H}{2} \text{ and } w_H \leq \pi_H \Leftrightarrow w_H \leq \frac{y_H}{2}. \quad (8.5)$$

The incentive compatibility (IC) condition of the agent requires that the agent prefers the high action, a_1 , over the low action, a_0 . Using (8.2) we know that there are two cases to consider:

⁵ See Itoh (2004) for the conditions under which such a contract is optimal. For instance, if there is a limited liability condition on the principal, then there is no loss in generality in assuming $w_L = 0$ because no output is produced in this state of the world (from (8.3), $y_L = 0$).

$w_H \geq \pi_H (\Leftrightarrow w_H \geq \frac{y_H}{2})$ and $w_H \leq \pi_H (\Leftrightarrow w_H \leq \frac{y_H}{2})$. Using (8.1), (8.2), (8.3), (8.5), when $w_H \geq \frac{y_H}{2}$, the IC condition of the agent requires that

$$p_1 (w_H - c - \alpha\gamma v(2w_H - y_H)) + (1 - p_1) (0 - c - 0) \geq p_0 (w_H - \alpha\gamma v(2w_H - y_H)) + (1 - p_0) \times 0. \quad (8.6)$$

When $w_H \leq \frac{y_H}{2}$, the IC condition requires that

$$p_1 (w_H - c - \alpha v(y_H - 2w_H)) + (1 - p_1) (0 - c - 0) \geq p_0 (w_H - \alpha v(y_H - 2w_H)) + (1 - p_0) \times 0. \quad (8.7)$$

Simplifying (8.6), (8.7) we can write the incentive compatibility condition as

$$\begin{cases} w_H - \alpha\gamma v(2w_H - y_H) \geq \frac{c}{p_1 - p_0} & \text{if } w_H \geq \frac{y_H}{2} \quad (IC^+) \\ w_H - \alpha v(y_H - 2w_H) \geq \frac{c}{p_1 - p_0} & \text{if } w_H \leq \frac{y_H}{2} \quad (IC^-) \end{cases}. \quad (8.8)$$

We have denoted the incentive compatibility conditions in the advantageous inequity and the disadvantageous inequity cases, respectively, by IC^+ and IC^- . Given the evidence on ultimatum games, where proposers typically do not offer more than half the share of the pie, we focus here on the case represented by IC^- . The optimal contract in this case, when the agent has other-regarding preferences, is described in the next proposition; readers interested in exploring the implications of the case, IC^+ , may do so as an exercise.

Proposition 8.25 Suppose that $\frac{y_H}{2} \geq \frac{c}{\Delta p}$, where Δp is defined in (8.4).

(i) In the optimal second best contract, $w_L = 0$ and w_H satisfies

$$w_H - \alpha v(y_H - 2w_H) = \frac{c}{\Delta p}.$$

(ii) The expected payment made by the principal in the optimal contract is increasing in α , and strictly increasing in α if $\frac{y_H}{2} > \frac{c}{\Delta p}$.

(iii) In the optimal second best contract, the agent earns positive rents.

Proof: (i) Since we are interested only in the case described by IC^- , let us find the set of values of w_H for which IC^- holds. For $w_H = \frac{y_H}{2}$, IC^- implies that $w_H = \frac{y_H}{2} \geq \frac{c}{\Delta p}$, which is also the assumed condition in the Proposition. The LHS of IC^- is increasing in w_H , so let us find the minimum value of $w_H = \hat{w}_H$ for which IC^- holds; this value is given by the solution to

$$\hat{w}_H - \alpha v(y_H - 2\hat{w}_H) = \frac{c}{\Delta p}. \quad (8.9)$$

Thus, the set of contracts for which IC^- holds is given by the interval $w_H \in [\hat{w}_H, \frac{y_H}{2}]$, where $\frac{y_H}{2} \geq \frac{c}{\Delta p}$; the higher the output in the good state of the world, the wider is the interval of incentive compatible contracts. It is now sufficient to show that $\hat{w}_H$ satisfies the individual rationality constraint of the agent, IR , when the principal wishes to induce the high action, a_1 . The relevant IR is given by

$$\widehat{w}_H - \alpha v(y_H - 2\widehat{w}_H) \geq \frac{c}{p_1}. \quad (8.10)$$

Using (8.9), we can rewrite (8.10) as $\frac{c}{\Delta p} > \frac{c}{p_1}$, which is true, hence, *IR* is satisfied (by assumption, the optimal $w_L = 0$).

(ii) The minimum expected payment of the principal is $p_1 \widehat{w}_H$. It suffices to show that $\widehat{w}_H$ is increasing in α . Differentiating the LHS of (8.9) with respect to α we get $\frac{\partial LHS}{\partial \alpha} = -v(y_H - 2\widehat{w}_H)$, which is strictly negative if $y_H > 2\widehat{w}_H$, thus, the optimal level of $\widehat{w}_H$ must increase to compensate for the fall in the LHS, in order to restore the equality in (8.9). If $\frac{y_H}{2} = \frac{c}{\Delta p}$, then we get the case $\widehat{w}_H = \frac{y_H}{2} = \frac{c}{\Delta p}$, but then $\widehat{w}_H$ is independent of α and $\frac{\partial LHS}{\partial \alpha} = 0$.

(iii) From the last sentence of the proof to (i), $\frac{c}{\Delta p} > \frac{c}{p_1}$, thus, the *IR* holds with a strict inequality and the agent earns positive rents. ■

Comparing Propositions 8.24, 8.25, the agent earns rents in the optimal contract when effort is unobservable, irrespective of whether he has self-regarding or other-regarding preferences. From Proposition 8.25(ii), the other-regarding preferences of the agent hurt the principal. The reason is that when realized output is y_L , there are no equity comparisons. However, when the realized output is y_H , the agent suffers from disadvantageous inequity if the wage in that state, w_H , is low. In order to ensure that the *IC* constraint of the agent binds in that state, the principal ends up offering a higher wage, and reducing his own profits.

In the presence of multiple agents, it may be that the reference group of the agent is not the principal, but rather the other agents. Consider two agents and to each of the agents, the principal offers an independent project (we rule out joint production). Each project has the same technology as in the case of the single agent. Thus, each agent exerts two possible levels of effort, $a_0 < a_1$, and there are two possible probabilistic outcomes for each agent, $0 \leq y_L < y_H$. The higher outcome is more likely for each agent under higher effort, i.e., $p_1 > p_0$. It is possible in this case that $\gamma < 0$, i.e., agents derive greater utility by coming out ahead of the other agent. Let w_{jk}^n be the wage offered to agent $n = 1, 2$ if the outcome of that agent's project is y_j and the outcome of the other agent is y_k such that $j, k = L, H$. For pedagogical simplicity we make the following assumption.

- A3. The agents are symmetric in the sense that they have identical α, γ . The function v is also identical for both agents and is given by $v(x) = x$. The reference group for each agent is the other agent. As in the case of a single agent, we restrict attention to the case in which if an agent gets a low outcome y_L , then his wage is zero, i.e., $w_{LL}^n = w_{LH}^n = 0$ for $n = 1, 2$.⁶ The optimal contract is symmetric, so $w_{jk}^1 = w_{jk}^2 = w_{jk}$, $j, k = L, H$.⁷ The objective of the principal is to minimize the expected payment across both agents.

Remark 8.2 *An immediate implication of assumption A3 is that it suffices to find the optimal values of only w_{HH} and w_{HL} .*

Assume now that assumptions A1, A2, and A3 hold. From assumption A1, the principal wishes to implement the high action from both agents.

The action a_1 , by each of the agents can result in four possible pairs of outcomes (y_H, y_H) , (y_H, y_L) , (y_L, y_H) , and (y_L, y_L) . These outcomes correspond to the respective pairs of wages

⁶ Itoh (2004) shows that this restriction is without loss in generality.

⁷ To be sure, w_{jk}^1 is the wage paid to agent 1 when his output is y_j and the output of agent 2 is y_k . Analogously, w_{jk}^2 is the wage paid to agent 2 when his output is y_j and the output of agent 1 is y_k .

$(w_{HH}^1, w_{HH}^2), (w_{HL}^1, w_{LH}^2), (w_{LH}^1, w_{HL}^2), (w_{LL}^1, w_{LL}^2)$ that occur with the respective probabilities $p_1^2, p_1(1-p_1), (1-p_1)p_1$, and $(1-p_1)^2$.

Suppose that we get the outcome pair (y_j, y_k) , so that the corresponding tuple of wages is (w_{jk}^1, w_{kj}^2) . In this state, the utility of agent 1 from action a_1 is

$$u(w_{jk}^1, w_{kj}^2, a_1) = \begin{cases} w_{jk}^1 - c - \alpha\gamma(w_{jk}^1 - w_{kj}^2) & \text{if } w_{jk}^1 \geq w_{kj}^2 \\ w_{jk}^1 - c - \alpha(w_{kj}^2 - w_{jk}^1) & \text{if } w_{jk}^1 \leq w_{kj}^2 \end{cases}. \quad (8.11)$$

The utility of agent 2 can be written analogously. From assumption A3, the contracts are symmetric, hence, we can dispense with superscripts for players. Using (8.11), we can write the expected utility of any agent from the action, $a_i, i = 0, 1$,

$$\begin{aligned} Eu(W, a_i) &= p_i^2(w_{HH} - c(a_i)) + p_i(1-p_i)[w_{HL} - c(a_i) - \alpha\gamma w_{HL}] \\ &\quad + (1-p_i)p_i[-c(a_i) - \alpha w_{HL}] - c(a_i)(1-p_i)^2. \end{aligned} \quad (8.12)$$

From any agent's perspective, the first and the last terms correspond to the outcomes (w_{HH}, w_{HH}) and (w_{LL}, w_{LL}) that occur with respective probabilities p_i^2 and $(1-p_i)^2$. In each of these states, there are no equity concerns, and by assumption, $w_{LL} = 0$. The middle two terms correspond to the outcomes (w_{HL}, w_{LH}) and (w_{LH}, w_{HL}) that occur with respective probabilities $p_i(1-p_i)$ and $(1-p_i)p_i$. In each case, inequity concerns are important (see (8.11)) and we have assumed that $w_{LH} = 0$. Simplifying (8.12) we get

$$Eu(W, a_i) = p_i[p_i w_{HH} + (1-p_i)w_{HL} - (1-p_i)\alpha w_{HL}(1+\gamma)] - c(a_i). \quad (8.13)$$

Since we would like to implement the high action, a_1 , thus, it follows that the individual rationality constraint of any agent is $Eu(W, a_1) \geq 0$, or

$$p_i[p_i w_{HH} + (1-p_i)w_{HL} - (1-p_i)\alpha w_{HL}(1+\gamma)] - c(a_i) \geq 0. \quad (\text{IR}) \quad (8.14)$$

Using (8.3) and (8.13), the incentive compatibility constraint is $Eu(W, a_1) \geq Eu(W, a_0)$, or

$$p_1 w_{HH} + (1-p_1)w_{HL} + \alpha w_{HL}[p_1 - 1 - (1-p_1)\gamma] \geq \frac{c}{p_1 - p_0}. \quad (\text{IC}) \quad (8.15)$$

From Remark 8.2, the objective of the principal is to choose w_{HH} and w_{HL} in order to minimize his expected cost

$$2p_1(w_{HL} + p_1(w_{HH} - w_{HL})),$$

subject to the IR and the IC of the agents in (8.14) and (8.15).

We introduce some useful terminology about the kinds of contracts that can be offered.

Definition 8.22 In a “team contract,” both agents receive a higher wage if their projects simultaneously succeed relative to the case where at least one project fails, i.e., $w_{HH} > w_{HL}$. In a “relative performance contract,” if one project fails and the other succeeds, the successful agent gets a higher wage relative to the case where both projects succeed, i.e., $w_{HH} < w_{HL}$.

In an “independent contract,” $w_{HH} = w_{HL}$, thus, the success or failure of the project of one agent is irrelevant for the wage of the other agent.

As one may expect, under self-regarding preferences, the independent contract is optimal because the problems of both agents are completely de-coupled; the proof is left for the reader.

Proposition 8.26 *Under self-regarding preferences ($\alpha = 0$), the optimal contract offered by the principal is non-unique. Any pair (w_{HL}, w_{HH}) that satisfies $p_1 w_{HH} + (1 - p_1) w_{HL} = \frac{c}{(p_1 - p_0)}$ is optimal. In particular, the independent contract in which $w_{HH} = w_{HL} = \frac{c}{p_1 - p_0}$ is also optimal.*

The optimal contract under other-regarding preferences is described next; the proof is left for the reader. The intuition behind the result is provided below.

Proposition 8.27 *Under other-regarding preferences ($\alpha > 0$), the optimal contract offered by the principal depends on the parameters of the model in the following manner.*

(i) *If $\gamma > \frac{p_1}{1-p_1}$, then the optimal contract is an extreme “team contract”*

$$w_{HL} = 0 \text{ and } w_{HH} = \frac{c}{p_1(p_1 - p_0)}.$$

The expected payment of the principal is independent of α and γ .

(ii) *Let $\gamma < \frac{p_1}{1-p_1}$ and $\gamma \leq \frac{1}{\alpha} - \frac{L_H}{L_L}$, where $L_H = \frac{p_1}{p_0}$ and $L_L = \frac{1-p_1}{1-p_0}$ are the likelihood ratios of getting the high and the low outcomes under, respectively, the high and the low actions. Then, the optimal contract is an extreme “relative performance evaluation contract,”*

$$w_{HH} = 0 \text{ and } w_{HL} = \frac{c}{(p_1 - p_0)} \frac{1}{(1 - p_1) + \alpha [p_1 - \gamma (1 - p_1)]}.$$

The expected payment of the principal is decreasing in α and increasing in γ .

(iii) *If $\gamma < \frac{p_1}{1-p_1}$ and $\gamma > \frac{1}{\alpha} - \frac{L_H}{L_L}$, then*

$$w_{HL} = \frac{c}{(p_1 - p_0)} \frac{1}{\alpha L_H} \text{ and } w_{HH} = \frac{c}{(p_1 - p_0)} \frac{1 - p_1}{p_1 L_H} \left(\frac{L_H}{L_L} - \frac{1 - \alpha \gamma}{\alpha} \right),$$

and the expected payment from the principal to the agents is increasing in γ , but is independent of α .

We now discuss the results in Proposition 27. Inequity averse agents are motivated by two considerations that do not influence agents with self-regarding preferences. Such agents dislike being behind, as reflected in the size of α , and dislike being ahead if $\gamma > 0$, as reflected in the size of $\alpha \gamma$ (which equals β in the Fehr–Schmidt model). Agents are behind when their action leads to the output y_L , while the other agent’s action leads to the output y_H . Agents are ahead in the converse case. The outcome depends on which of these two influences dominate.

For instance, in Proposition 8.27(i), when γ is large (or $\frac{p_1}{1-p_1}$ is small), then agents derive an even larger disutility from being ahead. Thus, when an agent produces y_H and the other agent produces y_L , his wage is $w_{HL} = 0$. An extreme form of team incentives is preferred to relative performance incentives in this case by paying a positive wage only if both agents are successful in producing y_H . Since there is no inequity in equilibrium, the payments of the principal are independent of α and γ . Thus, extreme team incentives ensure that agents never get left behind each other (provided they both put in the high effort level, a_1).

In Proposition 8.27(ii), we have the opposite case when γ is small. An extreme example of this case arises when $\gamma < 0$, i.e., an agent derives pride from coming out ahead. In this case, the inequity cost to the agent from being ahead is small (or negative if $\gamma < 0$), so, the opposite of team incentives, relative performance evaluation, is efficient.⁸ However, in this case, since positive wages are paid to one of the agents only when that agent produces a high output and the other a low output, issues of inequity aversion will be central to the satisfaction of the incentive compatibility conditions. Hence, the expected payment of the principal does depend on α and γ (and it is increasing in γ , as suggested by the intuition, above).

In general, the inequity aversion of the agents makes the individual rationality constraint of the agents most costly for the principal to satisfy if $\alpha(1 + \gamma) > 1$ (see (8.14)), resulting in larger wage payments relative to the self-regarding case. When $p_1 \rightarrow 1$, the signal (i.e., the realized output) is increasingly informative of the agent's effort. Both conditions, $\gamma < \frac{p_1}{1-p_1}$ and $\gamma \geq \frac{1}{\alpha} - \frac{L_H}{L_L}$, are likely to hold, so we have the case in Proposition 8.27(iii). In this case, a contract that is intermediate between an extreme team incentive contract and an extreme relative performance evaluation contract is offered. Each agent is offered a positive wage whenever his project does not fail. Comparing Propositions 8.26, 8.27, the optimal contract under self-regarding preference is non-unique but the introduction of even a small amount of other-regarding preferences ($\alpha > 0$) gives rise to a unique contract.⁹

Rey-Biel (2008) also considers inequity aversion in a situation where a principal hires two agents. The agents are inequity averse towards each other but not towards the principal. The main difference from the model in Itoh (2004) is that there is *joint production* of a single good between the two agents and there is no uncertainty. Hence, the outcome provides a noiseless signal of the effort levels of the agents. The principal who has self-regarding preferences exploits the inequity aversion of the two agents in designing the optimal wage contracts in the following manner.

The optimal wage levels are high and equal when both agents work hard (so a high output level is produced), thus, there is minimal inequity aversion. However, when the outcome signals with certainty that one of the agents has not worked hard but the other has, then the wage levels are used to deliberately create high inequality among the agents. Since the agents dislike inequality, it is easier for their incentive compatibility conditions to be satisfied in the presence of inequity aversion. Relative to purely self-regarding agents, the principal is able to induce a higher effort level at a lower wage cost when agents are inequity averse.

8.2.2 Reciprocity and moral hazard

Having considered the effects of *inequity aversion* in the presence of moral hazard, we now consider the effect of *reciprocity*. We follow the model of Englmaier and Leider (2012) but restrict attention to two actions, two outcomes, a risk-neutral principal and a risk averse agent. The rigorous modeling of these issues requires the use of psychological game theory; see Part 4 of the book. By contrast, Englmaier and Leider (2012) take a simpler, direct, and reduced-form approach.

The model is similar to that in Section 8.2.1. The agent chooses among two unobservable actions $a_0 < a_1$. The cost of action $i = 0, 1$ is c_i . Each action probabilistically determines one of two observable output levels, $0 \leq y_L < y_H$. Action a_i results in the outcome y_H with probability

⁸ Further issues of the optimality of relative performance evaluation under inequity averse agents are explored in Bartling (2011).

⁹ For a consideration of issues similar to Itoh (2004) see Bartling and von Siemens (2010) and, in a continuous outcome framework, Englmaier and Wambach (2010).

p_i such that $p_1 > p_0$. The utility function of the agent, defined over material rewards, u , is increasing and concave (we did not invoke risk aversion in Section 8.2.1). The outside option of the agent is zero. The *monotone likelihood ratio property* (MLRP) holds, i.e., $\frac{p_1}{p_0} > \frac{1-p_1}{1-p_0}$, so the relative probability of getting a higher signal under a higher action is greater.

A contract specifies, for $j = L, H$, a triple (w_L, w_H, a) , where $w_j \geq 0$ is the wage if the realization of output is y_j and $a \in \{a_0, a_1\}$ is the *non-contractible, desired level of effort*. The agent has limited liability ($w_j \geq 0$) and there is no renegotiation of contracts. We assume that the principal always wishes to induce the higher action, a_1 . Thus, we wish to focus attention on contracts of the form (w_L, w_H, a_1) in which the principal optimally chooses w_L, w_H . Let $u_H = u(w_H)$ and $u_L = u(w_L)$ and define the following

$$\bar{u}(a_i) = p_i u_H + (1 - p_i) u_L - c_i, \bar{\pi}(a_i) = p_i y_H + (1 - p_i) y_L, \quad (8.16)$$

where $\bar{u}(a_i)$ and $\bar{\pi}(a_i)$ are, respectively, the expected utility of the agent (net of effort costs) and the expected output of the principal when the agent chooses the action a_i , $i = 0, 1$. Conditional on any level of expected wage, the expected output, $\bar{\pi}$, is directly proportional to the principal's profit. Thus, when considering the effort choice of the agent, it is pedagogically convenient to refer to $\bar{\pi}$ as the expected profit of the principal. Define the following first differences

$$\Delta c = c_1 - c_0, \Delta \bar{\pi} = \bar{\pi}(a_1) - \bar{\pi}(a_0).$$

Consider the contract (w_L, w_H, a_i) , in which the desired, but non-contractible, effort is a_i . The utility of the agent from this contract when he chooses the action $a_j \in \{a_0, a_1\}$ is denoted by $U(a_j, a_i)$ and is given by

$$U(a_j, a_i) = \bar{u}(a_j) + r \bar{u}(a_i) \bar{\pi}(a_j), \quad r > 0. \quad (8.17)$$

Conditional on the contract (w_L, w_H, a_i) , the first term on the RHS is the expected utility of the agent when he chooses the action a_j . The second term captures considerations of reciprocity. In judging the kindness of the principal, the agent takes the outside option, normalized to zero, as the fair level of utility. But if $\bar{u}(a_i) > 0$, the agent derives positive rents from the contract, so he reciprocates by engaging in gift exchange. This is reflected in the interaction of the agent's rents from the intended contract with the expected profit of the principal from the action chosen by the agent, a_j . The parameter $r > 0$ reflects the relative weight placed on reciprocity considerations. The greater is r and the higher the level of rents, the greater is the level of internalization of the principal's expected profit by the agent.

We assume that the principal always finds it optimal to implement the action a_1 . For the principal, maximizing expected profits $p_1(y_H - w_H) + (1 - p_1)(y_L - w_L)$ is equivalent to minimizing expected wage costs. Thus, the principal's problem, P0, is

$$w_L^*, w_H^* \in \arg \min_{w_j \in [0, y_j], j=H,L} \bar{w}(a_1) = p_1 w_H + (1 - p_1) w_L \quad (8.18)$$

subject to

$$U(a_1, a_1) \geq U(a_0, a_1) \quad (\text{IC})$$

$$U(a_1, a_1) \geq 0. \quad (\text{IR})$$

The optimal wage profile w_L^*, w_H^* must induce the choice of a high effort level, a_1 (incentive compatibility constraint, IC) and provide the agent with at least his reservation utility of zero (individual rationality constraint, IR).

The main difference from the standard moral hazard problem is that the principal can induce a high effort level through two channels. (1) By optimally offering a mix of w_L, w_H , as in models of self-regarding preferences. (2) By offering rents to the worker, which tap into the worker's reciprocity and internalize the objective of producing high expected output for the principal.

Consider the transformation introduced by Grossman and Hart (1983). Let

$$w_j = h(u(w_j)), h = u^{-1}, \text{ so } h' > 0 \text{ and } h'' > 0, j = H, L. \quad (8.19)$$

The implications in (8.19) are drawn from the standard properties of inverse functions and the fact that $u' > 0$ and $u'' < 0$.¹⁰ Using (8.17), (8.19), and the notation $u_j = u(w_j), j = L, H$, we can rewrite the principal's problem, P0. The new, but equivalent, problem, P1, eliminates the wage levels and is expressed in terms of utilities of the agent in the two states $j = L, H$:

$$u_L^*, u_H^* \in \arg \min V = p_1 h(u_H) + (1 - p_1) h(u_L)$$

subject to

$$\bar{u}(a_1) - \bar{u}(a_0) + r\bar{u}(a_1)(\bar{\pi}(a_1) - \bar{\pi}(a_0)) \geq 0 \quad (\text{IC})$$

$$\bar{u}(a_1) + r\bar{u}(a_1)\bar{\pi}(a_1) \geq 0. \quad (\text{IR})$$

The optimal choices $u_j^*, j = H, L$ are restricted to the compact interval $[u(0), u(y_j)]$. In problem P1, in order to induce the high effort, a_1 , the principal minimizes a convex function (recall $h'' > 0$) subject to linear constraints. Thus, the satisfaction of the first order conditions with the relevant complementary slackness conditions is necessary and sufficient for an optimal solution.

We may now speak of the optimal contract as the triple (u_L^*, u_H^*, a_1) , which allows us to recover the optimal wage contract (w_L^*, w_H^*, a_1) through the relation $w_j^* = h(u_j^*)$.

Let the Lagrangian of the constrained minimization problem, P1, be denoted by L and let λ_{IC} and λ_{IR} be the Lagrangian multipliers on the IC and IR constraints. The first order conditions with respect to u_L and u_H are

$$u_L : h'(u_L) = \lambda_{IC} \left[1 - \frac{1-p_0}{1-p_1} + r\Delta\bar{\pi} \right] + \lambda_{IR} (1 + r\bar{\pi}(a_1)). \quad (8.20)$$

$$u_H : h'(u_H) = \lambda_{IC} \left[1 - \frac{p_0}{p_1} + r\Delta\bar{\pi} \right] + \lambda_{IR} (1 + r\bar{\pi}(a_1)). \quad (8.21)$$

In addition, we have the Kuhn–Tucker complementary slackness conditions, i.e.,

$$\lambda_{IC} \frac{\partial L}{\partial \lambda_{IC}} = 0, \lambda_{IR} \frac{\partial L}{\partial \lambda_{IR}} = 0 \quad (8.22)$$

¹⁰ For any feasible point, x , in the domain of h , $h'(x) = \frac{1}{u'(h(x))}$ and $h''(x) = -\frac{1}{(u'(h(x)))^2} u''(h(x))h'(x)$. Thus, if u is increasing and concave, then the inverse, h , is increasing and convex.

Denote the minimum value of the objective function of the principal by

$$V(r, \Delta\pi) = p_1 h(u_H^*) + (1 - p_1) h(u_L^*) \quad (8.23)$$

We first state the benchmark textbook result in the absence of reciprocity ($r = 0$).

Proposition 8.28 (*Optimal contracts in the absence of reciprocity*): Suppose that reciprocity is absent ($r = 0$). Then, in the optimal contract, (u_L^*, u_H^*, a_1) :

(i) The first order conditions are

$$h'(u_L) = \lambda_{IC} \left[1 - \frac{1 - p_0}{1 - p_1} \right] + \lambda_{IR}, \quad (8.24)$$

$$h'(u_H) = \lambda_{IC} \left[1 - \frac{p_0}{p_1} \right] + \lambda_{IR}, \quad (8.25)$$

which, in conjunction with the complementary slackness conditions, (8.22), give the optimal solution.

(ii) The IR constraint binds.

(iii) The principal rewards the agent more for outcomes that are relatively more likely under the desired action, a_1 .

Proof: (i) The first order conditions follow by setting $r = 0$ in (8.20), (8.21). This gives the two equations (8.24), (8.25). Since we have a convex minimization problem subject to linear inequality constraints, (8.24), (8.25), in conjunction with (8.22), give the solution to the optimal contract.

(ii) Suppose that the IR constraint does not bind at the optimal contract (u_L^*, u_H^*, a_1) . Then consider a new contract $(u_L^* - \epsilon, u_H^* - \epsilon, a_1)$, where $\epsilon > 0$ is a small number. The IC and IR constraints continue to hold (because $r = 0$) and the expected payment to the agent falls, increasing the expected profits of the principal. Hence, the original contract (u_L^*, u_H^*, a_1) at which the IR constraint does not bind is not optimal.

(iii) Suppose $\lambda_{IC} = 0$, so from (8.24), (8.25), $h'(u_L) = h'(u_H) = \lambda_{IR}$. In this case, a flat wage $w_L = w_H$ is optimal. When there are no problems of incentives, then it is optimal to fully insure the risk averse agent. But this creates a problem of incentives in implementing a high effort level. To see this, a flat wage gives $u_L = u_H = \hat{u}$. Then, using (8.16) we have $\bar{u}(a_1) = \hat{u} - c_1$ and $\bar{u}(a_0) = \hat{u} - c_0$. From the binding IR constraint we have $\hat{u} = c_1$. The IC constraint then implies the contradiction $0 \geq \Delta c$. Thus, a flat wage is not optimal.

Since the Lagrangian multipliers are positive in the presence of inequality constraints, the other possibility is $\lambda_{IC} > 0$, so the IC constraint must bind (from (8.22)). Notice that in each of (8.24), (8.25), since $h'' > 0$, an increase in the RHS increases the corresponding wage levels, w_L, w_H . From the MLRP, stated above, we know that $\frac{p_1}{p_0} > \frac{1-p_1}{1-p_0}$, hence, $w_L < w_H$. Thus, the principal rewards the agent for observing an outcome that is more likely under the desired action, a_1 . ■

Let us now see how the results are modified in the presence of reciprocity ($r > 0$).

Proposition 8.29 Let $r > 0$. Then the following hold.

(i) If an agent with the reciprocity parameter $r = r_1$ is induced to choose action a_1 by the contract (u_L, u_H, a_1) , then any agent with a reciprocity parameter $r = r_2 > r_1$ also chooses the action a_1 .

- (ii) The minimum expected cost of the principal, $V(r, \Delta\bar{\pi})$, defined in (8.23), is non-increasing in r and $\Delta\bar{\pi}$.
- (iii) When the rent of the agent is high enough, a flat wage schedule can implement the action a_1 . As the reciprocity parameter $r \rightarrow \infty$, the action a_1 can be implemented by a flat wage schedule with infinitesimal rents.

Proof: (i) Differentiating the LHS of the IC constraint with respect to r , we get $\bar{u}(a_1)(\bar{\pi}(a_1) - \bar{\pi}(a_0)) > 0$. Similarly, differentiating the LHS of the IR constraint with respect to r we get $\bar{u}(a_1)\bar{\pi}(a_1) > 0$. Thus, an increase in r relaxes both constraints. Hence, if the optimal contract can be implemented at r_1 it can be implemented at $r_2 > r_1$.

(ii) From part (i), an increase in r relaxes the IC constraint, and the IR constraint continues to hold. Hence, the expected profits of the principal can be no lower as r increases. In particular, if IR does not bind, then the expected profits of the principal will strictly increase as r increases, otherwise they are unchanged (but no lower). An increase in $\Delta\bar{\pi}$ relaxes the IC and IR constraints, hence, the expected profits of the principal are also increasing in $\Delta\bar{\pi}$.

(iii) Suppose that there is a flat wage profile, so $w_L = w_H$ but the contract leaves positive rents for the agent. Constant state-contingent wages imply that $u_L = u_H = \tilde{u} > 0$. The outside option of the agent is zero, thus, the IR constraint is

$$(\tilde{u} - c_1)(1 + r\bar{\pi}(a_1)) > 0.$$

Evaluating the IC constraint at the stated contract, we get

$$r(\tilde{u} - c_1)\Delta\bar{\pi} > \Delta c.$$

Thus, for high enough $\tilde{u}$, the IC constraint is satisfied. Clearly, the larger the reciprocity parameter r , the smaller is the level of rents, $\tilde{u}$, required to satisfy the IC constraint. ■

Comparing Propositions 8.28, 8.29 we see the following. In the absence of reciprocity, there is a conflict between insurance and incentives, so a flat wage is good for insurance but bad for incentives. However, in the presence of reciprocity, both insurance and incentives point in the same direction, hence, this may give rise to an optimal contract with flat wages. Indeed, the prediction of high-powered incentives in the absence of reciprocity (Proposition 8.28) is often violated in practice. See, for instance, the quote, due to Lemieux et al. (2009) in the introduction.

Lemma 8.9 *In the presence of reciprocity, the IC constraint binds for all $r > 0$.*

Proof: First suppose that both constraints, IC and IR, are slack when evaluated at the contract (u_L, u_H, a_1) . Then the principal's profits can be increased by the contract $(u_L - \epsilon, u_H - \epsilon, a_1)$, hence, this case cannot arise. The other possibility is that IC is slack but IR binds. Since IR binds, the agent gets no rents, hence, reciprocity of the agent become irrelevant. In effect, the behavior of the agent in this case is like a non-reciprocal agent ($r = 0$). If the IC is slack, so $\lambda_{IC} = 0$, then from (8.20), (8.21) we have $h'(u_L) = h'(u_H)$, so $w_L = w_H$, i.e., a flat wage schedule. But we know in this case that the self-regarding agent does not put in any effort, thus IC should be violated, contradicting the initial supposition that it does hold. Thus, the IC should bind when $r > 0$. ■

Lemma 8.9 shows that IC will always bind, so we have two additional possibilities. (i) IR binds. (ii) IR is slack. The next proposition indicates when each of these cases is likely to arise.

Proposition 8.30 *There exists some finite reciprocity parameter r^* such that (i) for all $r \leq r^*$, IR binds, and (ii) for all $r > r^*$, the IR constraint is slack and the optimal contract provides strictly positive rents to the agent.*

We leave the proof of Proposition 8.30 as an exercise for the reader. In case (ii) of Proposition 8.30, since IR is slack we have $\lambda_{IR} = 0$. Substituting $\lambda_{IR} = 0$ in (8.20), (8.21) and using the fact that $h'(u_L) = \frac{1}{u'(w_L)}$ (see footnote 10 above on the properties of an inverse function) we have that the optimal contract specifies

$$\frac{u'(w_H)}{u'(w_L)} = \frac{1 - \frac{1-p_0}{1-p_1} + r\Delta\bar{\pi}}{1 - \frac{p_0}{p_1} + r\Delta\bar{\pi}}. \quad (8.26)$$

Thus, the ratio of marginal utilities depends not just on the likelihood ratios but also on the extent of reciprocal feelings of the agent. We leave it to the reader to explore the effects of the degree of informativeness of signals on the optimal contract. Englmaier and Leider (2012) show that when signals are more informative about the effort choice of the agent, then the principal relies more on incentives (as compared to reciprocity) in order to induce the desired effort level. One testable prediction of this model, therefore, is to compare the incidence of incentive contracts in firms with different levels of noise in the production technology. These sorts of models are also potentially useful to study the optimality of different organizational forms.¹¹

8.3 Incomplete contracts under other-regarding preferences

Most real-life contracts are incomplete. In particular, in principal–agent relations, the effort level of agents is difficult to specify in full detail. High-powered incentive contracts predict high levels of effort when agents have self-regarding preferences. However, real life incentives are typically not high-powered, and apart from top management, fixed wage payments or mildly increasing wage schemes are quite common.

In this section, we consider a simple model of moral hazard in a principal–agent relation but with (1) a rich menu of contracts, (2) the presences of other-regarding preferences, and (3) uncertainty about preferences (self-regarding or other-regarding). We show that in the presence of other-regarding preferences, a range of contracts, such as *bonus contracts* and *trust contracts* become potentially profitable for a principal; indeed, even more profitable than purely *incentive contracts*. Under purely self-regarding preferences, the bonus and the trust contracts are shown to be dominated by incentive contracts. The converse may be true under other-regarding preferences.

The treatment in this section is based on Fehr et al. (2007). We give a detailed treatment for two reasons. First, understanding the basic theoretical framework is important in the economics of incentives. Second, the predictions of this model have been empirically tested; we consider the empirical results in Section 8.3.3, below.

¹¹ Englmaier and Leider (2012) make progress in this direction by identifying three different organizational forms in which there are two managers of a firm. They consider various heirarchical relations between them.

Consider a single, risk-neutral, principal who contracts a single, risk-neutral, agent to work for him. The reservation utilities of both parties are normalized at zero. The agent can expend effort $e \in [\underline{e}, \bar{e}]$ at some private cost $c(e)$ such that $c(\underline{e}) = 0$, $c' > 0$ and $c'' > 0$. The utility of the agent is given by

$$u = w - c(e) - C_A, \quad (8.27)$$

where C_A are other possible costs associated with a contract that are incurred by the agent, such as fines for non-fulfillment of contractual obligations; these are specified in more detail below. w is the wage received by the agent from the principal.

The output of the principal is given by $\theta v(e)$, where $\theta > 0$ is a constant productivity parameter, and $v(\underline{e}) = 0$, $v'(e) > 0$, $v''(e) < 0$. We also assume that

$$c'(\underline{e}) < \theta v'(\underline{e}), \quad (8.28)$$

i.e., the marginal benefit of the lowest effort level to the principal, exceeds the marginal cost.

Let e_c be some effort level that the principal desires to induce. The principal can write e_c as part of the contract, in which case we call it the contracted effort level, but when the effort level is non-verifiable, then e_c is non-binding. Effort is observed by both parties. However, the principal cannot provide hard evidence of the effort level to a third party unless he invests in a verification technology that costs $k > 0$. The verification technology unearths hard evidence of the actual effort level with some probability $p \in (0, 1)$. Based on this evidence, the principal can impose a fine $f > 0$ on the agent. The maximum possible fine is $\bar{f}$. We also make a technical assumption

$$c(e_c) - c(\underline{e}) \leq p\bar{f}, \forall e_c. \quad (8.29)$$

The profits of the principal are given by

$$\pi = \theta v(e) - w - C_P, \quad (8.30)$$

where C_P captures other possible costs (positive or negative) associated with the contract that are incurred by the principal, such as investment in a verification technology, or receipt of fines from the agent.

The sequence of moves in the multi-stage game is as follows. In Stage 1, the principal makes a *take it or leave it* offer to the agent after choosing (a) the type of contract to offer, and (b) whether to invest in the verification technology. In Stage 2, the agent decides (a) to accept or reject the contract, and (b) the effort level to expend. In Stage 3, if the initial investment in the verification technology has been made, then hard evidence of the agent's effort level is obtained with probability $p > 0$ and the terms of the initial contract are enforced.

Consider the following three types of contracts.

1. *Incentive contracts*: This is the typical form of contracts in classical contract theory. Assume that the principal invests in the monitoring technology, so hard evidence of the agent's effort level can be produced with probability $p > 0$ and the agent expends an effort level e . The contract specifies a triple (w, e_c, f) , where e_c is the contracted effort level and f is the

fine to be paid if verifiable evidence of shirking (i.e., $e < e_c$) is discovered. The ex-post utilities of the agent and the principal, u, π , are given respectively by:

$$u = \begin{cases} w - c(e_c) & \text{if } e = e_c \\ w - c(e) & \text{if } e < e_c \text{ (with probability } 1 - p) \\ w - c(e) - f & \text{if } e < e_c \text{ (with probability } p) \end{cases} \quad (8.31)$$

$$\pi = \begin{cases} \theta v(e_c) - w - k & \text{if } e = e_c \\ \theta v(e) - w - k & \text{if } e < e_c \text{ (with probability } 1 - p) \\ \theta v(e) - w - k + f & \text{if } e < e_c \text{ (with probability } p) \end{cases} \quad (8.32)$$

2. *Trust contract*: The trust contract specifies a pair (w, e_c) and there is no investment in the monitoring technology. Thus, shirking by the agent is never discovered and no fines are levied either. The contractual effort, e_c , is, therefore, non-binding. The wage payment $w \geq c(e)$ to the agent is not conditioned on the actual effort level of the agent. The contractual wage payment can be enforced by a court if necessary, so the agent is guaranteed to receive it, irrespective of the actual effort level, e . The respective utilities of the agent and the principal in a trust contract are:

$$u = w - c(e). \quad (8.33)$$

$$\pi = \theta v(e) - w. \quad (8.34)$$

Since e_c is unenforceable, the trust contract is more incomplete than the incentive contract.

3. *Bonus contract*: This contract is similar to a trust contract except for the presence of a non-enforceable bonus payment, $b \geq 0$, from the principal to the agent at Stage 3, conditional on having observed the Stage 2 outcome. Hence, the contract can be represented by a triple (w, e_c, b) . As in the case of the trust contract, e_c is not enforceable. The respective, ex-post, utilities of the agent and the principal are:

$$u = \begin{cases} w - c(e) & \text{when no bonus is paid} \\ w - c(e) + b & \text{when bonus is paid} \end{cases} \quad (8.35)$$

$$\pi = \begin{cases} \theta v(e) - w & \text{when no bonus is paid} \\ \theta v(e) - w - b & \text{when bonus is paid} \end{cases} \quad (8.36)$$

The bonus contract is the most incomplete of the three contracts because b and e_c are both unenforceable.

We now make an important assumption that concerns the nature of reciprocity. We assume that this assumption holds in the subsequent analysis in this section. For the empirical evidence behind this assumption, see Section 8.6.

- A1. When faced with an incentive contract, all types of principals and agents (other-regarding and self-regarding) behave selfishly. *This is the sense in which the model captures concerns for reciprocity.* Incentive contracts are perceived as unkind behavior by the principal and induce agents to behave in a self-regarding manner. Trust and bonus contracts (see below) are perceived by the agent as kind behavior by the agent and induce other-regarding preferences (unless the agent is inherently self-regarding). Furthermore, in a bonus contract, if the principal exhibits reciprocity, then the agent may put in high effort in the hope of receiving an, ex-post, bonus payment.

8.3.1 Optimal contracts under self-regarding preferences

If agents have self-regarding preferences, then reciprocity-based contracts, such as trust and bonus contracts, invite one-sided opportunism (trust contracts) or two-sided opportunism (bonus contracts). Self-regarding agents exert zero effort level because they are neither influenced by other-regarding preferences, nor by reciprocity. This contrasts with the observed evidence, say, in the gift exchange game.

Incentive contracts can, however, be very effective in eliciting the contracted effort, provided that the monitoring technology is effective (high p) and the maximum available fine, $\bar{f}$, is high enough. Proposition 8.31, below, formalizes these ideas and also characterizes the first best contract when both contractual parties have self-regarding preferences. The proofs in this section should be standard for most undergraduate students in economics, so they are all relegated as exercises.

Proposition 8.31 *Suppose that the principal and the agent have self-regarding preferences.*

- (i) *Consider the first best contract that maximizes the total surplus $u + \pi = \theta v(e) - c(e)$. The socially optimal effort level, e^* , is given by*

$$\theta v'(e^*) = c'(e^*), \quad (8.37)$$

and $u + \pi > 0$.

- (ii) *In the trust and the bonus contracts, the solution is summarized by*

$$e = \underline{e}, w = b = 0, u = 0, \pi = 0, u + \pi = 0. \quad (8.38)$$

- (iii) *Suppose that the principal invests in the monitoring technology. If $p\bar{f} \geq c(e^*) - c(\underline{e})$, then the solution under the incentive contract is summarized by*

$$e = e^* > \underline{e}; u = 0; \pi = \theta v(e^*) - c(e^*) - k \geq 0; u + \pi \geq 0. \quad (8.39)$$

If the deterrence technology is potent enough ($p\bar{f} \geq c(e^*) - c(\underline{e})$), the equilibrium effort under the incentive contract is identical to the first best contract. However, the aggregate payoff is lower, on account of the cost of the verification technology, $k > 0$. Hence, this is the second best outcome. The trust and the bonus contracts elicit the lowest effort levels $\underline{e}$; since $v(\underline{e}) = 0$, the firm's profits are zero in both cases.

The testable prediction of the model with self-regarding preferences, therefore, is that the principal will choose the incentive contract over the trust and the bonus contracts, when all three contractual forms are available; the evidence, described in Section 8.3.3, rejects this prediction.

8.3.2 Optimal contracts in the presence of other-regarding preferences

Now suppose that the principal and the agent have other-regarding preferences that take the Fehr–Schmidt (1997) form (abbreviated as FS preferences). Given assumption A1, individuals with FS preferences exhibit other-regarding preferences in the case of bonus and trust contracts but behave like self-regarding agents in the case of incentive contracts.

If all this is commonly known, then, in the trust contract, the principal could rationally hope that higher wages will be reciprocated by higher effort (as in the gift exchange game). Analogously, in a bonus contract, the agent rationally hopes the principal will reciprocate a high effort with a bonus payment. These factors are conducive for the agent to put in a high effort. Reciprocity

arises here on account of inequity aversion and not beliefs, which is the case when we apply the machinery of psychological game theory (see Part 4).

For pedagogical simplicity, we make the following assumptions.

$$v(e) = e; \quad c(e) = \frac{1}{2}e^2; \quad e \in [0, 1]. \quad (8.40)$$

$$\theta = 1. \quad (8.41)$$

Equation (8.40) restricts the marginal benefit of effort to be linear, the effort cost function to be quadratic, and the effort choice to be made from the unit interval. Given these assumptions, the marginal product of effort, $\theta v'(e) = 1$, is strictly greater than the marginal cost of effort, $c'(e) = e$, for all $e \in [0, 1)$ and equal at $e = 1$. Thus, from (8.37), a social planner would always want to elicit $e^* = 1$.

Under these specific functional forms, the utility of a self-regarding agent and a self-regarding principal is given, respectively, by

$$u = w - \frac{1}{2}e^2 - C_A \text{ and } \pi = e - w - C_P. \quad (8.42)$$

If the monetary payoffs of the agent and the principal are given by u and π as in (8.42) (which is a special case of (8.27), (8.30)), then their respective FS preferences, U and Π are given by:

$$U(u, \pi) = u - \alpha_A \max\{\pi - u, 0\} - \beta_A \max\{u - \pi, 0\} \quad (8.43)$$

$$\Pi(u, \pi) = \pi - \alpha_P \max\{u - \pi, 0\} - \beta_P \max\{\pi - u, 0\}, \quad (8.44)$$

where $\beta_i \in [0, 1]$, $\beta_i \leq \alpha_i$, $i = A, P$.

Let $0 < \lambda \leq 1$ denote the probability that the agent has self-regarding preferences, i.e., $\alpha_i = \beta_i = 0$. With probability $1 - \lambda$, the agent has other-regarding preferences. At the time of designing the incentive scheme of the agent in Stage 1, there is uncertainty: The principal does not know the agent's type, but knows the distribution of types. The principal cannot condition wage payments on the type of the agent; perhaps because the type information is non-verifiable.

In line with the experimental evidence, we make the following assumption that applies to the subsequent analysis in this section.

A2. The preference parameters obey the restrictions, $\alpha_i \geq \beta_i > 0.5$.¹²

Due to uncertainty about the type of the agent, the profit of the principal, π , is a random variable. Theory does not provide sufficient guidance on how to extend (8.44) in the presence of risk. We make the simplest pedagogical assumption that the principal maximizes his expected payoffs $E\P$,

$$E\P = \lambda \Pi(u, \pi \mid \text{self-regarding agent}) + (1 - \lambda) \Pi(u, \pi \mid \text{other-regarding agent}), \quad (8.45)$$

where the first and second terms on the RHS in (8.45) condition the profits of the principal on the type of the agent, self-regarding or other-regarding.

Suppose that the agent is other-regarding. It can then be shown that other-regarding agents are: (i) willing to transfer money to the other party to reduce disadvantageous inequality, and

¹² The assumption $\alpha_i > 0.5$ has better support than the assumption $\beta_i > 0.5$; see Table 6.1, above. However, the assumption $\beta_i > 0.5$ affords pedagogical simplicity.

(ii) engage in costly punishments, provided that punishments are not too costly and the envy parameter α is high enough. This is formalized in Lemma 8.10.

Lemma 8.10 *Suppose that $\alpha_A \geq \beta_A > 0.5$ (assumption A2) and the agent is other-regarding. Consider the Stage 2 problem of the agent to choose an effort level.*

- (1) *If $u > \pi$, the agent is willing to reduce inequality by transferring resources to the principal.*
- (2) *Suppose that the agent can, at a cost $\gamma < 1$, reduce the payoff of the principal by a unit. If $u < \pi$, the agent is willing to engage in costly punishment in order to reduce inequality if $\gamma \leq \frac{\alpha_A}{1+\alpha_A} < 1$.*

Proof: Let x_A and x_P be, respectively, the monetary payoffs of the agent and the principal. There are two cases to consider.

(a) $x_A > x_P$. In this case, the utility of the agent is given by $U(x_A, x_P) = x_A - \beta_A(x_A - x_P)$. Suppose now that the agent were to transfer a small amount $\varepsilon > 0$ of his own income to the principal, then his utility is

$$U(x_A, x_P) = x_A - \beta_A(x_A - x_P) + \varepsilon(2\beta_A - 1).$$

Since $\beta_i > 0.5$ it follows that the agent is better off by such a transfer of income. Hence, it follows that when inequality is to their advantage, other-regarding agents are willing to spend resources to benefit the disadvantaged partner.

(b) $x_A < x_P$. In this case, the utility of the agent is $U(x_A, x_P) = x_A - \alpha_A(x_P - x_A)$. Suppose that the agent can, at a cost $\gamma < 1$, reduce the payoff of the principal by a unit (it never makes sense to do so if $\gamma \geq 1$). The payoff of the agent in this case is

$$\begin{aligned} U(x_A, x_P) &= (x_A - \gamma) - \alpha_A[(x_P - 1) - (x_A - \gamma)] \\ \Leftrightarrow U(x_A, x_P) &= x_A - \alpha_A(x_P - x_A) + \alpha_A(1 - \gamma) - \gamma. \end{aligned} \quad (8.46)$$

Thus, the agent will prefer to punish the principal to reduce inequality if $\alpha_A(1 - \gamma) - \gamma \geq 0$ or equivalently if

$$\gamma \leq \frac{\alpha_A}{1 + \alpha_A} < 1. \quad (8.47)$$

This completes the proof. ■

TRUST CONTRACTS

From Proposition 8.31, under a trust contract, the self-regarding agent puts in the effort level $e = 0$ (this result holds in the special case of (8.40)). We now consider the effort choice of an other-regarding agent in Stage 2.

Lemma 8.11 *(a) Consider an other-regarding agent who accepts a trust contract. Then, in any “incentive compatible” trust contract, the agent will choose an effort level such that the payoffs of the principal and the agent are equated.*

The locus of (w, e) points that satisfy the incentive compatible contract are given by the condition

$$g(w, e) = e^2 + 2e - 4w = 0. \quad (8.48)$$

The effort reaction function of the other-regarding agent under an incentive compatible trust contract is given by¹³

$$e^T(w) = \sqrt{4w + 1} - 1 \geq 0. \quad (8.49)$$

(b) A self-regarding agent chooses $e = 0$, irrespective of the wage paid.

From (8.49), the effort level of the other-regarding agent is increasing in the wage paid, as in gift exchange experiments and models of efficiency wage. This arises on account of the other-regarding preferences of the agent (see Lemma 8.10).

Lemma 8.12 *In equilibrium, in a trust contract, the individual rationality constraints of the self-regarding and the other-regarding agents are respectively given by $w \geq 0$ and $w - \frac{1}{2}e^2 \geq 0$, where e is some incentive compatible effort level.*

Proof of Lemma 8.12: We know from Lemma 8.11 that in a trust contract, an other-regarding agent chooses effort $e^T(w) \geq 0$ and the effort choice of the agent equates the payoff with the principal. Using (8.43), since the outside option of the agent is zero, the principal must offer a wage such that $w - \frac{1}{2}e^2 \geq 0$. From Lemma 8.11 the self-regarding agent puts in a zero effort level, hence, he accepts the contract if $w \geq 0$. ■

We now state the next result that is simple to verify.

Lemma 8.13 *For a fixed $0 < e \leq 1$, the wage, w , that satisfies (8.48), the incentive compatibility condition of an other-regarding agent, is higher than the wage that satisfies the individual rationality constraint at equality for any strictly positive effort level, i.e., $w = \frac{1}{2}e^2$. When $e = 0$, the wage level that satisfies these two constraints is identical at $w = 0$. Hence, the satisfaction of the incentive compatibility constraint, for any strictly positive effort level by an other-regarding agent, will leave some rents to the agent.*

The result in Lemma 8.13 is analogous to the result in Proposition 8.30. Inequity averse agents repay the principal in terms of higher effort if the principal leaves them with rents.

We have considered, above, the Stage 2 problem for the case of an other-regarding and a self-regarding agent. We now consider the Stage 1 problem of the principal, separately, for the cases of other-regarding and self-regarding principals.

I. Trust contract offered by an other-regarding principal

Suppose that the principal has other-regarding preferences given in (8.44). Consider the Stage 1 problem of the principal.

With probability λ , the principal encounters a self-regarding agent who puts in zero effort level (see Lemma 8.11) and no output is produced. By definition, in a trust contract, the principal must honor the promise to pay a wage of w even if no output is produced. Thus, the principal faces disadvantageous inequity. Using (8.44), the principal's payoff in this case is $\Pi = -w(2\alpha_p + 1) < 0$.

With probability $1 - \lambda$, the principal encounters an other-regarding agent. Lemma 8.11 describes the outcome and (8.49) gives the effort level. The effort choice of the agent equalizes the payoffs

¹³ We are being a bit informal here because we also require that $e \in [0, 1]$, thus, $e^T(w) = \min\{\sqrt{4w + 1} - 1, 1\}$. We shall assume that $\min\{\sqrt{4w + 1} - 1, 1\} = \sqrt{4w + 1}$ to abstract from technical issues of boundary points. We trust that the reader can supply the necessary, but simple, formalism if required.

of both parties, so there are no equity considerations in equilibrium. Given (8.40), (8.41), the principal's payoff is given by $\Pi = e^T(w) - w$, which is identical to the material payoff π .

Combining the two possibilities, and using (8.45), the expected payoff of the other-regarding principal is given by

$$E\Pi = -\lambda w(2\alpha_P + 1) + (1 - \lambda)(e^T(w) - w), \quad (8.50)$$

where $e^T(w)$ is defined in (8.49). The problem of the other-regarding principal is to maximize (8.50) subject to the individual rationality constraint of the other-regarding agent, $w \geq \frac{1}{2}(e^T)^2$; the effort reaction function e^T is already incentive compatible. Since e^T is increasing in w , it is not necessarily optimal to choose w , so that the individual rationality constraint of the other-regarding agent binds. We show this in the next proposition; w_F^T is the wage offered by the other-regarding (or fair) principal in a trust contract.

Proposition 8.32

- (i) If $\lambda \geq \frac{1}{2(1+\alpha_P)}$, then in the only possible equilibrium, $(w_F^T, e_c) = (0, 0)$, and the individual rationality constraint of both types of agents binds. The payoffs of both types of agents and the payoff of the principal are zero.
- (ii) If $\lambda < \frac{1}{2(1+\alpha_P)} < \frac{1}{2}$, then there is an interior solution to the wage rate given by $w_F^T = \frac{(1-\lambda)^2}{(1+2\lambda\alpha_P)^2} - \frac{1}{4}$. The effort level of the other-regarding agent is given by $e_F^T = \frac{2(\lambda-1)}{(2\lambda\alpha_P+1)} - 1$. w_F^T is decreasing in α_P and λ , and both types of agents derive strictly positive rents. The expected profit of the other-regarding principal in a trust contract is

$$\Pi_F^T = -\lambda w_F^T(2\alpha_P + 1) + (1 - \lambda)(e_F^T - w_F^T). \quad (8.51)$$

- (iii) It is never the case that the other-regarding principal elicits the maximum feasible effort level, $e = 1$, from the agent.

From Proposition 8.32(ii), if the probability of the self-regarding agent, λ , is low enough, then it is worthwhile for the principal to offer high enough rents. In response to these rents, the other-regarding agent responds with a high level of effort, on account of his inequity aversion. The self-regarding agent also benefits from the rents being offered but he puts in a zero effort level. This does create disadvantageous inequity for the other-regarding principal. But if the disadvantageous inequity parameter, α_P , of the principal is low, the costs are low relative to higher effort obtained from the other-regarding agent. Otherwise, the case in Proposition 8.32(i) obtains.

Finally, the surplus maximizing, or the most efficient effort choice of the agent is $e = 1$. The model predicts that we should not observe this choice. In other models, where agents care for efficiency, say, in Charness and Rabin (2002), agents may well choose $e = 1$. However, the empirical evidence shows that in gift exchange games, agents typically do not make the surplus maximizing choice (see Section 5.3, above).

II. Trust contract offered by a self-regarding principal

We can recover the case of the self-regarding principal from that of the other-regarding principal by setting $\alpha_P = 0$ in Proposition 8.32.

The comparison between the regimes of an other-regarding and a self-regarding principal under trust contracts is summarized below. The simple proof is omitted.

Remark 8.3 *The wage rate offered by an other-regarding principal is always lower relative to that of a self-regarding principal. The other-regarding agent reciprocates a higher wage by a higher effort, hence: (i) The effort level of the other-regarding agent is higher when the principal is self-regarding. (ii) Expected output is larger in the regime of a self-regarding principal as compared to the regime of an other-regarding principal.*

When $\lambda > \frac{1}{2}$, no principal (other-regarding or self-regarding) offers a positive wage, hence, the trust contract breaks down. The reason is that the self-regarding principal does not suffer from inequity aversion (which is costly for an other-regarding principal) when he meets a self-regarding agent. Thus, a self-regarding principal faces a lower marginal cost from a marginal increase in λ . If $\lambda \in \left(\frac{1}{2(1+\alpha p)}, \frac{1}{2}\right)$, then the self-regarding principal offers a trust contract but the trust contract breaks down if the principal is other-regarding. If $\lambda < \frac{1}{2(1+\alpha p)}$, then both types of principals, self-regarding and other-regarding, offer a trust contract. The effort level of the self-regarding agent is zero, regardless of the type of the principal.

Why does a self-regarding principal offer a higher wage than an other-regarding principal under a trust contract? The intuition is that the other-regarding principal, unlike a self-regarding principal, dislikes disadvantageous inequity. When the other-regarding principal encounters a self-regarding agent, he suffers disadvantageous inequity, which is increasing in the wage offered. Since the wage contract is offered prior to the type of the agent being revealed, the other-regarding principal offers a relatively lower wage.

INCENTIVE CONTRACTS

Recall our assumption that in the presence of an incentive contract, all parties to the contract behave as if they had self-regarding preferences (assumption A1). Consider now the incentive contract described above in which a self-regarding principal meets a self-regarding agent (with probability 1).

If the self-regarding agent were to shirk, relative to the contractual effort level, e_c , then it would be best to put in the minimum effort level, $e = 0$. This is because the probability of detection and fines is independent of the level of effort. Thus, the incentive compatibility condition of the self-regarding agent is

$$(1-p)w + p(w-f) \leq w - \frac{1}{2}(e_c)^2. \quad (8.52)$$

Rewriting (8.52),

$$e_c \leq \sqrt{2pf}, \quad (8.53)$$

gives the set of effort levels of the agent that are incentive compatible.

The self-regarding principal chooses a contract (w, e_c) to maximize expected profits

$$E\pi = (1-p)(e-w-k) + p(e-w-k+df) = e-w-k+pdf, \quad (8.54)$$

where d is a binary variable such that $d = 0$ if $e = e_c$ and $d = 1$ if $e \neq e_c$. There are two constraints, the incentive compatibility constraint in (8.53) and the individual rationality constraint $w - \frac{1}{2}e^2 \geq 0$. The satisfaction of these constraints at the contracted effort, e_c , ensures that $d = 0$. The objective function $E\pi$ is decreasing in w , and the incentive compatibility

constraint is independent of w , hence, the individual rationality constraint always binds, i.e., $w = \frac{1}{2}e^2$. Denote the maximum value of the expected profit of the principal in an incentive contract by $E\P^I$. In light of the discussion, above, the results in the next proposition should be unsurprising.

Proposition 8.33 *In an incentive contract, the optimal contracted effort level is given by*

$$e_I = \min \left\{ 1, \sqrt{2pf} \right\}. \quad (8.55)$$

There are two main cases.

- (i) *If $\sqrt{2pf} \geq 1 \Leftrightarrow pf \geq 1/2$, then $e_I = 1$. The individual rationality constraint of the agent binds, so $w = 1/2$ and the expected profit of the firm is given by $E\P^I = \frac{1}{2} - k$.*
- (ii) *If $\sqrt{2pf} < 1 \Leftrightarrow pf < 1/2$, then $e_I = \sqrt{2pf}$. The individual rationality constraint of the agent binds, so $w = pf$ and the expected profit of the firm is given by $E\P^I = \sqrt{2pf} - pf - k$.*

BONUS CONTRACT OFFERED BY AN OTHER-REGARDING PRINCIPAL

The bonus contract is described above. Analogous to the results in Lemma 8.10, 8.11, an other-regarding principal chooses a bonus, b , in Stage 3, in order to equate the monetary payoffs of the two parties, so,

$$e - w - b = w + b - \frac{1}{2}e^2.$$

Solving out for b we get

$$b = b(e, w) = \frac{1}{2}e - w + \frac{1}{4}e^2. \quad (8.56)$$

The bonus payment is increasing in the effort level of the agent, which captures the reciprocity of the principal. The bonus also depends negatively, and one to one, on the wage level because these are substitute instruments in ensuring equality of payoffs between the principal and the agent. The remaining analysis is similar to the case of trust contracts except that both parties know that in Stage 3, the bonus payment is given by (8.56).

The preferences of a self-regarding agent are given by $u = w + b(e, w) - \frac{1}{2}e^2$, which, using (8.56), is strictly concave in e . From the first order condition, we find that in a bonus contract, the optimal effort choice of a self-regarding agent is $e_S^b = 1$. Hence, even a self-regarding agent puts in the maximum possible effort level if he knows that the principal is other-regarding, who will, optimally, choose to honor his commitment to pay a bonus.

Now consider an other-regarding agent. From Lemma 8.10, 8.11 the optimal effort choice of the other-regarding agent will equate his monetary payoff with the principal, i.e.,

$$w + b(e, w) - \frac{1}{2}e^2 = e - w - b(e, w). \quad (8.57)$$

It turns out that (8.57) is satisfied for any value of e (because the choice of $b(e, w)$ ensures that payoffs are equated ex-post). Hence, the payoff of the other-regarding agent is identical to that of a self-regarding agent and is given by $U = w + b(e, w) - \frac{1}{2}e^2$. Substituting $b(e, w)$ from (8.56), we get $U = \frac{1}{2}e - \frac{1}{4}e^2$. Clearly this payoff is also maximized at $e_F^b = 1$.

Given that the Stage 3 bonus plays the same role as a wage, and is offset one for one with the wage, we can focus on the case where the Stage 1 wage offer of the principal is zero. Since the other-regarding and the self-regarding agents both put in the maximal effort level, the other-regarding principal's expected payoff in a bonus contract is $E\Pi = e - b(e, w)$, which is independent of λ . On substitution of $e = 1$, $w = 0$ and (8.56), the expected profit in a bonus contract is given by

$$E\Pi_F^B = \frac{1}{4}. \quad (8.58)$$

We summarize these results below.

Proposition 8.34 *In a bonus contract, when the principal is other-regarding, the self-regarding and the other-regarding agents exert identical effort levels equal to 1, i.e., $e_S^b = 1 = e_F^b = 1$. The expected profit of the principal is $E\Pi_F^B = \frac{1}{4}$.*

COMPARISON OF PROFITS UNDER THE THREE CONTRACTS

Does the other-regarding principal prefer an incentive contract or a bonus contract? The answer depends on the parameters and there are many possibilities. Classical contract theory under self-regarding preferences predicts that the incentive contracts should always dominate. We consider only one example here, in which bonus contracts dominate all others. Using Proposition 8.33, and (8.58), when $\sqrt{2pf} \geq 1$,

$$E\Pi^I \geq E\Pi_F^B \text{ as } \frac{1}{4} \geq k,$$

and when $\sqrt{2pf} < 1$

$$E\Pi^I \geq E\Pi_F^B \text{ as } \sqrt{2pf} - pf \geq \frac{1}{4} + k. \quad (8.59)$$

Thus, the incentive contract dominates the bonus contract when (1) the deterrence parameters p, f are high enough, so that hard evidence of shirking is discovered with high enough probability and then punished with severe enough consequences, and (2) the cost of the monitoring technology, k is low enough. When $\lambda > \frac{1}{2}$ the trust contract is not offered by either an other-regarding or a self-regarding principal (see Remark 8.3). In this case if $k > \max\{\frac{1}{4}, \sqrt{2pf} - pf - \frac{1}{4}\}$, then the bonus contract dominates all other contracts.

These results are only illustrative of the departures one gets from the standard model when individuals have other-regarding preferences. A classical game theorist might argue that the existence of non-competitive rents embodied in wage levels above the market level can equally well be explained using infinitely repeated games between purely self-regarding firms and workers. However, such arguments are not persuasive on empirical grounds. (1) The evidence strongly confirms the existence of economic agents who exhibit other-regarding preferences; much of Part 2 of the book attempts to establish the relevant evidence base. (2) The model with other-regarding preferences generates these results without the machinery of repeated games and reputation formation. One can then design appropriate experiments to test the relative merit of these two alternative explanations, a task that we turn to in the next section.

8.3.3 Evidence on contract choice under contractual incompleteness

Fehr et al. (2007) examine, experimentally, the choice between incentive, trust, and bonus contracts. They ran several sessions with 10 periods in each session and 20–24 individuals in each session. Agents are randomly matched with a different principal in each period. When principals are given a choice between trust and incentive contracts (the TI treatment), there is a strong trend towards the incentive contracts over successive rounds of the experiment. In the final three periods, more than 80% of all contracts offered were incentive contracts. Trust contracts were tried in one of the rounds by at least 70% of the principals but were not preferred. Effort was significantly higher in the incentive contracts relative to the trust contracts.

Profits were negative, on average, in the incentive contracts because the majority of the incentive contracts, 58.5%, violated the no-shirking constraint in (8.53). Most principals used the maximum fine and asked for an effort level that was too ambitious. However, the demanded effort fell over time and the share of incentive compatible contracts increased with time. The incentive-compatible incentive contracts are more profitable than the trust contracts but the non-incentive compatible ones are less profitable than trust contracts. The trust contracts in Fehr et al. (2007) do not perform as well as those in Fehr et al. (1993). A potential reason is that effort–wage relation is far steeper in the latter and the set of effort choices is discrete.

When principals are given a choice between bonus and incentive contracts (the BI treatment), then the overwhelming majority of principals chooses the bonus contract. The results, averaged across all sessions, are shown in Figure 8.1. From period 6 onward, the bonus contract is chosen in approximately 90% of the cases and approaches 96% in the final period. In the BI treatment, in the bonus contract, the average effort level is relatively higher and the gap between the demanded and actual effort is the lowest.

On average, the principal's profit in the bonus contracts is about 4 times higher. Roughly 40% of the compensation of agents is paid out as a bonus by the principal. The principals are not fully

Figure 8.1 Share of bonus contracts and incentive contracts over successive rounds.

committed to their announced bonuses. Rather, the actual bonus paid out depends heavily on the effort level of the agent, as shown in Figure 8.2. In conclusion, across all three contractual forms, the principals strongly prefer the bonus contract to the other contracts.

Fehr and Schmidt (2007) address one shortcoming of the Fehr et al. (2007) paper. They allow principals to combine a voluntary bonus (the carrot) with an incentive contract that allows for fines (the stick). It was hoped that this more general contract would probably perform the best. However, they found that two-thirds of the principals still preferred the pure bonus contract to the more general contract and the latter did not elicit greater effort.

A lower bonus is offered in the combined contract as compared to a bonus contract alone. Since agents might not know the type of the principal, they may take the choice of a combined contract by the principal as a signal that the principal is self-regarding and, so, less likely to offer a bonus. In anticipation, agents put in a low level of effort, which leads to lower profits in the combined contract relative to the bonus contract. The belief that principals who are less fair are also the ones more likely to choose the more general contract and less likely to pay a bonus is confirmed in the experimental findings.¹⁴ This evidence further underpins assumption A2 in the theoretical model made above.

The evidence in Fehr et al. (2007) indicates that implicit contracts were chosen in 88% of the cases even when an explicit contract was available. Implicit contracts also elicited higher effort and were more profitable. The key to the success of the implicit contracts was the mutual

¹⁴ In an insightful paper, Bénabou and Tirole (2003) consider the conflict between *intrinsic* and *extrinsic* motivation as a result of asymmetric information in a principal-agent framework. They find conditions under which incentives will or will not be an effective instrument. For instance, roughly paraphrased, one of their results is that incentives may crowd out intrinsic motivation when the principal is better informed and the agent has low ability in performing a task. Under these conditions, giving the agent a high-powered incentive may lead the agent to infer that his ability is actually low, which may be demotivating. These results also have a bearing on the difference in experimental practice in economics and psychology. Experimental economists emphasize the role of incentives, or extrinsic motivation, while experimental psychologists emphasize the role of intrinsic motivation and downplay the use of incentives in experiments. Most of the experimental results that we report are conducted under full information, so they are not suitable to test or apply the results of Bénabou and Tirole (2003).

reciprocity of the principal and the agent. For instance, reciprocal principals were expected to honor their promise to pay a bonus, hence, eliciting greater effort. Explicit contracts might on the other hand be perceived to be hostile, so they elicit lower effort.

Suppose that there are two parties to a contract and at least one party must make relation-specific investment in the relationship. An influential view in the property rights approach predicts that the institution of *joint ownership* will hamper short-term *relation-specific investment* because each party will fear that, ex-post, its investment will be held up by the other party (Hart, 1995). One proposed solution is to vest *residual control rights* in the hands of the party that makes the investment in the physical asset (Grossman and Hart, 1986).

A simplified version of the Grossman and Hart (1986) framework is considered in the two-player experiments conducted by Fehr et al. (2008). In the first stage, one or both players are asked to choose the form of their relationship, e.g., *single* or *joint* ownership (see below). In the second stage, the two players, A and B, make respective investments, $a, b \in \{1, 2, \dots, 10\}$, that lead to a joint surplus $v(a, b)$. The cost of the investment equals the level of the investment. Investments are made sequentially: B invests first, followed by A who observes B's investment decision before choosing his own investment. Two possible regimes are considered.

1. Under *A-ownership*, A hires B on a fixed wage contract that pays a wage w . Net of the respective investments, the payoffs of A and B are respectively given by $v(a, b) - a - w$ and $w - b$.
2. Under *joint ownership*, each player gets one half of the total surplus, net of their respective investment costs. So the respective payoffs of A and B are: $\frac{1}{2}v(a, b) - a$ and $\frac{1}{2}v(a, b) - b$.

The game has been set up in such a way (by an appropriate choice of $v(a, b)$) that the first best levels of investments are $a = b = 10$. The predictions of the standard incomplete contracts model for self-regarding preferences are as follows. Under A ownership, B has no incentive to invest, so b takes its lowest value, $b = 1$. Under joint ownership, each individual has to share half the marginal return with the other party. Given the setup of the problem, this induces the lowest possible investment for each player $a = b = 1$.¹⁵

The predictions of the model with self-regarding preferences are rejected by the experimental evidence. Player A chooses joint ownership in more than 80% of the cases. The respective investment levels chosen by the players, on average, under joint ownership, are $a = 6.5$ and $b = 8.9$. Furthermore, A earns more, on average, if he chooses joint ownership, relative to A ownership. The explanation is that joint ownership is more conducive to reciprocal behavior. Player B expects A to behave reciprocally. This would be true even if player B is self-regarding but knew that the other player has other-regarding preferences. Such expectations (which are fulfilled in equilibrium) induce player B to invest.

To summarize: the experimental evidence shows that incentive contracts are often outperformed by bonus contracts; incentive contracts can be viewed as hostile; and the institution of joint ownership can tap into the reciprocity of economic agents rather than holding up investment through opportunistic channels.

Suppose that n ex-ante identical agents work in a team for a principal and everyone has self-regarding preferences. Each of the n agents undertakes a sub-project, whose success is guaranteed by working hard; under shirking, the sub-project succeeds with probability $0 \leq p_i < 1$.

¹⁵ Essentially, A's choice of $a = a(b)$ is given from $0.5v_a(a(b), b) = 1$. Substituting in the first stage, the optimal choice of b is found from $0.5 \left[v_a(a(b), b) \frac{da}{db} + v_b(a(b), b) \right] = 1$. For the functional forms chosen in the experiments, it turns out that $a = b = 1$.

Effort on the sub-project or its outcome cannot be contracted on. Each sub-project is part of a grand project whose success can be verified by all parties, hence, the wage vector of the n agents, $(w_1, w_2, \dots, w_n)$, is conditioned solely on its outcome. Let $0 \leq \hat{n} \leq n$ agents work hard on their sub-projects. Then the probability that the grand project succeeds is $p(\hat{n})$ where p is an increasing and convex function. The aim of the principal is to minimize aggregate wage payments such that all the agents find it incentive compatible to work hard.

Under these conditions, Winter (2004) showed that it is optimal to pay unequal wages for equal work. Thus, wage inequality (or discrimination) among agents is efficient. The intuition is along the following lines. Since effort has the nature of a public good, agents would wish to free-ride on the effort levels of others. Each agent, if rational, can foresee this. Hence, he may withhold costly effort because if others do not work hard, the project is unlikely to succeed, which, in turn, does not justify his effort. If some agents are paid high enough discriminatory wages, so as to raise their stakes in the success of the grand project, the remaining agents feel sufficiently reassured to also work hard. Thus, discrimination in wages allows agents to coordinate their beliefs on the success of the grand project. Conditional on these beliefs, they indeed work hard, which fulfills the original beliefs.

Cabrales et al. (2010) and Goerg et al. (2010) report experimental support for this framework. The experiments show that efficiency is lower under equal pay for equal work, relative to pay discrimination. However, the experimental results of Abeler et al. (2010) that we have examined in Chapter 6 show that equal pay for unequal effort levels reduces effort levels in subsequent rounds and reduces output.

In actual practice, the implementation of a discriminatory wage scheme may run into difficulties with various employment legislations.¹⁶ A more fundamental concern with this approach is that other-regarding preferences have been widely documented, not only in experimental games (Part 2 of the book is a testament to this claim) but also in a range of principal-agent situations. Insofar as principals can rely on the other-regarding preferences of even a fraction of the agents, or on their reciprocity, the optimal contracts are likely to be markedly different. Indeed, the empirical contracts in Cabrales et al. (2010) and Goerg et al. (2010) concentrate on a narrow range of contracts that rule out reciprocity-based contracts such as bonus and trust contracts, which are found to be efficacious, as the evidence in this section suggests.

There might be substantial heterogeneity with respect to worker characteristics such as their risk aversion and other-regarding preferences. Will workers of different productivity levels and different personal characteristics self-select or sort themselves into fixed wage contracts and incentive contracts (such as piece rate wages, tournaments, or revenue sharing)? It is quite difficult in field studies to observe the sorting decision. Hence, it is not clear if the observed positive effects of incentives on effort are the result of pure-incentive effects or the result of sorting of more productive workers into incentive contracts. By contrast, experiments allow a clean separation of these different motives.

Dohmen and Falk (2011) address these questions within a novel experimental design. They find that more productive workers self-select themselves into incentive schemes relative to fixed wage schemes. Output and effort are higher under the incentive contracts but these effects are driven largely by the sorting effects of workers. Furthermore, more risk averse subjects, and women, are

¹⁶ However, it is possible that firms may find other means of engaging in such practices. For instance, non-pecuniary discrimination or seniority based pay, etc. However, non-pecuniary discrimination and seniority based pay have other well-known sources also.

more likely to self-select themselves into the fixed wage contract. Somewhat surprisingly, other-regarding preferences play only a marginal role in the self-selection decision.

Dohmen and Falk (2011) assume that it is not possible for firms to know the relevant traits of potential employees, hence the use of contractual form as a screening device. Englmaier et al. (2014) give the complementary argument that several proxies about the characteristics of workers are available to firms. These include the CV of the workers (firms might shortlist, say, 4 candidates from an application pool of 100), ability, personality tests, and interviews.¹⁷

In a novel set of experiments, Englmaier et al. (2014) first elicit the productivity and reciprocity parameters of individuals. Productivity is elicited by giving subjects a real effort task that requires matching words to a four digit code in a list. Reciprocity is elicited by the degree of *trustworthiness* in a trust game. Firms may be given no information (treatment N), only information about trust (treatment T), only information about productivity (P), or information about productivity and trust (treatment PT). Once the relevant information (which includes no information in treatment N) is given to the firm, the firm and the worker play a standard gift exchange game. One can then compare the wage, effort level, and profit level of the firm in each treatment.

The results are as follows. There is a substantial wage premium for productivity and trust. More productive and more trustworthy subjects receive significantly higher wages. However, the wage premium for productivity is twice as large as the premium for trust. In regression analysis, with the effort level of the worker as the dependent variable, once the wage is included as an explanatory variable, then productivity and trust add no further explanatory power. The reason is that wages are endogenous, and they correctly incorporate the effects of productivity and trustworthiness. Firms make the highest profits when the workers have both desirable features, productivity and trust. More trustworthy workers also induce a smaller variation in the profits and output levels of the firm.

8.4 Reciprocity and long-term contracts

The explanation of the structure of long-term relations, say, between firms and their suppliers, is of fundamental importance in industrial organization. Consider infinitely repeated games in which considerations of future costs and benefits of current actions give rise to *instrumental reciprocity*. In addition, suppose that individuals also exhibit *intrinsic reciprocity*. What is the interaction between these two different types of reciprocity? For instance, are these two types of reciprocity complementary or substitutes? These issues are addressed by Brown et al. (2004), which we now consider.

A repeated experiment was performed with 15 trading periods and 238 subjects who were assigned to play either the role of a firm or a worker. To model the importance of issues of reputation formation, each firm and worker were assigned an *ID* number. Each firm could only hire one worker in any period. Any period consisted of two subperiods. In the first subperiod, a firm could offer a contract (w_b, e_n, ID) , i.e., the contract specifies a *binding* wage level, w_b , a *non-binding* effort level, e_n , and the firm's identification number, *ID*. Firms can make either a *public offer* (open to all workers) or a *private offer* (open only to a worker with a particular *ID*

¹⁷ For instance, in the hiring process for academics in universities, the ability and personality characteristics are sought to be discovered through references, CV, one-to-one meetings with staff, job talk in the department, and interviews with committees.

number). In each period, and in each treatment, there were ten workers and seven firms, so there was always an excess supply of workers.

The experiments considered the following three treatments.

1. In the complete contracts condition, or *treatment C*, there is third party enforcement, i.e., the experimenter makes sure that the contracted effort level is always honored. Thus, the contracted effort level, e_n , equals actual effort level, e_a .
2. In the incomplete contracts condition, or *treatment ICF*, there is no third party enforcement of the contract, so it is possible that $e_n \neq e_a$.

In each of these two treatments, there is the possibility that the firm hires the same worker for more than one period, which constitutes a *long-term relation*. Hence, long-term relations, if they are observed, are purely endogenous.

3. To better understand the effectiveness of long-term relations, a control treatment, *treatment ICR*, is introduced. This is identical to treatment ICF, except that long-term relations are ruled out. In the actual experiments, this was achieved by jumbling the ID numbers of players at the end of each period, so that firms could not guarantee hiring the same worker through private offers even if they wanted to.

In the event of a successful contract between a firm and a worker, the payoff of the self-regarding firm, π , and the self-regarding worker, u , are respectively

$$\pi_s = 10e - w; u_s = w - c(e). \quad (8.60)$$

The cost function of effort, $c(e)$, is increasing and convex; it is shown in Table 8.1.

If a firm or a worker is unable to enter into a contract with the other party, then their respective payoffs are $\pi_s = 0$, $u_s = 5$, where the worker's outside option, e.g., unemployment benefits, is given by 5. Thus, the total social surplus in the worker–firm relationship (net of the worker's outside option) is given by

$$S = \pi_s + u_s - 5 = 10e - c(e) - 5. \quad (8.61)$$

8.4.1 The outcome with self-regarding preferences

We consider self-regarding preferences first, followed by other-regarding preferences in the next section.

Lemma 8.14 *The socially efficient level of effort in any period is given by $e = 10$.*

Proof: In any period, marginal benefit of a unit of effort is 10, while the highest marginal cost is 3 (see Table 8.1). Further, the payoffs are independent across periods. Hence, in any period, it is optimal to choose the highest effort level, $e^* = 10$. ■

Table 8.1 The cost of effort function.

e	1	2	3	4	5	6	7	8	9	10
$c(e)$	0	1	2	4	6	8	10	12	15	18

Source: Brown et al. (2004).

Lemma 8.15 *In the ICF and ICR treatments, in any pairwise interaction, and in every period, the worker chooses the lowest effort level $e_I = 1$ and the firm pays a wage $w_I = 5$. The total social surplus $S_I = 5$ is reaped entirely by firms.*

Proof: Effort is not enforceable by a third party in the ICF and ICR treatments, workers receive a binding wage, w_b , and there is full information in each of the finite number of periods. Consider the last period. Self-regarding workers choose the least possible effort, i.e., $e_I = 1$. Anticipating this, firms choose a wage rate to ensure that the workers get no more than their outside option, so $w_I = c(1) + 5 = 5$. Substituting $w_I = 5$, $e_I = 1$ in (8.61) and using Table 8.1 we get that $S_I = 5$. However, since workers simply get their outside option, the entire surplus is reaped by firms. Now consider the penultimate period. In this period, the matching of firms and workers may be different but the solution is identical to that in the last period. Continuing backwards in this manner, we obtain an identical solution in each period. ■

Lemma 8.16 *In the complete contracts treatment, treatment C, in every period, the optimal effort level is $e_c = 10$, wage is $w_c = 23$ and the surplus is $S_c = 77$.*

Proof: A third party, the experimenter, ensures that the contracted effort level in treatment C is binding. Consider the last period. As in the proof of Lemma 8.14, it is optimal to induce the highest effort level. The wage must now ensure that the worker's individual rationality constraint is satisfied, so $w_c = c(10) + 5 = 23$. Substituting $e_c = 10$ in (8.61) and using Table 8.1 we get that $S_c = 77$. By backward induction, the same outcome occurs every period.

Lemma 8.17 *Under self-regarding preferences, firms are indifferent between making private and public offers in the three treatments, C, ICF, ICR.*

Proof: Since there are no issues of reputation building, there is no additional gain from hiring a worker more than once. In any period, any worker is as good as another. Hence, private offers are just as good as public offers. ■

8.4.2 The outcome with other-regarding preferences

Suppose that at least some workers have other-regarding preferences of the Fehr–Schmidt form (FS). Recall that there are 15 trading periods. We make the following assumptions.

- A1. In any period, each individual compares his/her payoffs only with their trading partner. Thus, if i, j are trading partners, with respective material payoffs x_i and x_j , the FS utility of player i is:

$$U_i = x_i - \alpha_i \max \{x_j - x_i, 0\} - \beta_i \max \{x_i - x_j, 0\}. \quad (8.62)$$

- A2. $\alpha_i = \beta_i = 0.5 + \epsilon$ where ϵ is some small but strictly positive number.
A3. By giving up a dollar, each player can punish the trading partner by an amount $\delta > 1 + \frac{1}{0.5+\epsilon}$.
A4. 60% of all players are other-regarding, while 40% are purely self-regarding (this is roughly consistent with some of the empirical evidence reviewed in Chapter 12).
A5. Other than in treatment ICR, in any period, firms can choose to fire the existing worker or hire the worker for the next period.
A6. There is no discounting of future payoffs.

Lemma 8.18 *Under assumptions A1–A6, if players have other-regarding preferences, they prefer to equalize payoffs with their trading partners.*

Proof: Suppose first that $x_j > x_i$. Using (8.62), the payoff of player i is $U_i = x_i - \alpha_i (x_j - x_i)$. Suppose that player i now gives up n units to punish the trading partner in order to equate payoffs, i.e., $x_j - n\delta = x_i - n$. Thus, $n = \frac{x_j - x_i}{\delta - 1}$. The post-punishment payoff of player i is $U_i = x_i - n = x_i - \frac{x_j - x_i}{\delta - 1}$. Given the original supposition that $x_j > x_i$, an equalization of payoffs improves player i 's utility if $x_i - \frac{x_j - x_i}{\delta - 1} > x_i - \alpha_i (x_j - x_i)$ or $\alpha_i > \frac{1}{\delta - 1}$. Substituting $\alpha_i = 0.5 + \epsilon$ we get the condition $\delta > 1 + \frac{1}{0.5 + \epsilon}$, which is true by assumption A3 above.

Now suppose that $x_j < x_i$. Using (8.62), the payoff of player i is $U_i = x_i - \beta_i (x_i - x_j)$. In order to equalize payoffs, suppose that player i makes a transfer of $(x_i - x_j) / 2$ to player j . The post-transfer payoff of player i is $U_i = x_i - \frac{x_i - x_j}{2}$. It is worth making the equalizing transfer if $x_i - \frac{x_i - x_j}{2} \geq x_i - \beta_i (x_i - x_j)$, which holds because $\beta_i > \frac{1}{2}$. Thus, both players find it optimal to equalize payoffs. ■

THE SOLUTION UNDER ASYMMETRIC INFORMATION

The remaining theoretical discussion is entirely organized around Proposition 8.35 below, which collects all the relevant results in this section. Workers have asymmetric information about the type of the firm; the type of the firm can be self-regarding or other-regarding. Prior to hiring a worker, firms also do not know if the worker is self-regarding, although, from assumption A4, they know that 60% are other-regarding and 40% are self-regarding. Thus, there is two-sided asymmetric information. Let us first offer the insights that underpin Proposition 8.35.

The finite period setup is realistic (e.g., because workers eventually retire). It also allows the workers' types to separate in the last period because self-regarding workers will always shirk in the last period. Since other-regarding workers respond to higher wages with higher effort (as in gift exchange games), the firm may find it profitable to offer rents to the workers. While self-regarding workers do not *intrinsically reciprocate*, however, the attractiveness of rents also induces them to *instrumentally reciprocate*. Hence, self-regarding workers would like to build a reputation for reciprocity and enjoy rents—they milk this reputation for as long as it is possible in the finite horizon game. This behavior suits other-regarding firms because profits are increasing in the effort levels of workers. Thus, *reputation effects interact in an important manner with reciprocity effects*.

The possibility that a fraction of the workers are other-regarding (assumption A4) means that even in the last period of the game, the firm can offer rents to the workers and, rationally, hope that other-regarding workers will respond with greater effort. Consider a self-regarding worker in the penultimate period of the game. If the worker shirks, then he will be fired, hence, he will be unable to avail himself of the last period rents. The contract offered in the penultimate period must ensure that the current gain to shirking of the self-regarding worker is smaller as compared to the expected future loss of rents, as in models of efficiency wages (Shapiro and Stiglitz, 1984).

Such repeated contracts that satisfy incentive compatibility in each period, provide the necessary inducement for self-regarding workers to put in greater effort. This, in turn, facilitates the endogenous formation of long-term contracts and we can expect the ICF treatment to foster greater effort and rents relative to the ICR treatment, which does not allow long-term relations. One may, thus, also expect a higher share of private offers relative to public offers in the ICF treatment.

Why does the firm not offer very low rents in the penultimate period? The reason is that it will then be perceived as being self-regarding itself and workers with other-regarding preferences would react negatively to lower wages offered by reducing their effort. As is typically the case with repeated games, there are a large number of equilibria. Finally, in treatment C, because the contracts are always enforced with the help of a third party, there is no need to give any incentives or rents. And there is no need to form long-term relations either. So one would expect a preponderance of public offers in treatment C.

We now use these insights to formalize the relevant results in Proposition 8.35.

Proposition 8.35 *Consider two-sided asymmetric information in which the type of the firm and the worker (self-regarding or other-regarding) is private information. The game is played over 15 periods and the outside option of any worker is 5. Assumptions A1–A6 hold. In the perfect Bayesian equilibrium of the model:*

- I. *The strategy of the other-regarding and the self-regarding workers is as follows:*
 - (a) *Other-regarding workers choose their effort levels to equalize payoffs with their trading partners every period and are willing to work if their individual rationality constraint is satisfied.*
 - (b) *Faced with a contractual, but non-binding, effort level, e_n , self-regarding workers choose to shirk (i.e., choose $e < e_n$) in any period if the cost of effort, $c(e_n)$, is more than the expected loss from being fired.*
- II. *The strategy of the other-regarding and self-regarding firms is as follows:*
 - (a) *Firms renew the contract of a worker in period t if in period $t - 1$ the worker put in $e = e_n$. Otherwise the worker is fired and earns his outside option in all future periods. Public offers are made by the firm in the first period and in any period following the decision of workers to shirk ($e < e_n$).*
 - (b) *Both types of firms (self- and other-regarding) engage in a pooling contract for the first 14 periods but offer separating contracts in the 15th period. In periods 1–13, the contract offered is $(w_b, e_n) = (59, 10)$. In period 14, the contract offered is $(w_b, e_n) = (40, 7)$. If $e = e_n$, then the payoffs of the firm and the worker are equalized in the first 14 periods. In period 15, the self-regarding firm offers the contract $(w_b, e_n) = (34, 6)$ but it is not unique. The other-regarding firm offers the contract $(w_b, e_n) = (5, 1)$.*
- III. *The out of equilibrium beliefs are as follows:*
 - (a) *All workers believe that the firm will terminate employment in period $t + 1$ if it does not pay a fair wage (that equalizes payoffs) in period t .*
 - (b) *Higher average effort levels can be sustained in the ICF treatment relative to the ICR treatment. Long-term relations arise endogenously in the ICF treatment and there are greater private offers in the ICF treatment relative to the ICR treatment.*

Proof: Consider self-regarding firms first. From Lemma 8.18 we know that an other-regarding worker will always equalize payoffs, i.e.,

$$10e - w = w - c(e). \quad (8.63)$$

Denote the solution to this equation by $e(w)$; this is the effort reaction function of the agent. For pedagogical convenience we abuse notation by writing $c'(e)$ for the marginal cost of effort, although the effort levels are actually discrete. Using (8.63),

$$\frac{de(w)}{dw} = \frac{2}{10 + c'(e)} > 0, \quad (8.64)$$

hence, other-regarding workers will always reciprocate a higher wage offer with higher effort, as in gift exchange games.

We solve the game using backward induction.

(1) Consider first, the last period, period 15: Given the stated strategies in the proposition, a pooling equilibrium is played in the first 14 periods, hence, the type of the firm, other-regarding or self-regarding, is not revealed to the workers. Using (8.60) and assumption A4, the expected payoff of a self-regarding firm is given by

$$E\pi_s = 0.6 [10e(w) - w] + 0.4 [10 - w]. \quad (8.65)$$

The other-regarding worker reciprocates higher wage with higher effort (8.64). But the self-regarding worker chooses to shirk and put in the minimum effort level, $e = 1$, because it is the last period. Differentiating (8.65) with respect to w and using (8.64) we get

$$\frac{\partial E\pi_s}{\partial w} = \frac{12}{10 + c'(e)} - 1. \quad (8.66)$$

Since the cost of effort function is weakly convex throughout, for an interior solution, solving (8.66) gives $c'(e) = 2$. From Table 8.1, $c'(e) = 2$ for all effort levels in the set $\{3, 4, \dots, 8\}$, hence, we have multiple equilibria. Let us choose the particular solution $e = 6$. To induce the other-regarding worker to undertake an effort level $e = 6$, the wage must be such that the payoffs of the worker and the firm are equalized (see Lemma 8.18). Substitute $e = 6$, $c(6) = 8$ in (8.63) to get $w = 34$. Hence, the (non-unique) contract offered by the self-regarding firm in period 15 is $(w_b, e_n) = (34, 6)$.

Since a pooling equilibrium is played in the first 14 periods, the type is unknown at the start of period 15. The expected payoff of the self-regarding firm $E\pi_s$ is given in (8.65). The payoff of the worker is $u = w - c(e)$. Using (8.62), the utility of an other-regarding firm is given by

$$\pi_f(k) = \pi_s - \alpha_f \max\{u_k - \pi_s, 0\} - \beta_f \max\{\pi_s - u_k, 0\},$$

where $k = f, s$ is the type of the worker—other-regarding or self-regarding—and π_s denotes the self-regarding material payoff of the firm, given in (8.60). Using assumption A4, the expected profit of the other-regarding firm from the contract (w_b, e_n) is given by

$$E\pi_f(w_b, e_n) = 0.6\pi_f(f) + 0.4\pi_f(s). \quad (8.67)$$

What is the optimal contract offered by the other-regarding firm in the last period? One can show that the other-regarding firm will prefer the contract $(w_b, e_n) = (5, 1)$ to any other contract that induces an effort level from the other-regarding worker belonging to the set $\{3, 4, \dots, 8\}$. Recall that this is the set of effort levels that the self-regarding firm finds it optimal to induce from the other-regarding worker. The self-regarding worker, of course, only puts in the minimum effort level $e = 1$ in period 15 because there is no future to worry about. We show that it is non-optimal for the other-regarding firm to elicit the effort level $e = 3$ (a similar check can be made against the other effort levels, i.e., 4, 5, $\dots$, 8).

Suppose first that the other-regarding firm offers the contract $(w_b, e_n) = (5, 1)$. It is simple to check that the other-regarding worker also chooses the same effort as a self-regarding worker, i.e., $e = 1$, because it equalizes the payoffs with the firm (see Lemma 8.18) and ensures that the individual rationality constraint is met (recall that the outside option of the worker is 5). Since both types of worker choose $e = 1$, using (8.67), we get that, corresponding to the contract $(w_b, e_n) = (5, 1)$, the expected profit of the other-regarding principal is

$$E\pi_f(5, 1) = 5. \quad (8.68)$$

Let us now compute the payoff of the other-regarding firm from the contract $(w_b, e_n) = (w_b, 3)$, where the non-contractible effort level is $e_n = 3$. The actual effort level supplied by the self-regarding worker $e_a = 1$ because it is the last period. What level of wage, w_b , does the firm need to offer, so that the other-regarding worker chooses $e = 3$? Since the other-regarding agent equalizes material payoffs with the principal, substitute $e = 3$, $c(3) = 2$ in (8.63) to get $w_b = 16$. Substitute $w_b = 16$, $e = 3$ in (8.65) to get:

$$E\pi_s = 0.6 [10 \times 3 - 16] + 0.4 [10 - 16] = 6. \quad (8.69)$$

The respective payoffs of the self-regarding and other-regarding workers are $16 - c(1) = 16$ and $16 - c(3) = 14$. It is simple to calculate that $\pi_f(f) = 14$ and $\pi_f(s) = -6 - 22\alpha_f$. Thus, we get the payoff of the other-regarding firm as

$$E\pi_f(16, 3) = 0.6 \times 14 + 0.4 (-6 - 22\alpha_f). \quad (8.70)$$

Comparing (8.68), (8.70), $E\pi_f(5, 1) > E\pi_f(16, 3) \Leftrightarrow 5 > 6 - 8.8\alpha_f \Leftrightarrow 8.8\alpha_f > 1$, which holds because $\alpha_f > 0.5$ (assumption A2). Hence, the contract $(5, 1)$ dominates the contract $(16, 3)$ for the other-regarding firm. A similar exercise shows that it is not optimal for the other-regarding firm to induce any effort level other than $e = 1$.

We conclude that in period 15, the self-regarding firm offers $(w_b, e_n) = (34, 6)$, while the other-regarding firm offers $(w_b, e_n) = (5, 1)$. Thus, the two types of firms offer a separating contract in period 15.

(2) Now consider period 14: Workers do not know the type of the firm. But given the strategies, they are aware of the contracts that will be offered in period 15 by both types of firms. From assumption A4, they know the respective proportions of the types of the firms. Hence, the expected future payoff of other-regarding workers, $E\pi_f$, from not shirking in period 14, so ensuring that they get hired by the same firm in period 15 is

$$E\pi_f = 0.6(5 - c(1)) + 0.4(34 - c(6)) = 13.4. \quad (8.71)$$

A self-regarding worker, on the other hand, will put in $e = 1$ in period 15, hence, his expected future payoff, $E\pi_s$, from not-shirking in period 14 is

$$E\pi_s = 0.6(5 - c(1)) + 0.4(34 - c(1)) = 16.6.$$

If the worker shirks in period 14, then given the strategies in the proposition, he is fired and earns his outside option of 5. So the expected future net gain from not-shirking in period 14 for the

other-regarding and self-regarding workers is respectively $13.4 - 5 = 8.4$ and $16.6 - 5 = 11.6$. Since the worker receives a binding wage, the current gain to a self-regarding worker from shirking in period 14 is $c(e_n) - c(1) = c(e_n)$ (from Table 8.1, $c(1) = 0$) where e_n is the non-binding effort level in period 14. Hence, the self-regarding worker shirks if the current gain from shirking is greater than the expected future loss from shirking, i.e.,

$$c(e_n) > 11.6. \quad (8.72)$$

From Table 8.1, the set of effort levels which satisfy this inequality is $\{8, 9, 10\}$. Hence, in period 14, any effort level $e \leq 7$ will induce no-shirking from the self-regarding worker. A higher effort level leads to greater output and an other-regarding worker equalizes payoffs. Hence, inducing a higher effort level from the set of incentive-compatible effort levels for the self-regarding worker allows the principal to enjoy a higher payoff. Thus, it is optimal for the firm to induce $e_n = 7$ in period 14.

Using (8.63) and Table 8.1, the firm has to then pay a payoff equalizing wage $w_b = \frac{10 \times 7 + c(7)}{2} = 40$. Why is it not optimal to pay $w > 40$? If $w > 40$, then other-regarding workers will reciprocate with extra effort, however, self-regarding workers will not reciprocate because their no-shirking constraint will be violated. But does the extra effort from other-regarding workers make it worthwhile to offer $w > 40$? The answer is in the negative. The firm makes no additional profits from self-regarding workers. The extra profit made on account of the other-regarding workers is $\frac{d}{dw} (10e(w) - w)$, which when evaluated at $e = 7$ gives $\frac{20}{12} - 1 = 0.67$. However the extra wage cost on account of the self-regarding workers is 1. Hence, the net change in expected profit is $-1 + 0.67 = -0.33 < 0$. It is also not optimal to pay $w < 40$. Given out of equilibrium beliefs, $w < 40$ is construed as an unfair wage, hence, the expectation is that workers will not be rehired by the firm for period 15. But this induces full shirking from workers in period 14. Hence, $w_b = 40$ is the optimal wage for period 14.

The firm must also make a private offer to the worker at the end of period 14. If it did not do this, then there is a (large) possibility that the current worker will not be rehired. This dilutes the incentives of the worker to work in period 14.

(3) Let us now focus on period 13: Workers know (from the firm's stated strategy) that for period 14, the pooling contract offered is $(w_b, e_n) = (40, 7)$, while for period 15, with probability 0.6, the firm is other-regarding and offers the contract $(w_b, e_n) = (5, 1)$, while with probability 0.4 the firm is self-regarding and offers the contract $(w_b, e_n) = (34, 6)$. The expected future rent (in periods 14 and 15) to a self-regarding worker who does not engage in shirking in period 13 is

$$[40 - c(7) - 5] + [0.6(5 - c(1)) + 0.4(34 - c(6)) - 5] = 33.4. \quad (8.73)$$

The two square brackets capture expected rents in periods 14 and 15 respectively. Analogous to (8.72), the self-regarding worker will shirk in period 13 if

$$c(e_n) > 33.4.$$

Hence, from Table 8.1, the set of effort levels that will not induce shirking is the entire set, i.e., $\{1, 2, \dots, 10\}$. Since additional effort is valuable for the firm, in order to induce an other-regarding worker to supply $e = 10$, the firm must offer a payoff equalizing wage $w_b = \frac{10 \times 10 + c(10)}{2} = 59.0$. It is, therefore, optimal to offer the contract $(w_b, e_n) = (59, 10)$ in period 13. Using backward induction it is optimal to offer this contract also in the first 12 periods.

Since only one-shot interactions take place in the ICR treatment, the maximum effort level $e = 10$ cannot be sustained in this condition. Finally, accepting a wage equal to the outside option in period 15 is rational for an other-regarding worker because there is an oversupply of workers. If some of them are perceived to be self-regarding workers who will accept the outside option, then an other-regarding worker cannot punish the firm by rejecting a low offer. ■

8.4.3 Experimental results

The experimental results are in line with the predictions of the theoretical model (Proposition 8.35). These results are as follows:

1. The relative share of private offers is substantially greater in the ICF treatment relative to the ICR and the C treatments. Furthermore, most of the private offers (63–79% after period 5) are made to workers already working for the firm. Hence, voluntary long-term relations are maintained through private offers when there is an opportunity to do so.
2. As predicted, about 90% of the trades in treatment C took place in interactions that lasted for one or two periods only. This contrasts with the ICF condition where only a third of the trades took place in one-shot encounters. About 50% of the trades in the ICF condition took place in relationships that lasted four or more consecutive periods and about 40% in relationships that lasted eight or more consecutive periods. The separation rate between workers and firms declined significantly after period 3, suggesting the possibility of a search phase for a good match in the initial periods. A comparison of the length of the relationship under the two treatments is shown in Figure 8.3, which plots the cumulative frequency of the length of relations. The cumulative distribution function under treatment ICF first order stochastically dominates the distribution function under treatment C.
3. Under the ICF treatment, firms pay a rent to workers in order to induce them to put in the contracted effort level. Since rents enhance effort, due to the gift exchange mechanism, they can be interpreted as a form of *efficiency wages*. On the other hand, in treatment C, there is no need to pay efficiency wages because workers put in the contracted effort due

Figure 8.3 A comparison of the length of the worker–firm relationship under the two treatments.

Source: Brown et al. (2004) with permission of the Econometric Society.

to third party intervention. In the ICR treatment, on the other hand, there is no future to worry about, hence, efficiency wages are pointless. Thus, a clear prediction of the model is that wages and effort would be highest in the ICF treatment. These predictions are verified in Figures 8.4, 8.5. From Figure 8.4, it can be seen that the average wage is always highest in the ICF treatment except for the first few periods when the wage in the C treatment is higher. Further, the wage gap between the ICF and the ICR treatments increases over time and the gap in wages between the ICF and the other treatments is statistically significant. From Figure 8.5, there is an increase in effort over time in the ICF treatment. Effort drops off towards the end, as predicted in theory. Not surprisingly, effort is highest in treatment C, because it can be costlessly implemented through a third party and additional effort, net of the wage costs, is valuable. Furthermore, as predicted by the theory, the experimental results show that there is contingent contract renewal, i.e., a worker is more likely to have his contract renewed if he undertakes higher effort. For a worker providing the maximum effort level, the probability that the contract will be renewed in the following period is close to 1.

4. In choosing between alternative contractual forms, the incomplete contracts literature often takes the view that the contractual form which maximizes the total surplus in the relationship will be the institutional solution; for instance, the formation of firms in preference to the conduct of transactions at arms-length relationships (Hart, 1995). The experimental results indicate that the joint surplus in a relationship is higher, the longer it lasts. Since the ICF treatment is the one most conducive to long-term relations, it is not surprising that, on average, it has a higher joint surplus relative to the ICR treatment. The highest surplus is in treatment C because the contract can be costlessly enforced. Insofar as contracts cannot be costlessly enforced in the real world, and treatment C is an idealized benchmark case, the predicted institutional solution is the ICF treatment. Figure 8.6 shows the association between profitability and the length of the relationship in the three treatments.

Figure 8.5 Average temporal effort in each treatment.

Source: Brown et al. (2004) with permission of the Econometric Society.

In Figure 8.6, the ICR and the C treatments are represented at the two extremes with the ICF treatment in the middle. Two important features of these results are the following. First, the surplus is shared less equally in the C and the ICR treatments relative to the ICF treatment. Second, the total surplus in the ICF treatment is increasing in the length of the relationship.

The experimental results suggest that initial conditions are the crucial determinant of a relationship developing into a long-term one. Of the initial relationships between workers and firms, 75% do not survive. However, 80% of the relations that survive for at least two periods go on to survive for the full duration of the experiment. Of the relationships that survive, an important factor seems to be the magnitude of the wage. If the initial wage is high, then initial effort is also high and the relation is more likely to survive. There is a gradual increase in wage and effort in relationships that survive longer than 6 periods. One can conjecture that this gradual increase in wage and effort creates greater mutual trust and makes the relationship more enduring.

In Brown et al. (2004) considered above, there is an excess supply of labor. In contrast, Brown et al. (2012) implement an experimental setup with an excess demand for labor. Denote the contracts C and ICF in Brown et al. (2004) by C-S and ICF-S to reflect the excess supply condition. Likewise denote the corresponding contracts under excess demand by C-D and ICF-D; contracts ICR-D and ICR-S are defined analogously. The point of the exercise is to see if the extent of unemployment has a bearing on the formation of relational contracts. Figure 8.7 compares the mean effort levels under the following two comparisons, ICF-D and ICF-S; ICR-D and ICR-S.

The evidence shows that firms are equally likely to offer contract renewal for non-shirking workers under conditions ICF-S and ICF-D. However, in the excess demand condition, workers turn down the contract renewals more often, so they switch firms more often. Hence, there is a lower formation of relational contracts. But the proportion of trades taking place in condition ICF-D is still larger than those taking place under C-D. In this sense, bilateral long-term contracts continue to play an important role even under excess demand. The effort levels under excess supply and excess demand for labor are similar.

What other factors are conducive for improving payoffs in finite period relationships? Van Dijk et al. (2002) produce experimental evidence to show that the continuation of relations produces *social ties* between the parties to a relationship. This strengthens their willingness to cooperate in the relationship, hence, providing an additional mechanism, other than instrumental reciprocity, that can sustain cooperative behavior. Gächter and Falk (2002) find that subjects in experiments cooperate more if they know there is a possibility that they will be paired with the same partners in the future.¹⁸ Engelmann and Fischbacher (2009) confirm similar findings by giving a fraction of the subjects an opportunity to develop a reputation. They find that altruistic rewarding and the desire to build a reputation are important considerations for their subjects in experiments.

One argument that has been made in countering the results of cooperative behavior in one-shot games is that subjects in experiments are unable to distinguish between one-shot and repeated interactions. Hence, cooperation is some form of *maladaptation* that results from cognitive failure; for instance, Roth and Erev (1995) and Binmore et al. (1995). We have already considered these arguments, above, in the context of the ultimatum game. We have seen that individuals understand the strategic differences between one-shot and repeated interactions.

8.4.4 The nature of the firm and other-regarding preferences

When should transactions be carried out within a firm and when should they be carried out in arms-length relationships? This question has had a distinguished history in economics, particularly since Coase (1937). Simon (1951) posed this question as the choice between *employment contracts* within the firm and *sales contracts* offered by one entity to another. The advantage of an employment contract is that it offers greater flexibility in decisions to the employer. Within legal bounds, it allows the employer to control more closely the type of task that an employee will undertake. The cost of an employment contract is that employees may be treated more opportunistically by the employer (within legal bounds); this may reduce the intrinsic

¹⁸ Dal Bó (2002) finds similar results for the prisoner's dilemma game. Cooperation increases when the probability of future interaction with the same partner increases from 0.5 to 0.75.

Figure 8.7 Comparison of mean effort levels under various treatments.

motivation of employees and make them reluctant to accept such a contract unless rents are high. The sales contract, by contrast, offers less flexibility to the employer but prevents opportunistic treatment of the employee, making the latter more likely to accept the contract at a lower rent.

Bartling et al. (2013) formalize similar trade-offs between two parties, a principal and an agent. The two parties sign one of two contracts, a sales contract or an employment contract, prior to the realization of one of two equiprobable states of the world—state 1 and state 2. There are three possible tasks, task 1–3, that the principal can assign to the agent. Table 8.2 shows the relevant, state-contingent and task-contingent, economic information. This includes the revenues of the

Table 8.2 The relevant economic information in each state of the world.

		Task 1	Task 2	Task 3
State 1	Revenue	160	80	190
	Cost	0	40	130
	Surplus	160	40	60
	Principal's profit	160–wage	80–wage	190–wage
	Agent's income	wage	wage–40	wage–130
State 2	Revenue	30	200	230
	Cost	0	40	130
	Surplus	30	160	100
	Principal's profit	30–wage	200–wage	230–wage
	Agent's income	wage	wage–40	wage–130

Source: Bartling et al. (2013).

principal, the cost of the agent, the total surplus to be shared between the two parties, the principal's profit, and the agent's income. Task 3 always gives the highest revenues in each state but agents incur very high costs in undertaking it, hence, it is never efficient in any state. In state 1, task 1 is most efficient (total surplus is 160) and in state 2, task 2 is most efficient (total surplus is 160). The outside option of the principal and the agent is respectively 0 and 30.

A *sales contract* takes the form (w_b, task) , where w_b is a binding wage and task specifies one of the three tasks. Thus, before any uncertainty about the state of the world is realized, the agent, in a sales contract, already knows which contractual task has been specified. An important cost of such a contract is that the ex-ante choice of the task may not be ex-post optimal. An *employment contract*, takes the form $(w_b, \text{principal chooses task ex-post})$. Thus, the principal has *residual control rights* on the choice of one of the three tasks after observing the state of the world. Such a contract gives greater flexibility to the principal on task choice, but leaves open the possibility that the principal might choose the more exploitative task 3 and *abuse his legal power*. Thus, this is a problem of *employer moral hazard*. Once the state of the world is realized, the contracts are executed.

The game is played between eight principals and eight agents, over 15 periods. All players are assigned ID numbers at the start of the game. In the first stage, the principal makes a *private offer* that is addressed to a particular agent by specifying the ID number. This is followed by a *public offer* to other agents. In the second stage, agents observe these offers. If an agent receives more than two private offers he can accept only one. Once agents have accepted the private offers, if any, the unmatched agents are randomly matched with the public offers of the principal. In the end of this process, at least one agent is matched with one principal.

There are two main treatments. In treatment RANDOM, the ID numbers are randomly reassigned at the beginning of each period. Thus, when a principal makes contract offers or agents examine the contract offers, they cannot identify the past behavior of the other party. By contrast, in the treatment FIXED, the ID numbers stay fixed over the 15 periods, hence, principals can specify the ID number of the agent they would like to be matched with. In this case, the agent can use his past experience with the principal to make a more informed acceptance decision. In the treatment RANDOM, there is no point for the principal to build a reputation for not abusing authority (say, by not choosing task 3). However, building a reputation is critical in treatment FIXED. A third treatment, UNFAIR, is identical to RANDOM except that with an 80% chance, task 3 is exogenously chosen.

Proposition 8.36 *Suppose that the principal and the agent are self-regarding. The optimal contract for the principal is to offer a sales contract of the form $(w_b, \text{task 2})$. The employment contract is never optimal.*

Proof: Consider first, an employment contract. Suppose that we are in the last period, period 15, in any of the treatments RANDOM, FIXED, or UNFAIR. In an employment contract, since w_b is binding, the self-regarding principal will demand that the agent undertake task 3 because it is revenue maximizing. The cost of the agent is 130 and his outside option is 30. Hence, rational agents will accept an employment contract only if $w_b \geq 160$. These arguments also hold for the particular sales contract, $(w_b, \text{task 3})$. Since both states of the world are equiprobable, so the expected profit of the principal from an employment contract and from the sales contract $(w_b, \text{task 3})$ is $0.5(190 - 160) + 0.5(230 - 160) = 50$.

By contrast, the principal's expected profit from the sales contract (i) $(w_b, \text{task 1})$ is $0.5(160) + 0.5(30) - 30 = 65$, and (ii) $(w_b, \text{task 2})$ is $0.5(80 - 40) + 0.5(200 - 40) - 30 = 70$. Hence, the sales contract $(w_b, \text{task 2})$ is optimal in period 15. We can now solve the game with backward induction.

The sales contract (w_b , task 2) is optimal in every period. In particular, note that in the treatment FIXED, both players know that the principal will act opportunistically in an employment contract in period 15, hence, there is no point for the principal to develop a reputation for non-abusive behavior in period 14. Using backward induction, the same applies, successively, in rounds 13, 12, ..., 1.

Thus, the sales contract (w_b , task 2) that gives the principal an expected profit of 70, dominates an employment contract that offers an expected profit of 50. ■

Suppose now that we allow for a proportion, $\lambda \in (0, 1)$, of self-regarding principals and the remaining proportion $1 - \lambda$ of other-regarding principals who have the Fehr–Schmidt preferences. However, the preferences of each player is private information. This turns the game into a signaling game and one needs to find the perfect Bayesian equilibria of the game, as in Proposition 8.35 above. The presence of other-regarding principals potentially alters the solution because they do not try to exploit their residual control rights in an employment contract by choosing task 3. Unlike Proposition 8.35 that fully characterizes a perfect Bayesian equilibrium, here we offer an informal conjecture that illustrates the potential equilibria in the model.

Conjecture 8.1 *Suppose that there is asymmetric information about the type of the principal; with probability $\lambda \in (0, 1)$, the principal is self-regarding, and with probability $1 - \lambda$, the principal is other-regarding.*

- (a) *In each treatment, and in each period, in one possible perfect Bayesian equilibrium, all principals offer the sales contract (w_b , task 2).*
- (b) *Consider the treatment RANDOM. If a self-regarding agent is sufficiently optimistic that the principal is other-regarding ($\lambda \leq \frac{w-50}{110}$), then he may accept the employment contract. Self-regarding principals always abuse their residual control rights by asking for task 3.*
- (c) *There can be no employment contracts in the treatment UNFAIR.*
- (d) *In the treatment FIXED, we “may” observe employment contracts and long-term contracts between the principal and the agent in which, ex-post, the principal requires the efficient tasks (task 1 in state 1 and task 2 in state 2).*

Basis for Conjecture 8.1: (a) Bayes’ rule does not impose restrictions on out of equilibrium beliefs in such games. So let us impose the extreme beliefs that if the agent observes an employment contract, he assigns the posterior belief that the principal is self-regarding with probability 1. But this means that the agent is sure that the principal will abuse his authority by choosing task 3 in an employment contract. From Proposition 8.36 we know that the sales contract (w_b , task 2) is optimal in every period.

(b) Suppose that both types of principals offer an employment contract in period 15 and a pooling wage w . Agents believe that the self-regarding principal will choose to abuse his authority by choosing the revenue maximizing task 3, while the other-regarding principal will find it optimal to elicit an efficient task (task 1 or task 2). From Table 8.2, the cost of effort for tasks 1 and 2 is identical in states 1 and 2, and task 1 is efficient in state 1 and task 2 in state 2. Thus, a self-regarding agent should accept the employment contract if

$$\lambda [w - 130] + (1 - \lambda) [0.5(w) + 0.5(w - 40)] \geq 30 \Leftrightarrow \lambda \leq \frac{w - 50}{110}. \quad (8.74)$$

Thus, given w , the self-regarding agent should accept the employment contract only if he believes that the probability of encountering a self-regarding principal is low. If the agent is other-

regarding, then we have to proceed as in Proposition 8.36 by allowing extra rents for the inequity-averse agent. In the treatment RANDOM, there is no benefit for a self-regarding principal to try to build a reputation for not abusing residual control rights. Thus, such a principal will always choose to abuse authority. However, for a low enough λ there may be equilibria with employment contracts in each period.

(c) In treatment UNFAIR, task 3 is exogenously imposed with probability 0.8. Thus, even in the best case scenario in which task 1 is chosen in state 1 and task 2 in state 2, the surplus (net of the agent's outside option of 30) in the relation is

$$0.8 [0.5 (190 + 230) - 130] + 0.2 [0.5(160) + 0.5(200 - 40)] - 30 = 66.$$

From Proposition 8.36, we know that this is dominated by a net surplus of 70 from a sales contract (w_b , task 2), hence, employment contracts should never be offered in treatment UNFAIR.

(d) Consider treatment FIXED. The formal proof can be given along the lines of Proposition 8.35. However, note that even self-regarding principals will attempt to pool with other-regarding principals in order to build a reputation for non-exploitative choice of efficient tasks (task 1 in state 1 and task 2 in state 2). The benefit of doing so is that the agent will not update his priors about the type of the principal and accept the principal's private employment offer in the next period. However, if the principal abuses the agent's trust in any period, then the agent rejects the private offer of the principal in the next period and, possibly, updates his posteriors that the type of the principal is self-regarding (this depends on the exact specification of the out of equilibrium beliefs). In the spirit of Kreps and Wilson (1982) and Milgrom and Roberts (1982) (see also Proposition 8.35) principals will try to build a reputation and milk it for a while, then revert back to their preferred contracts in the end. For instance, self-regarding principals will choose task 3 in period 15, irrespective of the treatment and this is foreseen by agents. ■

The empirical results are as follows. In treatment RANDOM, the prediction is that authority will always be abused if players have self-regarding preferences (Conjecture 8.1). Yet, we observe that power is abused only in 51% of the cases (task 3 is chosen) but in the remaining cases one of the efficient tasks, 1 or 2, is chosen. Thus, the purely self-regarding preferences case is rejected.

Figure 8.8 shows the payoffs of the principal and the agent in the sales and employment contracts in treatment RANDOM (left panel) and treatment FIXED (right panel). In each case, on

average, the principal earns a higher payoff in the employment contract, relative to the sales contract. In treatment RANDOM, on average, agents receive a higher payoff in sales contracts as compared to employment contracts. This finding is reversed in treatment FIXED and, in an employment contract, agents earn, on average, significantly higher than their outside option of 30 (i.e., they receive positive rents); by contrast agents barely earn their outside option, on average, in an employment contract in treatment RANDOM. In both treatments, principals who abuse their residual control rights in employment contracts earn higher payoffs than those who do not, yet both types of principals earn more relative to a sales contract. Further insights into these results are provided in Figure 8.9.

From the left panel in Figure 8.9, in all treatments, the employment contract is predominantly offered in the beginning. However, over time, agents observe that the self-regarding principals abuse trust by choosing task 3. This, in particular, is the case in treatment RANDOM. Hence, agents who have had an abusive experience, begin in successive rounds to reject the employment contract in favor of the sales contract. In a sales contract, principals typically ask for one of the efficient tasks, task 2. Yet, one still observes that in treatment RANDOM, the share of the employment contract stabilizes at about 40%. What accounts for this high percentage, relative to the predictions of the self-regarding model?

A crucial role is played by the presence of principals with other-regarding preferences. We can see this by comparing the share of employment contracts in the following two treatments: RANDOM and UNFAIR. In the latter, an employment contract is never optimal (Conjecture 8.1(c)). The differences between the two treatments (left panel of Figure 8.9) are statistically significant and employment contracts are almost eliminated in the last few periods in treatment UNFAIR. Thus, it is likely to be the case that in treatment RANDOM, agents expect the presence of a significant fraction of principals with other-regarding preferences.

In contrast to these two treatments, the proportion of employment contracts in treatment FIXED begins from a high level and hovers around the 80–90% mark (there is also an endgame effect). The main reason for the prevalence of the employment contract in treatment FIXED is that principals do not abuse their residual control rights as much, in comparison to the other contracts. This is confirmed from the right panel of Figure 8.9, which shows a statistically significant negative correlation between the share of employment contracts and the abuse of power. This is

the reason why in the right panel of Figure 8.8 (treatment FIXED), on average, the principal and the agent are better off relative to a sales contract. This is despite the fact that the agent has a negative payoff when he faces a principal who abuses his residual control rights.

The main reason that principals abuse their residual control rights relatively less in treatment FIXED is that agents terminate employment relations with abusive principals in the succeeding period. The cost to the principal of this event is that it might lead the principal to be identified as a self-regarding principal (this depends on the precise specification of out of equilibrium beliefs in a formal model). That this will lead to lower subsequent profits for the principal is also confirmed by the data.

Long-term relations do not emerge in a sales contract under the treatment FIXED but do emerge under an employment contract. The reason is that no reputation building is possible under a sales contract as there are no residual control rights that a principal can exploit.

The *efficiency* (actual surplus relative to maximum potential surplus) of employment contracts is significantly greater than sales contracts. This might be an important clue why *vertical integration* takes place in actual practice. The *transaction costs* identified in the traditional industrial organization literature typically originate from contract rigidity and the hold-up problem (Gibbons, 2010). However, the nature of the transaction costs identified in this paper is significantly distinct from the earlier ones. There are three main transaction costs: (i) Some potentially profitable contract offers are rejected by the agents (see also Bartling et al., 2012). (ii) Sales contracts are rigid and do not allow ex-post alteration of tasks. (iii) Some principals do abuse their residual control rights in an employment contract. Indeed, in the treatment FIXED, these transaction costs are lower in an employment contract relative to a sales contract and, hence, efficiency is higher.

Furthermore, these experiments provide exogenous variation in the principal's ability to build a reputation (FIXED versus RANDOM treatments) that alter the costs of integration such as the abuse of power by the principal but not the costs of non-integration (rigidity of task choice under sales contracts). By contrast, existing field evidence provides mainly correlational evidence only (Bartling et al., 2013, p. 715). This should also serve to caution those who might unconditionally espouse the superiority of field evidence relative to lab experiments.

8.5 Extrinsic and intrinsic motivation: theoretical framework

Consider the opening remarks from Ellingsen and Johannesson (2008):

Douglas McGregor's (1960) celebrated management book *The Human Side of Enterprise* argues that managers who subscribe to the conventional economic view that employees dislike work—McGregor labels it Theory X—may create workers who are “resistant, antagonistic, uncooperative”. That is, managerial control and material incentives may trigger the very behaviors that they are designed to avert. Conversely, managers who subscribe to the more optimistic view that employees see their work as a source of self-realization and social esteem—Theory Y—may create workers who voluntarily seek to fulfill the organization's goals.

A major part of the agenda for the theoretical literature, that we consider in this section, is to provide some foundations for Theory Y.

In this section, we consider formal theoretical models that simultaneously examine the effect of incentives on extrinsic and intrinsic motivation. This is an active and productive area of research.¹⁹

8.5.1 Self-signaling and social signaling

In this section, we consider the models due to Bénabou and Tirole (2003, 2006). Consider first, a simplified version of the more general model in Bénabou and Tirole (2003). In this model, incentives signal the amount of trust that a principal has in an agent.

Consider a principal and an agent, both risk neutral, who are engaged in some project. There is asymmetric information about the cost, $c \in [\underline{c}, \bar{c}]$, of the project that the agent will bear if the project is undertaken. The principal knows the actual value of c but the agent only knows the density, f , and the probability distribution of costs, F . For any wage, w , received by the agent and any cost, c , the agent's utility is $w - c$. The agent chooses the effort level, e , to either shirk, $e = 0$, or work hard, $e = 1$. If the project is unsuccessful, then both parties get a payoff of 0. If the agent works hard, then the project is successful with probability $\theta \in (0, 1]$ and the respective payoffs of the principal and the agent are $W > 0$ and $V > 0$; with probability $1 - \theta$, the project is unsuccessful. If the agent shirks, then the project is always unsuccessful. The outside option of the agent is normalized to 0.

The agent does not know the value of c , but he receives a private signal of the cost, c , given by $\sigma \in [0, 1]$ with conditional density $g(\sigma | c)$ and conditional distribution $G(\sigma | c)$. A higher value of the private signal, σ , is *good news* in the sense that it signals a lower value of the cost. This is formally incorporated by using the *monotone likelihood ratio property* (MLRP). For any two values of $\sigma : \sigma_L < \sigma_H$, and cost $c : c_L < c_H$, the MLRP property states that

$$\frac{g(\sigma_H | c_H)}{g(\sigma_L | c_H)} < \frac{g(\sigma_H | c_L)}{g(\sigma_L | c_L)}, \text{ or } \frac{g(\sigma_H | c_H)}{g(\sigma_H | c_L)} < \frac{g(\sigma_L | c_H)}{g(\sigma_L | c_L)}. \quad (8.75)$$

Using Bayes' rule,

$$\Pr(c_L | \sigma_H) = \frac{1}{1 + \frac{g(\sigma_H | c_H) f(c_H)}{g(\sigma_H | c_L) f(c_L)}} \text{ and } \Pr(c_L | \sigma_L) = \frac{1}{1 + \frac{g(\sigma_L | c_H) f(c_H)}{g(\sigma_L | c_L) f(c_L)}},$$

thus,

$$\frac{\Pr(c_L | \sigma_H)}{\Pr(c_L | \sigma_L)} = \frac{1 + \frac{g(\sigma_L | c_H) f(c_H)}{g(\sigma_L | c_L) f(c_L)}}{1 + \frac{g(\sigma_H | c_H) f(c_H)}{g(\sigma_H | c_L) f(c_L)}}. \quad (8.76)$$

Using (8.75), (8.76) we get that $\Pr(c_L | \sigma_H) > \Pr(c_L | \sigma_L)$, which is the precise sense in which a higher value of σ is good news.

Lemma 8.19 *The MLRP in (8.75) implies that*

$$\frac{[1 - G(\sigma_H | c_L)]}{[1 - G(\sigma_L | c_L)]} \geq \frac{[1 - G(\sigma_H | c_H)]}{[1 - G(\sigma_L | c_H)]}.$$

¹⁹ See, for instance, Hwang and Bowles (2011), Ellingsen and Johannesson (2008), Bénabou and Tirole (2003, 2006), and Besley and Ghatak (2005).

The proof of Lemma 8.19 is left as an exercise for the reader.

The principal does not observe the effort level of the agent. If the project is successful, the principal contractually offers a performance based monetary bonus, b , to the agent. This is equivalent to an expected wage offer of $w = \theta b$, contingent on the agent working hard ($e = 1$). The bonus could alternatively be interpreted as the monetary value of working conditions, praise, and friendliness. Thus, in the event that the agent works hard and the project is successful, the respective payoffs of the principal and agent are $W - b$ and $V + b$.

The agent may be willing to work hard if the cost of the project is not too high. The principal benefits if the agent works hard, otherwise each gets a payoff of only 0. Hence, the principal may wish to manipulate incentives in order to signal to the agent that the project has low cost and hope that this will boost the *self-confidence* of the agent and his interest in the task. The agent is aware of the principal's incentives to do so. Thus, he uses, jointly, his private signal, σ , and the bonus payment, b , to make an inference of the cost, c .

The full information benchmark is simple to find. The incentive compatibility condition and the individual rationality conditions are identical in this model. If the agent shirks, then the agent gets zero, which is also the outside option. The risk-neutral agent works hard if the expected payoff exceeds the outside option of zero, i.e., $\theta(V + b) - c \geq 0$. The principal only needs to ensure that this condition binds. Thus, a higher bonus makes it more likely that the agent will work hard.

Now consider the solution under asymmetric information. We derive a perfect Bayesian Nash equilibrium of the model. Under asymmetric information, the agent attempts to infer the cost of the project by observing, jointly, σ and b . Denote by $E[c | \sigma, b]$, the expected level of the cost, conditional on σ, b . Since a higher private signal, σ , is good news about costs, thus, for a fixed b , $E[c | \sigma, b]$ is decreasing in σ .

The payoff of the agent from shirking ($e = 0$) is zero. Hence, the risk-neutral agent works hard ($e = 1$) if the expected payoff from working hard is positive; this is the incentive compatibility condition,

$$\theta(V + b) - E[c | \sigma, b] \geq 0. \quad (8.77)$$

Figure 8.10 gives a diagrammatic representation of the condition in (8.77) for two different levels of bonuses, $b_1 < b_2$. The curve $E[c | \sigma, b]$ is decreasing in σ . The shape is purely for illustrative purposes and the upward shift with respect to the bonus ($b_1 < b_2$) is proved in Proposition 8.37. It is obvious from Figure 8.10 and (8.77) that for any bonus, b , there is a cutoff point $\sigma^*(b)$ such that $E[c | \sigma^*(b), b] = \theta(V + b)$, and

$$\begin{cases} \sigma \geq \sigma^*(b) & \Rightarrow e = 1 \\ \sigma < \sigma^*(b) & \Rightarrow e = 0 \end{cases} \quad (8.78)$$

The probability that $\sigma \geq \sigma^*(b)$ is given by $1 - G(\sigma^*(b))$. Given the best response function of the agent in (8.78), a principal who knows the actual cost to be c , chooses the bonus level, b , to maximize his expected profit

$$E\pi = [1 - G(\sigma^*(b) | c)]\theta(W - b), \quad (8.79)$$

where the expectation is taken over the distribution of σ . One may think of each possible level of cost, $c \in [\underline{c}, \bar{c}]$, as the type of the principal. Thus, an optimal strategy for the principal is a choice

Figure 8.10 Diagrammatic representation of the condition in (8.77).

of b for each $c \in [\underline{c}, \bar{c}]$. Denote the set of optimal values of b by B^* . The results are summarized in the following proposition and we sketch a heuristic proof.

Proposition 8.37

- (i) If $b_1, b_2 \in B^*$ and $b_1 < b_2$, then the cutoff private signal beyond which the agent decides to work hard is relatively lower under b_2 , i.e., $\sigma^*(b_2) < \sigma^*(b_1)$.
- (ii) A higher level of bonus is bad news for the agent. Let b_H and b_L be the optimal levels of bonus when the cost is respectively c_H and c_L , $c_H > c_L$. Then $b_H > b_L$.
- (iii) Higher bonus payments reduce the perceived attractiveness of the task for the agent. For all pairs of signals (σ, σ') , and optimal bonus payments $b_1 < b_2$, $b_1, b_2 \in B^*$, we have $E[c | \sigma, b_1] < E[c | \sigma', b_2]$.

Proof: (i) Suppose that the statement in (a) is false. Then for some $b_1 < b_2$ in B^* we have $\sigma^*(b_2) > \sigma^*(b_1)$. But then, instead of offering b_2 , the principal could offer a lower bonus b_1 . This increases the expected profits of the principal, given in (8.79), in two ways. By reducing σ^* it increases the first term $[1 - G(\sigma^*(b) | c)]$. The second term, $\theta(W - b)$, increases directly when the bonus level falls. This contradicts the original supposition that b_2 is an optimal level of bonus. Thus, we cannot have $\sigma^*(b_2) > \sigma^*(b_1)$.

(ii) Suppose that the bonus b_i , $i = H, L$ is optimal when cost is c_i . Let $\sigma_2 = \sigma^*(b_H)$ and $\sigma_1 = \sigma^*(b_L)$ be the cutoff points for the private signals. Then, we get from (8.79) that

$$[1 - G(\sigma_2 | c_H)] \theta(W - b_H) > [1 - G(\sigma_1 | c_H)] \theta(W - b_L), \quad (8.80)$$

$$[1 - G(\sigma_1 | c_L)] \theta(W - b_L) > [1 - G(\sigma_2 | c_L)] \theta(W - b_H). \quad (8.81)$$

When the actual cost of the principal is c_H the bonus b_H is optimal ((8.80)) and when the actual cost is c_L the bonus b_L is optimal ((8.81)). From (8.80), (8.81) we get

$$\frac{[1 - G(\sigma_1 | c_L)]}{[1 - G(\sigma_2 | c_L)]} > \frac{(W - b_H)}{(W - b_L)} > \frac{[1 - G(\sigma_1 | c_H)]}{[1 - G(\sigma_2 | c_H)]}.$$

Since $c_L < c_H$, Lemma 8.19 implies that $\sigma_1 = \sigma^*(b_L) > \sigma_2 = \sigma^*(b_H)$. Since σ^* is a decreasing function it follows that $b_L \leq b_H$. Thus, a high bonus, b_H , conveys bad news for the agent that costs are high, c_H .

(iii) There cannot be a separating equilibrium. Suppose to the contrary that there is a separating equilibrium. Then each type of the principal, $c \in [\underline{c}, \bar{c}]$, announces a distinct level of bonus. Since the principal's action is fully revealing of his type in a separating equilibrium, hence, there is no need for the agent to use an imperfect private signal, σ . Suppose that we support such an equilibrium by imposing particularly pessimistic out of equilibrium beliefs that if the bonus payment in a separating equilibrium, b_i for some type $c_i \in [\underline{c}, \bar{c}]$ changes to any $b_j \neq b_i$, then the principal is of the worst, or highest cost, type, $\bar{c}$.

But if the agent is going to ignore his private signal, σ , then the principal of type $\bar{c}$, should choose the lowest bonus payment possible and improve his profits. This breaks the separating equilibrium. Thus, the proof of part (b) implies that pooling occurs over intervals. For $b_1 < b_2$, if the principal pays bonus b_1 for costs $c \in [\tilde{c}_0, \tilde{c}_1]$ and bonus b_2 for costs $c \in [\tilde{c}_2, \tilde{c}_3]$, then $\tilde{c}_1 < \tilde{c}_2$. Thus, all cost levels for which a higher bonus is offered are also higher, hence, the expected costs under the higher bonus are also higher, so for all pairs of signals (σ, σ') , $E[c \mid \sigma, b_1] < E[c \mid \sigma', b_2]$. Therefore, higher rewards are given for less attractive tasks (forbidden fruits) and they reduce intrinsic motivation. ■

Bénabou and Tirole (2003) consider intrinsic and extrinsic motivation, Bénabou and Tirole (2006) add to the mix a reputational motivation. For instance, while the Bénabou and Tirole (2003) model deals with situations where one party to a formal or informal contract has private information (child rearing, education, monitoring of employees), a different framework is needed when one makes prosocial decisions such as blood donations, charitable giving, in-kind donations, choosing a fuel efficient car, and voting. Such a framework is provided in Bénabou and Tirole (2006) that we now turn to.

Suppose that an agent can choose some prosocial action a from a set of real-valued numbers, A , at some cost $C(a)$. The action a confers some *intrinsic utility*, u_I , on the agent, per unit of the action, a (e.g., the agent may feel good about the action of donating blood). A principal chooses a monetary reward, $y \geq 0$, per unit of the action, a , for the agent. The *extrinsic utility* derived by the agent from the monetary reward per unit is u_E . For instance, the government (principal) may decide to tax exempt or subsidize the charitable contributions of citizens. Thus, the *private benefit* to the agent from the action, a is

$$P(a, y) = a(u_I + u_E y) - C(a). \quad (8.82)$$

The agent has private information on his *type* or *identity*, which is summarized by $(u_I, u_E) \in R^2$. The other players know that the pair (u_I, u_E) is drawn from the density $f(u_I, u_E)$. Others attempt to learn or infer (u_I, u_E) from the action taken by the agent, a , and the monetary reward given by the principal, y . The reward, y , creates additional difficulties in inferring intrinsic and extrinsic motivations from actions. For instance, society may wish to infer the degree of altruism of a contributor to charity, however, this calculation is made difficult if the tax regime allows charitable contributions to be tax exempt.

Social signaling is incorporated into the model by a concern for reputational payoffs. Denote by $E[u_I \mid a, y]$, $E[u_E \mid a, y]$, respectively, the posterior expectation of others about the agent's intrinsic utility and extrinsic utility. Then the *reputational payoff* is given by

$$R(a, y) = v(E[u_I \mid a, y] - E[u_E \mid a, y]). \quad (8.83)$$

In (8.83), the parameter $v > 0$ represents the *social visibility* of the action a (e.g., the number of people who observe the action) and it captures the extent of *reputational concerns* of the agent. An increase in $E[u_I | a, y]$ improves the reputation payoff of the agent by increasing the social perception of his intrinsic motivation. This term corresponds to the notion of *warm glow* from giving in the literature on charitable donations. On the other hand, an increase in $E[u_E | a, y]$ reduces the reputation payoff of the agent because it increases the social perception of his extrinsic motivation, or greed. In a more general model, the terms $E[u_I | a, y]$, $E[u_E | a, y]$ in (8.83) could be differentially weighted, as in Bénabou and Tirole (2006). Furthermore, there could be individual heterogeneity in these terms which make the problem of inferring motivations from actions even more difficult. We abstract from these considerations here.

The aggregate utility of the agent, U , indexed by the type $(u_I, u_E) \in R^2$, is given by $P(a, y) + R(a, y)$, thus,

$$U = a(u_I + u_E y) - C(a) + v(E[u_I | a, y] - E[u_E | a, y]). \quad (8.84)$$

The agent chooses action a to maximize U , defined in (8.84). Assuming that the problem is well-behaved, the first order condition that is sufficient to determine the optimal action is

$$(u_I + u_E y) + vR_a(a, y) = C'(a), \text{ where } R_a(a, y) = \left(\frac{\partial E[u_I | a, y]}{\partial a} - \frac{\partial E[u_E | a, y]}{\partial a} \right). \quad (8.85)$$

The LHS of (8.85) gives the marginal benefit of increasing a and the RHS, the marginal cost. The marginal benefit has three sources: *intrinsic*, *extrinsic*, and *reputational*. Suppose that we fix a particular value of $a > 0$. Then, from (8.85), the set of people who contribute (called the “high contributors”) satisfy the inequality $(u_I + u_E y) + vR_a \geq C'(a)$, which can alternatively be written as

$$u_E \geq \frac{1}{y} (C'(a) - vR_a(a, y)) - \frac{1}{y} u_I. \quad (8.86)$$

When the inequality in (8.86) binds, the agent chooses a and when it does not bind, the agent chooses an action greater than a . Three different loci of combinations of (u_I, u_E) on which (8.86) binds are shown in Figure 8.11, as I, II, and III; these loci are created by varying the size of rewards, y . In u_I, u_E space, the region above any such locus gives the set of points (u_I, u_E) for which an action greater than a is chosen.

When there are zero rewards ($y = 0$), (8.86) reduces to $u_I^*(a, 0) = C'(a) - vR_a(a, 0)$. This is shown in Figure 8.11 by the vertical line, labeled I. Since there are no extrinsic rewards in this case, the actions of agents do not reveal anything about their extrinsic motivation. All the individuals whose identity or type (u_I, u_E) lies on or to the right of curve I contribute at least an amount a , under zero rewards, while those to the left contribute strictly less than a .

Now suppose that there is a jump in rewards to a strictly positive level ($y > 0$). The slope of the (u_I, u_E) locus is now given by $-\frac{1}{y}$. Two loci are shown in Figure 8.11, corresponding to $y > 0$; these are labeled as II and III. The curve labeled II shows the immediate effect, prior to the adjustments in the reputational concerns arising through the term R_a . Thus, there is no change in the abscissa (see (8.86)) which stays fixed at $u_I^*(a, 0)$. The curve labeled III shows the final effect once the reputational concerns have played out. In the case shown in the figure, reputational

Figure 8.11 Loci of combinations of (u_I, u_E) on which (8.86) binds.

Source: Bénabou and Tirole (2006) with permission from the American Economic Association.

concerns shift the abscissa to the right. The abscissa is now given by $u_I^*(a, y) = C'(a) - vR_a(a, y)$. We now explain these effects in greater detail.

The immediate effect captured by curve II shows the extra set of individuals who now find it worthwhile to contribute at least a , in response to the presence of extrinsic incentives ($y > 0$ rather than $y = 0$). These people (new contributors) are represented by the area $A + B$. This is the classical positive effect of incentives. The reputational effect that is incorporated in curve III is more subtle. The relative intrinsic utility of the “new contributors” must be lower than that of the “high contributors” because the former did not find it worthwhile to contribute in the absence of extrinsic rewards. This reduces the overall average level of intrinsic utility of the set of contributors and the overall reputation of the set of contributors for prosocial behavior. However, the set of non-contributors has now also shrunk because the “new contributors” who have relatively high intrinsic utility among this group have transited to the set of contributors. Hence, the reputation from contributing an amount $a - \Delta a$ also goes down. Thus, the reputational effect for a marginal contributor is ambiguous, hence, the abscissa in (8.86) can go up or down. Curve III is drawn on the supposition that the reputation effect is negative ($R_a(a, y) < R_a(a, 0)$), so the abscissa goes up.

Comparing curves I and III, we are in a position to assess the final effect of incentives. Incentives stimulate contributions from a set of greedy individuals (high u_E relative to u_I). This is shown by the area B in Figure 8.11. However, there is an extra set of marginal contributors shown by the area C . The intrinsic utility u_I of these individuals is higher relative to their extrinsic utility u_E , so (based on (8.86)) they no longer find it optimal to take action a after the introduction of extrinsic incentives. This potentially explains several findings such as the work of Titmuss (1972) in the context of crowding-out effect of incentives for blood donations. Comparing curves I and III, the overall effect on total contributions will depend on the relative size of the areas, B and C as well as the shape of the probability density of individuals, $f(u_I, u_E)$, over these areas.

8.5.2 *Intentions, altruism, and esteem*

In this section, we consider theoretical models of principal–agent relations in which type-based reciprocity plays a key role (Ellingsen and Johannesson, 2008). These are models of two-sided

asymmetric information in which both players can be self-regarding or altruistic. Players hold other players in greater esteem if they are perceived to be altruistic. Furthermore, players value being esteemed more by other players who are perceived to be altruistic. This can explain why, a principal who chooses a kind action in the presence of an unkind action is regarded in greater esteem, because the principal signals clearly to the agent that he is kind. Agents then reciprocate, trusting actions by a kind principal, because the esteem received from a kind principal is valued more highly. Kindness may mean choosing a trusting action when a non-trusting action is available, or choosing a less controlling action when a more controlling action is available. We characterize an intuitive equilibrium of this two-sided signaling game and apply it to explain the experimental findings of McCabe et al. (2003) and Falk and Kosfeld (2006). We also consider the basic intuition behind some of the other related theoretical literature.

Consider two players $i \in N = \{\text{Principal, Agent}\}$. The pure strategy set of player $i \in N$ is denoted by S_i and the mixed strategy set by Σ_i . Consider the class of two-stage games where the principal first chooses a publicly observable strategy from the set Σ_P . The agent then sequentially chooses a strategy from the set Σ_A . There is two-sided asymmetric information about the altruism of the players. Each player belongs to one of two possible, privately known, types $\theta \in \Theta = \{\theta_L, \theta_H\}$, $0 \leq \theta_L < \theta_H < 1$. The prior belief of player $i \in N$ that the opponent is of type θ_H is p_i^0 .

Suppose player i of type θ_i chooses his action $s_i \in S_i$. Let h_i be the history of game, and let the belief of the player that his opponent is of type θ_H be $\mu_i(h_i, \theta_i)$. Let H_i be the set of all possible histories of the game when player i makes his move. Denote by $\bar{h}$, the terminal history of the game; it is summarized by the strategies followed by the two players for the whole game, σ_P, σ_A (defined below). Thus, we may write $\mu_i(\bar{h}, \theta_i) = \mu_i(\sigma_P, \sigma_A, \theta_i)$. We assume that players use Bayes' rule to update their beliefs.

The utility of a risk-neutral player $i \in N$ is given by

$$u_i = y_i + \theta_i y_j + \eta_i, \quad (8.87)$$

where y_i is the monetary payoff of player $i \in N$ and y_j is the monetary payoff of the opponent, player $j \neq i$. The size of θ_i measures the degree of *altruism* that the player feels for the opponents; since we have restricted $\theta_j > 0$, $j = L, H$ we are ruling out spite or envy. The term η_i measures player i 's feelings of being *esteemed* by player j . It is measured as follows. Let θ_{ij} be the esteem with which player i views player j . Conditional on the type of player i , θ_i , this is defined as the expected value of the altruism of player j at the terminal node.

$$\theta_{ij} = E[\theta_j | \theta_i, \bar{h}] = \mu_i(\bar{h}, \theta_i) \theta_H + [1 - \mu_i(\bar{h}, \theta_i)] \theta_L. \quad (8.88)$$

Players hold their opponents in greater esteem if they think they are more altruistic. Thus, there is respect for character virtues.

Let $\chi_j = \chi(\theta_j)$ be the salience of the esteem that an opponent of type θ_j has for player i . Now define η_i as

$$\begin{aligned} \eta_i = & \mu_i(\bar{h}, \theta_i) \chi_H (\text{Expected esteem of a type } \theta_H \text{ opponent for player } i) \\ & + [1 - \mu_i(\bar{h}, \theta_i)] \chi_L (\text{Expected esteem of a type } \theta_L \text{ opponent for player } i) \end{aligned} \quad (8.89)$$

or,

$$\begin{aligned} \eta_i = & \mu_i(\bar{h}, \theta_i) \chi_H \left[\left[\mu_j(\bar{h}, \theta_H) \theta_H + [1 - \mu_j(\bar{h}, \theta_H)] \theta_L \right] \right] \\ & + [1 - \mu_i(\bar{h}, \theta_i)] \chi_L \left[\left[\mu_j(\bar{h}, \theta_L) \theta_H + [1 - \mu_j(\bar{h}, \theta_L)] \theta_L \right] \right]. \end{aligned} \quad (8.90)$$

We are now in a position to evaluate the utility function in (8.87). First, although (8.87) only incorporates altruism (through the second term), the authors claim that richer other-regarding preferences, such as those in Fehr and Schmidt (1999), do not alter their results. Second, the feeling of being esteemed by a player is greater if more virtuous opponents hold them in higher regard. Consider, for instance, the first term on the RHS of (8.89). The expected esteem of a more altruistic player j is weighted by the term $\mu_i(\bar{h}, \theta_i) \chi_H$. Clearly this term is higher if the belief of player i about the altruism of player j , $\mu_i(\bar{h}, \theta_i)$, is higher. Thus, the model is similar in spirit to models of type-based reciprocity, such as that by Levine (1998). Third, an alternative way of dealing with beliefs about esteem and beliefs about beliefs about esteem, require the machinery of psychological game theory. This is discussed in Part 4 of the book.

A strategy for any player $i \in N$ is given by $\sigma_i : \Theta \times [0, 1] \times H_i \rightarrow \Sigma_i$. It specifies a mixed strategy of a player for each possible type of a player, for any beliefs about the opponent, and for any history of the game. Let $\sigma_P^* = (\sigma_P^*(\theta_H), \sigma_P^*(\theta_L))$ and $\sigma_A^* = (\sigma_A^*(\theta_H), \sigma_A^*(\theta_L))$ denote the equilibrium type-contingent strategies of the principal and the agent. Let $\mu_P^* = (\mu_P^*(\theta_H), \mu_P^*(\theta_L))$ and $\mu_A^* = (\mu_A^*(\theta_H), \mu_A^*(\theta_L))$ be the respective equilibrium type-contingent beliefs.

Definition 8.23 (*Intuitive equilibrium*): An equilibrium of the two-stage two-player game is a pair of type-contingent strategies (σ_P^*, σ_A^*) and a pair of type-contingent beliefs (μ_P^*, μ_A^*) such that the following hold.

- (1) Given the beliefs of any player $i \in N$, μ_i^* , the strategy σ_i^* maximizes the utility of player $i = A, P$.
- (2) The beliefs μ_i^* of player $i \in N$ satisfy Bayes' rule whenever possible.
- (3) Off the equilibrium path, beliefs must satisfy the Cho–Kreps intuitive criterion.

Consider the trust game of McCabe et al. (2003) shown in Figure 8.12. In the voluntary trust game (VTG) in Panel A, player 1 (Principal) has two choices: Trust (T) or No Trust (NT). In the involuntary trust game (ITG) in Panel B, player 1 has only one choice, T. Player 2 (Agent) has identical choices in both cases: Reward (R) and Not Reward (N). In classical game theory, the choice of player 2 should be identical in both cases. However, McCabe et al. (2003) find that the frequency of the choice of R for player 2 is significantly higher in the VTG as compared to the ITG. Thus, the principal's choice of trust conveys a better signal of his sociality when the NT option is available.

Let us now explain these experimental results using the theoretical framework developed in this section. Assume that each player has two possible types $\theta \in \Theta = \{\theta_L, \theta_H\}$ such that θ_H is the relatively more altruistic type. The solution is set out in Proposition 8.38. The intuition behind the results is as follows. First, in the VTG, altruistic principals (high θ_H) are more likely to play T because they place a higher value on the payoffs of the agent that arise from playing T rather than NT. Second, in a separating equilibrium where the more altruistic principal plays T but the self-regarding principal plays NT, the action of the principal fully reveals the type. More altruistic agents feel greater esteem from playing the action R, when they know that they are dealing with

Figure 8.12 A trust game that differentiates between voluntary and involuntary trust.
Source: Ellingsen and Johannesson (2008) with permission from the American Economic Association.

altruistic principals (type-based reciprocity). Hence, there is likely to be a separating equilibrium in which the more altruistic agent plays R and the self-regarding agent plays N in the VTG game.

Proposition 8.38 (Ellingsen and Johannesson, 2008): *Consider the trust games shown in Figure 8.12. For an open set of parameters, there exists a unique intuitive equilibrium (Definition 8.23) such that:*

- (i) *An altruistic principal (type θ_H) plays T and a self-regarding principal (type θ_L) plays NT.*
- (ii) *Both types of agents play N in the ITG. Altruistic agents (type θ_H) play R in the VTG.*

Proof: We only prove the existence part. For the proof of uniqueness see Ellingsen and Johannesson (2008).

Consider first the ITG. Both types of player 2s must choose N in this game as part of the stated equilibrium in the proposition. A sufficient condition is that the altruistic player 2 who benefits most by gaining self-esteem prefers to play N over R. Player 1 never gets a chance to update his beliefs because he moves first. Hence, the relevant beliefs for him are captured by his initial belief that player 2 is of type θ_H (denoted by p_1^0). Similarly, since player 1 has no choice but to play T, player 2 does not update his beliefs either, hence, the belief of player 2 that player 1 is of type θ_H is given by p_2^0 .

Using (8.87), (8.88), and (8.90), the utility of player 2 of type θ_H from playing N under the worst possible evaluation from player 1 (i.e., $\mu_1(\bar{h}, \theta_H) = p_1^0 = 0$) is

$$u_2(N, \theta_H, p_1^0 = 0) = 30 + 15\theta_H + \theta_L (p_2^0 \chi_H + (1 - p_2^0) \chi_L).$$

Similarly, the utility of a type θ_H player 2 from playing R under the best possible evaluation from player 1 (i.e., $\mu_1(\bar{h}, \theta_H) = p_1^0 = 1$) is

$$u_2(R, \theta_H, p_1^0 = 1) = 25 + 25\theta_H + \theta_H (p_2^0 \chi_H + (1 - p_2^0) \chi_L).$$

Under these conditions,

$$u_2(N, \theta_H, p_1^0 = 0) > u_2(R, \theta_H, p_1^0 = 1) \Leftrightarrow p_2^0 \chi_H + (1 - p_2^0) \chi_L < \frac{5 - 10\theta_H}{\theta_H - \theta_L}. \quad (8.91)$$

Now consider the VTG. As part of the separating equilibrium, player 1 of type θ_H always plays T in this case, while player 1 of type θ_L always plays NT. The prior beliefs of player 2 are updated in a manner that is consistent with Bayes' rule. Thus, on observing T, player 2 sets $\mu_2(\bar{h}, \theta_H) = 1$, and on observing NT he sets $\mu_2(\bar{h}, \theta_H) = 0$. So, conditional on being given the move $(\mu_2(\bar{h}, \theta_H) = 1)$, we first need to show that the altruistic player 2 will prefer to play R.

$$u_2(R, \theta_H, \mu_2 = 1) = 25 + 25\theta_H + \chi_H\theta_H.$$

In computing the last term, note that consistent with the strategies of player 2, player 1 sets $\mu_1(\bar{h}, \theta_H) = 1$ in (8.90). Similarly, the payoff of the altruistic player 2 from playing N is

$$u_2(N, \theta_H, \mu_2 = 1) = 30 + 15\theta_H + \chi_H\theta_L. \quad (8.92)$$

If player 2 plays N, then, given the strategies, he is revealed to be a type θ_L player, hence, the beliefs of player 1 about him, at the terminal node are $\mu_1(\bar{h}, \theta_H) = 0$. Using this fact in (8.90) gives the last term on the RHS of (8.92), $\chi_H\theta_L$. Thus, the required condition for an altruistic agent to play R in the VTG game is

$$u_2(R, \theta_H, \mu_2 = 1) > u_2(N, \theta_H, \mu_2 = 1) \Leftrightarrow \chi_H > \frac{5 - 10\theta_H}{\theta_H - \theta_L}. \quad (8.93)$$

Now consider a self-regarding agent (type θ_L) in the VTG. Proceeding analogously to the derivations above, such a player prefers to play N over R (as required in the equilibrium strategy profile) if

$$u_2(R, \theta_L, \mu_2 = 1) < u_2(N, \theta_L, \mu_2 = 1) \Leftrightarrow 25 + 25\theta_L + \chi_H\theta_H < 30 + 15\theta_L + \chi_H\theta_L,$$

or, if

$$\chi_H < \frac{5 - 10\theta_L}{\theta_H - \theta_L}. \quad (8.94)$$

Now consider the incentive compatibility conditions of player 1 in the VTG. Player 1 believes that with probability p_1^0 he faces a type θ_H player 2 who will play R, and with probability $1 - p_1^0$, a type θ_L player 2 who will play N. Hence, using (8.87), (8.88), and (8.90), the utility of a type θ_H player 1 from playing T is

$$u_1(T, \theta_H, p_1^0) = p_1^0 [25 + 25\theta_H + \chi_H\theta_H] + (1 - p_1^0) [15 + 30\theta_H + \chi_L\theta_H].$$

Since we are constructing a separating equilibrium, in the first term on the RHS, each of the players assigns probability one that the other is altruistic. Hence, we get the term $\chi_H\theta_H$. In the

second term on the RHS, player 1 assigns probability zero that player 2 is type θ_H ($\mu_1(\bar{h}, \theta_H) = 0$), while player 2 assigns probability 1 that player 1 is type θ_H ($\mu_2(\bar{h}, \theta_L) = 1$); substituting these facts in (8.90) gives the term $\chi_L \theta_H$. Similarly, we can define

$$u_1(NT, \theta_H, p_1^0) = p_1^0 [20 + 20\theta_H + \chi_H \theta_L] + (1 - p_1^0) [20 + 20\theta_H + \chi_L \theta_L].$$

Thus,

$$u_1(T, \theta_H, p_1^0) > u_1(NT, \theta_H, p_1^0) \Leftrightarrow p_1^0 > \frac{5 - 10\theta_H - \chi_L (\theta_H - \theta_L)}{10 - 5\theta_H + (\theta_H - \theta_L) (\chi_H - \chi_L)}. \quad (8.95)$$

By now, the method of proof should be transparent to the reader. Proceeding analogously, a self-regarding player 1 (type θ_L) prefers to play NT (as stated in the equilibrium profile in the proposition) if

$$u_1(T, \theta_L, p_1^0) < u_1(NT, \theta_L, p_1^0) \Leftrightarrow p_1^0 < \frac{5 - 10\theta_L - \chi_L (\theta_H - \theta_L)}{10 - 5\theta_L + (\theta_H - \theta_L) (\chi_H - \chi_L)}. \quad (8.96)$$

We require that the inequalities in (8.93), (8.94), (8.95), and (8.96) hold simultaneously. One set of parameter values for which this is true is $p_1^0 = \frac{2}{5}$, $\chi_L = \theta_L = 0$, $\theta_H = \frac{1}{3}$ and $\chi_H = 6$. Since this statement is robust to small changes in the parameter values, it holds for an open set of parameter values around the stated values. ■

We now consider the effects of *control-aversion* on the part of agents in a principal-agent relation. By choosing incentives that reveal a controlling nature, the agent's effort level may be reduced even when neoclassical theory predicts no such effect.

Consider the Falk and Kosfeld (2006) study in which a principal (player 1) can choose either to control or not control an agent (player 2). The agent is given an endowment of 120 money units and he can transfer any amount $[0, 120]$ back to the principal. For every unit of transfer made by the agent, the experimenter ensures that the principal receives 2 units, hence, the amount received by the principal lies in the interval $[0, 240]$.

Prior to the agent's decision, the principal has two options. (i) Either specify that the agent transfer a minimum amount $\bar{x} = 10$ (so that the principal receives at least $2\bar{x} = 20$). (ii) Or do not specify a minimum transfer. When a minimum transfer $\bar{x}$ is specified, the agent transfers an average amount of 17.5, while in the absence of such minimum transfers it is 23. About 70% of the principals choose to trust the agent by not specifying a minimum transfer. Further, if a minimum amount is exogenously specified, say, by the experimenter, then there is no difference in the amounts transferred. Hence, control-aversion seems to be the most likely explanation of these findings.

Consider now an explanation of these experimental results based on the Ellingsen and Johannesson (2008) framework. The strategy of the agent is $s_A \in [0, 120]$ if the principal chooses to trust (T), and $s_A \in [10, 120]$ if the principal chooses to control (C). The strategy of the principal is a binary choice, $s_P \in \{T, C\}$. Thus, the utility functions of the principal and the agent are, respectively

$$u_P(s_P, \theta_i) = 2s_A + \theta_i(120 - s_A) + \eta_P, \quad (8.97)$$

$$u_A(s_A, \theta_i) = (120 - s_A) + \theta_i s_A + \eta_A. \quad (8.98)$$

As before, we assume that each player belongs to one of two possible, privately known, types $0 \leq \theta_L < \theta_H < 1$. The next proposition describes a separating equilibrium in this game that illustrates the negative effects of control-aversion. We leave the proof as an exercise.

Proposition 8.39 (Ellingsen and Johannesson, 2008): *There exists an open set of parameters such that there are intuitive equilibrium outcomes of the Falk and Kosfeld (2006) game with the following features:*

- (i) *An altruistic principal (type θ_H) plays T, while a self-regarding principal (type θ_L) plays C.*
- (ii) *A self-regarding agent (type θ_L) transfers the lowest amount possible, i.e., 0, when the principal plays T, and 10 when the principal plays C. An altruistic agent (type θ_H) transfers an amount $y \in (10, 120)$. However, the altruistic agent always transfers a greater amount if the principal plays T rather than C.*

Admittedly the results in Propositions 8.38, 8.39 hold for a simple class of games. However, they powerfully illustrate a view of incentives that runs contrary to existing models in neoclassical contract theory, in which incentives are typically, universally, good. These results qualify the existing models in important ways. If a principal mistrusts an agent, when he has an unused alternative that clearly signals trust, then agents may respond with lower effort levels. Furthermore, agents do not like being controlled—controlling them when there is an unused alternative that clearly signals mistrust also reduces effort.

Bénabou and Tirole (2006) also show (see Section 8.5.1), in a model where individuals have private information about multidimensional characteristics, that incentives may undermine effort. As in the blood donation example given above, incentives create an adverse selection problem by attracting individuals who are purely materialistic. Hence, it becomes difficult to signal one's esteem in the presence of such incentives. However, the Ellingsen and Johannesson (2008) model makes the additional prediction that when principals have a choice between two kinds of incentives—one signaling trust and the other signaling mistrust then the former elicits greater effort.

These results are related to those in Sliwka (2007). Here, in addition to the usual two kinds of *steadfast agents*, self-regarding and other-regarding, there is a third type, the *conformists*. The human virtues of conformists are more malleable and less steadfast. They behave like other-regarding agents if they think that there is a sufficiently large number of other-regarding agents. In other words, they are influenced by social norms. Thus, such an agent feels remorse from harming someone if he believes that there are sufficiently many other types of agents who would feel remorse.

The principal can choose either to trust or control the agent. The overall distribution of types of agents is unknown to the agents but the principal has superior information (perhaps he is more experienced). By choosing to trust, when control is available, the principal signals to the agents that the proportion of other-regarding agents is high. This is the signal that the conformists need in order to work hard. Such a transmission mechanism can also be invoked if the principal has a choice between say, a fixed wage scheme and an incentive scheme; the former may be used to signal to the conformists that the frequency of other-regarding agents is high.

Herold (2010) considers a principal-agent relation in which there are two types of agents. A *trustworthy agent* who shares the principal's concern to produce a high output level and a *self-regarding agent* who cares purely for the wage received and the cost of effort. The types of the agents are privately known to them. The principal receives a private signal of the type of the agent. Based on this signal, the principal has two possible types. The trusting principal has a

high signal of the trustworthiness of the agent. The distrusting principal has a low signal of the trustworthiness of the agent. Conditional on the signal, each type offers either a trust contract that is independent of the realization of output (flat wage contract) or an incentive contract in which the wage is conditional on the output level. The principal can signal his type by a choice of the contract—trust or incentive contract.

The effort level of the trusting agent is positively influenced by his belief that the principal is trusting. Furthermore, the principal knows that the trusting agent shares his mission, and requires a lower cost in terms of incentives to produce the same output level. This effect is enhanced if the production function is such that the output depends on the joint efforts of the agent and the principal, and these effort levels are complementary. Hence, a trusting principal gains by separating from a mistrusting principal. In a separating equilibrium, the trusting principal chooses a trust contract and the distrusting principal chooses an incentive contract. An incentive contract, in this framework, is bad news for the trustworthy agent and leads to lower effort levels and output levels.

8.6 Extrinsic and intrinsic motivation: empirical evidence

Motivated by the theoretical models in Section 8.5, we now consider the empirical evidence on intrinsic and extrinsic motivation.

8.6.1 Incentives may signal a hostile intent

In principal–agent interaction, an agent might perceive the following two contractual situations in entirely different ways. In the first, a hostile incentive, say, a fine, is available to a principal and is used. In the second, the hostile incentive is available, but not used by the principal; see, for instance, Section 8.5.2. Empirical tests of these issues are considered by Fehr and Gächter (2001). They modify the basic gift exchange game in Fehr et al. (1997), in the following three potential ways. First, when agents exert inadequate effort (i.e., the actual effort e_a is lower than the non-enforceable, but desired, effort, e_n), they are caught with a probability $p = 0.3$ (in the standard gift exchange game, $p = 1$). Second, in the event that an agent is caught, a fine $f \in [0, f_{\max}]$ may be levied. Third, the contract may specify a *non-binding* bonus, $b_n \in [0, b_{\max}]$, in addition to the binding wage, w , and the non-binding effort, e_n ; thus, this contract is even more incomplete relative to Fehr et al. (1997).

In order to differentiate the effects of various incentives, the following three conditions are considered. (1) *No incentives*, which is similar to the basic gift exchange game. (2) *Negatively framed incentives*, when a fine is possible. (3) *Positively framed incentives*, when a bonus is possible.

The main experimental results are summarized in Figure 8.13. The vertical axis measures the actual effort level, e_a , while the horizontal axis measures rents offered to the worker in different treatments. For a fixed level of rents, the effort levels are highest when no incentives are given. Instead of appealing to the instrumental reciprocity of agents (the incentive treatments) principals can do better by relying on the intrinsic reciprocity of agents (the no-incentive treatment).

One possible explanation of the results is to invoke the role of intentions, as in Section 8.5.2, or to explain the results using psychological game theory (see Part 4 of the book). The no-incentive treatments indicate a trusting principal, thus, agents reciprocate the trust. The incentive treatments on the other hand indicate a lack of trust. In particular, fines might be interpreted as hostile intent. Accordingly, agents may respond with negative reciprocity by putting in a lower level

Figure 8.13 Effort and rents in three cases.

Source: Reprinted from *European Economic Review*, 46: 687–724. Fehr, E. and Falk, A., “Psychological foundations of incentives.” Copyright © 2012, with permission from Elsevier.

of effort. Furthermore, it seems that the framing of incentives is quite important. Effort levels are higher in the positive frame (bonuses) relative to the negative frame (fines). These issues cannot be explained by using self-regarding preferences.

We quote here from Fehr and Gächter (2001). “it may be the case that explicit performance incentives reduce the willingness to voluntarily cooperate.” This possibility may arise because explicit performance incentives may create an atmosphere of threat and distrust. Bewley (1999) reports that “many managers stress that explicit punishment should be rarely used as a way to obtain cooperation ... In particular, explicit incentives may destroy trust—and reciprocity-based incentives, hence, may lead to welfare loss.”²⁰

Fehr and Rockenbach (2003) extend the trust game in the following way. Consider a static game played between an investor and a responder. Each of the players is endowed with 10 MUs (monetary units) and each MU is equivalent to half a German mark. The investor can decide to send (or invest) i MUs, that belong to the set $\{0, 1, 2, \dots, 10\}$ to a responder, via the experimenter. The experimenter triples the amount and passes it on to the responder. The responder then returns r MUs back to the investor. The respective payoffs of the investor and the responder at the end of the game are $10 - i + r$ and $10 + 3i - r$. The investor can also announce some desired transfer, r^* , back from the responder.

The investor can decide to impose a fine on the responder if $r < r^*$. The fine reduces the responder's payoff but does not increase the investor's payoff. Hence, we have three possible cases. In the first, no fine is available. In the second, it is available and is used; this possibly signals unkind intentions to the responder. In the third, it is available and is not used, which signals kind intentions to the responder. Fehr and Rockenbach (2003) find that the total surplus between the investor and the responder and the average payoff of the investor are highest in the third case; see Figure 8.14. Hence, the responder's perception of the principal's intentions (hostile or kind) determines the outcome; kinder intentions produce better outcomes.²¹

²⁰ There is a large psychological literature which suggests that incentives might crowd out intrinsic motivation. Within the Fehr–Schmidt model, intrinsic motivation may be interpreted as reciprocity driven effort.

²¹ There is some evidence that the amounts given in the trust game might be influenced by demographic variables such as age, marital status, health status, etc.; for instance, Fehr and Schmidt (2006). The elderly and the more healthy tend to give back more in the role of a responder.

In experiments conducted by Dickinson and Villeval (2008), a principal chooses different probabilities of monitoring the agent's effort; these probabilities are observed by the agent. When the effort of the agent directly increases the principal's payoff, then an increase in the monitoring intensity is found to reduce the agent's effort. Similar findings about the potentially negative effect of incentives on effort are reported in other papers that we describe in greater detail elsewhere in this chapter (Fehr et al., 2007; Fehr and Schmidt, 2007).

8.6.2 Control aversion and choking under high incentives

Incentives may signal a desire on the part of principals to "control" agents. Agents may be *averse to control*. This idea goes back to a literature in psychology (Deci and Ryan, 1985; Deci et al., 1999). In this view, incentives conflict directly with the desire of agents for *autonomy* and *independence*. Consider the following example from Ryan and Deci (2000): "Students who are overly controlled not only lose initiative but also learn less well, especially when learning is complex or requires conceptual, creative processing . . . Similarly, studies show children of parents who are more autonomy supportive to be more mastery oriented—more likely to spontaneously explore and extend themselves—than children of parents who are more controlling."

In Falk and Kosfeld (2006), an agent can choose some action $x \in [0, \bar{x}]$ for a principal. Increasing x is costly to the agent but beneficial to the principal. There are two treatments. In the first, the agent's choice is unrestricted—call this a *trust contract*. In the second treatment, the principal sets a lower limit, $\underline{x}$, to the agent's action. Thus, effectively, the agent now must choose x from the interval $(\underline{x}, \bar{x}]$ —call such a contract an *incentive contract*. If the agent had purely self-regarding preferences, then in the trust contract he would choose $x = 0$ and in the incentive contract he would choose $x > \underline{x}$. It turns out that for low levels of $\underline{x}$, the principal's profits under the trust

Figure 8.15 Median choice of action by the agent over when the principal does, and does not, control.

Source: Falk and Kosfeld (2006) with permission from the American Economic Association.

contract are greater than the profits under the incentive contract. Only when $\bar{x}$ is high enough does the incentive contract do as well as the trust contract.

Falk and Kosfeld (2006, p. 1611) summarize their main result as follows: “Explicit incentives backfire and performance is lower if the principal controls, compared to if he trusts.” Their main transmission mechanism (p. 1611–2) is that “agents do not like to be restricted and perceive control as a negative signal of distrust.” Consistent with this hypothesis, principals who try to control the behavior of agents, relative to those who do not, are found to hold more pessimistic beliefs about the performance of the agent.

In order to test this mechanism further, they implement a control treatment in which the experimenter (but not the principal) directly enforces x from the interval $(\underline{x}, \bar{x}]$, where $\underline{x}$ is identical to that chosen in the incentive contract. The control treatment does not signal a lack of trust or the desire to control on part of the principal, because the choice is made by the experimenter. Consistent with the authors’ suggested transmission mechanism, the principal’s profits are higher in the control treatment relative to the profits in the incentive contract.

In a second control treatment, the authors embed their game in a gift exchange game in which the principal chooses the pair $(w, \underline{x})$ where w is a fixed wage. The results are shown in Figure 8.15. As expected, the agent chooses a higher x when w is higher; this is the gift exchange channel. Furthermore, for most wage levels (30 or above in Figure 8.15), the choice of x is lower in the contract $(w, \underline{x})$, $\underline{x} > 0$ (labeled “principal controls” in Figure 8.15) relative to the contract $(w, 0)$ (labeled “principal does not control” in Figure 8.15), which is consistent with the control aversion hypothesis.

The relation between incentives and effort in economics relies on two sequential channels. In the first, performance-based pay increases the worker’s motivation. In the second channel, improved motivation results in greater effort. Ariely et al. (2009a) test for the second channel. They rely on several factors, which indicate that an increase in incentives may have a detrimental effect on effort (p. 2): “These include increased arousal, shifting mental processes from ‘automatic’ to ‘controlled’, narrowing of attention, and preoccupation with the reward itself.” The Yerkes–Dodson law in psychology, based on experiments on rats, posits an optimum level of arousal for each task, with effort falling as the level of arousal differs from the optimal in both directions. The results of Neiss (1988) for human motor performance are consistent with this law. Thus, it is

possible that high incentives over-arouse the subject, focus attention away from the task to the reward, or highlight negative emotions, such as feelings of regret, in case the reward is missed.

Choking refers to emotional responses that make high incentives counterproductive for the sorts of reasons described above (Loewenstein, 2000). The meaning of the term is well understood in common usage. Consider, for instance, the following typically self-effacing quote from Simon Hattenstone in the *Guardian* dated June 22, 2012, prior to the London Olympics:

Britain is no stranger to the choke. Reading the newspapers, or overhearing pub conversations, you might well imagine it's a national pastime. The England football team? Ach, we'll crack up when it comes to penalties. Murray at Wimbledon? Wait till it comes to the crunch. The Olympics? More tears from Paula Radcliffe. Of course, this is an unfair generalization. All those cited have performed at the highest level, and Britain has produced any number of champions. Yet it's undoubtedly true that in a summer in which so many will be playing for the highest stakes, many of the great sporting hopes, from whatever country, will buckle under the pressure.

Ariely et al. (2009a) give six tasks to subjects in an experiment that test memory, motor skills, and creativity. Subjects were randomly assigned to the tasks. There are three treatments, differentiated by the level of incentives: Incentives are very small, medium, or very large. The 6 tasks are simple games. A game called "Packing quarters" measures creativity; this involved fitting nine metal pieces into a wooden frame in a fixed amount of time. Two games, "Simon" and "Recall last three digits" test for memory; these involve recalling a sequence of numbers. Motor skills are tested using three games: "Labyrinth," "Dart Ball," and "Roll-Up." The results are shown in Figure 8.16.

The measure of performance that is used in these six tasks is share of earnings relative to maximum possible earnings. Figure 8.16 shows the average performance in each of the games (Panel(a) pools across all games). It is obvious that relatively high monetary incentives can have perverse effects on performance, but there was no noticeable difference between the low and the medium incentive conditions.

These results used a between-subjects treatment in rural India. A potential criticism of these results is that the subjects might not have played these kinds of games before. Hence, in a second set of experiments, a within-subjects treatment is implemented for MIT students, using games that the subjects would be familiar with. Subjects perform two possible tasks—adding a fixed set of numbers within a certain amount of time that measures cognitive skills, and repeatedly pushing a small sequence of keys to proxy for a physical task. The results are shown in Figure 8.17. The results of the cognitive task are similar to the earlier, between-subjects, treatment and high incentives are detrimental to effort. However, the results of the physical task are the opposite; high incentives are effective in this case.

Bartling et al. (2012) propose a new framework to test for the trade-off between control aversion caused by limited discretion on the one hand, and the misuse of discretion by workers on the other. Suppose that an employer hires an employee by offering a contract (w_b, e_n) , where w_b is the binding wage level and e_n is the non-binding effort level (or *requested effort* that cannot be contractually enforced). The payoffs of the employer and the employee are, respectively, $\pi = be_a - w_b$ and $u = w_b - e_a$, where e_a is the actual effort level, and $b > 0$ is the marginal productivity of effort.

The employer can offer one of two possible contracts. In the *full discretion contract* (contract-F), the employee chooses $e_a \in \{1, 2, \dots, 10\}$ and the productivity parameter $b = 5$. By contrast, in the *limited discretion contract* (contract-L) the employee chooses $e_a \in \{3, 4, \dots, 10\}$ and $b = 4$.

Figure 8.16 Mean earnings as a percentage of maximum earnings in different games.

Figure 8.17 Mean earnings as a percentage of maximum earnings in different games.

Source: Ariely, D., Gneezy, U., Loewenstein, G., and Mazar, N. "Large stakes and big mistakes," *Review of Economic Studies* (2009) 76(2): 451–69, by permission of Oxford University Press.

These numbers illustrate the trade-off between *efficiency* and *control*; contract-F is more efficient because b is higher, but the employee may shirk. The reason b is lower under contract-L is that the employee's flexibility is reduced; for instance, control may be associated with inflexible hours that do not suit the employee. The payoff functions and the technology is known to all players and the outside option of the employee is zero.

The employers and employees are matched randomly over 15 periods. There are two treatments. In the *base treatment*, the employer does not receive any information about the past effort levels of the agent. In the *screening treatment*, the employer is told about the effort choice of the employee, e_a , in the last three rounds but not the type of contracts (contract-F or contract-L) that were offered or the requested effort level, e_n .²²

Consider the solution under self-regarding preferences. In the last round, the employee puts in the minimum effort possible under each of the two contracts ($e = 1$ under contract-F and $e = 3$ under contract-L). The employer offers a wage to ensure that the individual rationality constraint of the employee binds, so $w - e = 0$. It is straightforward to check that the profit of the employer under contracts F and L is, respectively, 4 and 9. Thus, the employer optimally chooses contract-L. By backward induction, this is the solution in each round and it is identical under the base treatment and the screening treatment.

The solution under other-regarding preferences of the employer and the employee is along the lines discussed in Section 8.4; see for instance, Proposition 8.35. In this case, employers (self-regarding or other-regarding) will attempt to tap into the reciprocity of other-regarding agents. Self-regarding employees will tend to mimic the actions of the other-regarding employees in order to get rents. The results depend on the proportion of self-regarding and other-regarding employees, and the magnitudes of the inequity parameters of other-regarding players (as in Proposition 8.35).

While we do not prove these results here, under reasonable restrictions, one gets the following results.²³ In the base treatment, employers choose contract-L, i.e., they choose to control. In the screening treatment, however, employers offer contracts conditional on the previous levels of efforts of the employees (screening). When the previous effort levels are high, the employers offer contract-F and a high wage level in order to tap into the employees' reciprocity. For low previous effort levels, they offer the contract-L. The opportunity to build a reputation also induces employees to put in higher effort levels. Such an incentive is even higher if employers compete for workers, putting more upward pressure on wages.

In principle, one could have highly variable contracts. For instance, contract-F or contract-L, any positive wage level, and any, feasible, requested effort level. However, predominantly, two types of jobs are offered by the employers that we may call, respectively, as the *trust strategy* and the *control strategy*. The trust strategy has the following four fold features: (contract-F, high w_b , high e_n , high employee surplus). By contrast, the control strategy has the following four fold features: (contract-L, low w_b , low e_n , low employee surplus).²⁴ The trust strategy is based on tapping into the other-regarding employees' reciprocity, while the control strategy is designed to minimize shirking by self-regarding employees.

²² For instance, employers may have access to reference letters of potential employees that may not provide all possible information.

²³ Readers can consult Section A1 of the online appendix in Bartling et al. (2012) for the details.

²⁴ The employee surplus is defined as $\min \left\{ 1, \frac{w_b - e_n}{b e_n - e_n} \right\}$.

Which of the two strategies, trust and control is more profitable? The answer, as shown in the upper row of Figure 8.18, depends on the reputation of the employees. Let us group employees into three groups by their average past effort levels, $\bar{e}$, over three rounds: *Low reputation* if $\bar{e} < 3.5$, *medium reputation* if $3.5 \leq \bar{e} < 6.5$, and *high reputation* if $6.5 \leq \bar{e}$.

In the base treatment, contract-L is significantly more profitable than contract-F for employers, conditional on workers of all three types of reputations. In the base treatment, employers who offer contract-F, make losses for all levels of wages. The outcome is identical in the screening treatment when workers are of low reputation. However, the opposite is true for workers of medium and high reputation. In this case, under a screening contract, contract-F is relatively more profitable. The main reason for these results can be seen in the second row of Figure 8.18. The slope of the effort–wage response is too flat in the base treatment to justify the cost of a higher wage payment. By contrast, in the screening treatment, the effort–wage response is sufficiently steep to justify higher wage payments. Indeed, in an attempt to build a reputation, even self-regarding employees may mimic other-regarding employees and respond with a high effort choice. Regression results confirm the insights from Figure 8.18.

Recall the results of Falk and Kosfeld (2006) and Ariely et al. (2009a), above. These papers show that greater control reduces effort. This finding is not replicated in the second row of Figure 8.18. In fact, other than the high reputation employees in the screening treatment, one gets the opposite result, namely, that average effort is higher in contract-L. However, the high reputation employees also receive higher wages in a screening contract. Hence, these results neither support nor reject the *hidden costs of control*.

Figure 8.18 Average profits and average effort levels conditional on the employees' reputations.

It turns out that most employers in the two treatments converge towards the optimal contract over time. In other words, when the reputation of the employees is medium or high, employers choose to control in the base treatment and trust in the screening treatment. The results are shown in Figure 8.19. However, not all employers optimize. There is greater optimization in the base treatment. For instance, in the screening treatment, 45% of the employers fail to optimize when faced with employees of medium to high reputations.

A similar trend is found with respect to the employees. A significant percentage of self-regarding employees do not attempt to mimic the other-regarding employees by responding to high wages with high effort levels. Hence, they forgo an opportunity to improve their payoffs. This leads to *segmented labor markets*. Some employees work hard, are offered good jobs (the trust strategy of the employers) and have higher payoffs relative to others who shirk and get offered bad jobs (the control strategy). Despite the presence of a positive fraction of these non-optimizing employees, the opportunity to screen workers increases the profits of the employers. The reason is that there is a sufficiently large fraction of employees who take the opportunity of screening to build reputations for hard work and they are rewarded by good jobs. These features of the results are strengthened even further when competition is introduced in a separate treatment.

8.6.3 Moral disengagement

Implicit incentives such as bonuses may engage the *moral frame*, while *explicit incentives* may sometimes turn off the moral frame. Bowles and Polanía-Reys (2012, p. 373) write: “market-like incentives trigger what psychologists term ‘moral disengagement’ (Bandura, 1991), a process that occurs because ‘people can switch their ethicality on and off’ (Shu et al. 2011).” In a similar vein,

Schotter et al. (1996, p. 38) write: “While we are not claiming that people change their nature when they function in markets, it may be that the competition inherent in markets and the need to survive offers justifications for actions that, in isolation, would be unjustifiable . . . The morality of economic agents embedded in a market context may therefore be quite different from their morality in isolation.”

Hoffman et al. (2008) consider two treatments. In the first treatment, subjects are randomly assigned to the roles of proposers and responders in a standard ultimatum and dictator game. In the second treatment, subjects have to earn the right to be proposers. This is achieved by ranking the subjects, based on the number of correct answers to a general knowledge quiz. The top half of the ranked students is then assigned the role of a proposer and the bottom half is assigned the role of a responder. Further, proposers are told that they are “sellers” and responders are told that they are “buyers.”

In this “exchange version” of the ultimatum game, subjects play the game shown in Figure 8.20. Note that this game is identical to a standard ultimatum game, although it is framed differently, hence, standard frame-invariant economic theory predicts that the results should be identical in the two games. However, in the exchange version of the ultimatum game, sellers (or proposers) make lower offers relative to the standard ultimatum game and this difference is statistically significant. Buyers (or responders) are also less likely to reject offers in the exchange version of the game. Similar results carry over to the dictator game when a standard dictator game is compared with its exchange version: dictators make significantly lower offers. One plausible interpretation of these results is that the “moral frame” of the ultimatum and the dictator games is altered when these are framed as exchange games.

In Schotter et al. (1996), subjects in the experiment play two rounds of an ultimatum game and subjects are split into three groups. The first group forms the set of proposers in round 1. The second and third groups are, respectively, the responders in rounds 1 and 2. The proposers in round 1 play a tournament in the sense that they are ranked by the amounts that they could keep for themselves successfully (i.e., in cases where their offer was accepted). The top half of the proposers in round 1, who win the tournament, then go on to play the ultimatum game in round 2. Thus, as in Hoffman et al. (2008), proposers have to earn the right to play in round 2. The competitive tournament environment produces lower offers by proposers in round 2, i.e., the presence of incentives induces more self-regarding outcomes.

Cardenas et al. (2000) conduct experiments in three rural areas in Colombia among communities that live on the edge of forests. As part of their lives, these communities harvest a common resource, wood, from the forest. Subjects in the experiments engage in a common pool resource

game. As is typical in these problems, the efficient solution involves a degree of resource conservation, while in the Nash solution there is an over-exploitation of resources on account of free-riding.

The authors consider two groups of subjects. All subjects first play nine rounds of the common pool resource game. As expected, there is over-exploitation of the common resource. In the subsequent nine rounds, one group of subjects can communicate (Com), while the other cannot (Reg). Further, group Reg is subjected to government incentives to prevent over-exploitation in the form of a quota. Communication in group Com is designed to mimic the real-world alternative to regulation in such problems, namely, local cooperative efforts.²⁵ It was found that group Reg, who faced government incentives made choices close to the Nash equilibrium, while group Com made much more efficient choices.

Henrich et al. (2010) consider results for three games, the dictator game (DG), the ultimatum game, and the third party punishment game (TPG). The TPG is a three player game in which the first two players play a dictator game, while the third player can punish the proposer in the dictator game for low offers, by levying a fine at a personal cost. The subjects in the experiments are drawn from 15 diverse societies that include Amazonian tribes, African hunter-gatherers, and US students. Fines were not uncommon. Across all societies, the average offer in DG is 37%, while in the TPG it is 32%. In 4 out of the 6 societies where the offers in DG and the TPG are significantly different in a statistical sense, the offers are significantly lower in the TPG. Thus, the incentives embodied in the fines actually reduce offers. This crowding-out effect of incentives disappeared if one restricted attention to offers made by dictators who subscribed to one of the world's religions such as Islam or Christianity (as compared to other local or traditional religions).

Gneezy and Rustichini (2000a) explore the implications of introducing a fine in private day care centers in Haifa. They choose 10 day care centers that are observed over 20 weeks. In the first 4 weeks, the number of parents who came late to pick up their children was observed for all 10 centers. In 6 out of the 10 centers, a fine of 10 Israeli Shekels for picking up children late was announced in week 5. The remaining 4 centers were the control group that continued to operate without a fine. The 6 centers where the fine was levied between periods 5–16, had the fine removed in the beginning of week 17. Parents were observed again for the remaining 4 weeks to see if incentives have long-lasting effects.

The results are shown in Figure 8.21. There was an immediate jump in the number of parents arriving late after the introduction of the fine. The *reciprocity relation* between the parents and day care center staff seems to have altered with the introduction of the fine to an *exchange relation* (a form of switching-off of ethicality). Those parents who had a high opportunity cost of their time, seemed to be willing to pay the fine to pick up their children late (although this was not formally tested). There is no reason to believe that the opportunity cost altered after the imposition of the fine. It was also found that from weeks 17–20, when the fine was removed, the parents in day care centers where the fine had been levied, continued to come late and their late arrival stabilized at the end of the period. Thus, incentives may have a long-lasting effect on reciprocity relations. Similar results are found by Holmås et al. (2010) who find that disincentives in the form of fines for prolonging hospital stay in Norway had the opposite effect.

One possible explanation for the negative effect of incentives is that incentives may be too low. On the other hand, higher incentives may have a positive effect. This line of reasoning is pursued in Gneezy and Rustichini (2000b).²⁶ In the first experiment, the IQ experiment, university

²⁵ See, for instance, Ledyard (1995) in the context of public goods.

²⁶ See also Heyman and Ariely (2004) who find that giving no incentives is better than giving small incentives; the latter reduce motivation and effort.

subjects with an average age of 23 are asked GMAT style questions. Four treatments, with 40 students each, are implemented that differ in the degree of incentives offered; the respective rewards for a correct answer in these treatments are 0, 0.1, 1, and 3 New Israeli Shekels (NIS). In a second experiment, the donation experiment, students were grouped in twos and had to collect money for a good cause. There were three treatments here. In treatment 1a, students were given no monetary incentives but were told that the results of their efforts would be made public and that society wishes for them to collect as much money as possible. In treatment 1b, students were promised an incentive of 1% of the amount they collected and in treatment 1c, an incentive of 10% of the money collected.

The results are as follows. In the IQ experiment, the number of correct answers in the four treatments is respectively 28.4, 23.075, 34.7, 34.1. The number of correct answers with low incentives (monetary incentives 0, 0.1) is significantly lower as compared to high incentives (monetary incentives 1, 3). There is a significant marginal reduction in the number of correct answers when one moves from zero incentives (intrinsic motivation) to very low incentives (0.1). There is no statistical difference in the number of correct answers when incentives are already high (1, 3).

In the donations experiment, the average collections in the three treatments, 1a, 1b, and 1c, respectively, is NIS 238.67, 153.67, 219.33. There is a statistically significant reduction in collections when one goes from treatment 1a (intrinsic motivation) to treatment 1b (1% monetary payments). There is a statistically significant increase in collections as one moves from low incentives in treatment 1b to higher incentives in treatment 1c (10% monetary payments). However, even with high incentives, the collections are not higher than those that arise from purely intrinsic motivation.

Frey and Oberholzer-Gee (1997) showed that Swiss residents were more likely to agree to nuclear waste disposal in their communities out of a sense of civic duty as compared to a situation where they were offered monetary compensation. The monetary compensation may also potentially indicate to the residents that the potential risks of the plant are high.

In an unusual and interesting experiment, Falk and Szech (2013) explore if markets erode morality when subjects could choose between earning money and saving the life of a mouse. In the individual (or non-market) treatment, subjects had to choose between receiving 10 euros,

or saving the life of a young, healthy mouse, who could live for two more years. One may presume that in most cultures, the unjustified and intentional taking of a life must be considered immoral. In the bilateral treatment, a seller and a buyer bargain over the division of 20 euros. Should bargaining conclude successfully, then the life of the mouse is lost, but the two players get to share 20 euros. The multilateral treatment is similar to the bilateral treatment except that there are several buyers and sellers who simultaneously bid in a double auction format.

The authors conjecture three possible channels through which morality may be eroded in markets. First, in the bilateral and the multilateral treatments, responsibility for killing the mouse is more diffused relative to the individual treatment. Hence, guilt may be shared, and shared even more widely in the multilateral treatment, relative to the bilateral treatment. Second, the observation that others are willing to engage in trade (at the moral cost of the mouse's life) may loosen one's own morality in favor of the self-interest motive. Third, markets may draw attention to a non-moral frame by focusing the attention of individuals on negotiations, bargaining, and competition.

In the individual treatment, 45.9% of the subjects are willing to accept 10 euros, rather than save the mouse's life. In the bilateral and the multilateral treatments, 72.2% and 75.9%, respectively, of the subjects are willing to enter into a bargaining agreement that potentially gives them 10 euros, rather than save the mouse's life. These percentages are significantly higher relative to the individual treatment. Further, in the individual treatment, 72.2% and 75.9% of the subjects are willing to have the mouse killed, but only in return for much higher sums of money, respectively, 47.50 and 50 euros. Hence, morality would appear to decay in markets. It would be of interest to examine the precise channels through which these effects operate.²⁷

Ellman and Pezanis-Christou (2010) use insights from social psychology to explore the effect on the ethicality of decisions by varying the organizational form within firms and the levels of communication among players. In their three-player variant of the dictator game, a third player is passive. The first two players, who are members of the firm, decide whether to take an action that improves the profits of the firm, but harms the third player. In the *vertical organizational form*, the two-player firm has one boss who makes the decision and the other player is a subordinate. The subordinate cannot take a decision but can quit, which shuts down the firm. In the *horizontal organizational form*, both players in the firm take a decision by consensus.

When responsibility for the decision is diffused, such as in the horizontal organizational form, then each of the players feels a lower level of responsibility for an unethical decision. Indeed, the authors find that with unrestricted communication between the two players in the firm, vertical organizational forms exhibit more ethical behavior. The authors also recover an important role for communication. Communication may enhance ethicality for several reasons. For instance, communication may aid in transmitting norms of ethicality. Subordinates in horizontal structures may also feel a greater sense of social responsibility when they are able to transmit their views to superiors. Communication may also create an *observer effect*, whereby when one is observed by others one exhibits greater sociality (recall the evidence from dictator games in Section 5.2).

8.6.4 *Morality may be difficult to signal in the presence of incentives*

Consider the work of Bénabou and Tirole (2006) in Section 8.5.1 that addresses issues of altruism and social participation in several diverse contexts such as charitable contributions, voting, and

²⁷ Falk and Szech (2014) already make headway in this direction by considering alternative treatments that differ in the extent to which any one subject is pivotal in the decision to kill the mouse.

blood donation. Positive actions by an individual, such as higher charitable contributions, may improve one's own self-image (self-signaling) and could also be a medium through which one engages in social signaling to others such as family, friends, relatives, and colleagues. Individuals may be privately informed of their degree of altruism and they may derive utility from positive signals of their altruism to themselves and to others. Incentives may, however, dilute the reputational value of the signal by making it noisier. Hence, incentives may be counterproductive in eliciting greater effort.

In a pioneering study, Titmuss (1971) found that individuals are more likely to donate blood on a voluntary basis as compared to the case where they are compensated to donate blood; this became known as the *crowding-out effect of incentives*. Mellström and Johannesson (2008) use Swedish subjects to test the crowding-out effect, taking account of gender differences among subjects. Three treatments are considered. In the first, there are no incentives for giving blood and in the second there is a fixed monetary incentive of SEK 50 (the equivalent of US\$7) for donating blood. The results are shown in Figure 8.22.

Across all subjects in experiments, as we move from treatment 1 to treatment 2, the percentage of subjects who decide to donate blood falls from 43% to 33% but this difference is not statistically significant. However, there are noticeable gender differences. There is no crowding-out for men, but for women there is a statistically significant crowding-out effect and blood donations fall from 52% to 30%. A third treatment offers the kind of incentives that the *Economic Journal* gives to its referees. Subjects can choose to receive SEK 50 for their blood donations or have SEK 50 contributed, on their behalf, to a Swedish charity. In this case, when individuals choose the option to contribute to charity, there is no crowding out. This result is consistent with the Bénabou and Tirole (2006) explanation because contributions to charity may allow one to use contributions to signal one's type.

Lacetera et al. (2012) consider a very large sample of 500,000 blood donations to the American Red Cross (ARC) in Ohio between 2006 and 2008. The ARC collects blood in so called *blood drives*; each blood drive is a single event that solicits blood donations and there are an average

Figure 8.22 Percentage of blood donors under varying levels of incentives.

Source: "Crowding out in blood donation: was Titmuss right?" Mellström, C. and Johannesson, M., *Journal of the European Economic Association*, 6: 845–63. Copyright © 2008 European Economic Association.

of 36 donors per blood drive. They find a positive effect of non-monetary incentives (blankets, T-shirts, mugs, coupons) on blood donations. Higher incentives induce greater blood donations on two accounts: An increase in the turnout and an increase in the number of units donated. A significant part of this increase in donations, about 45%, is caused by substitution from other spatially and temporally separated blood drives. Thus, one should exercise caution in estimating the overall effect of incentives on blood donations.

Reich et al. (2006) find no effect of incentives, in the form of T-shirts, on blood donation. Goette and Stutzer (2008) find a positive effect of incentives that take the form of a free lottery ticket worth USD 5, although the bulk of the effect came from occasional donors, while committed donors exhibited no effect. In their review, Goette et al. (2010) opine that non-monetary incentives are more likely to induce greater blood donations, which is consistent with the signaling hypothesis. Furthermore, while survey evidence suggests that health related incentives (e.g., free cholesterol test for donors) are most effective, randomized trials show that they are not. In general, the evidence does not allow one to make conclusive policy implications. As Goette et al. (2010) say: "Overall, the results provide no support for the predictions from theories of motivational crowding. They provide moderate support for the view that incentives help to tip the balance in favor of more blood donations. However, several studies also found no effects, and this type of heterogeneity remains to be explained."

Angrist and Lavy (2009) consider incentives given to high school grade 12 students in Israel (Bagrut certification) to improve grades. Successful students go on to university, while the unsuccessful ones have an uncertain future. Hence, the economic gains for the students from doing well in these examinations would seem to be very high. However, anti-dropout measures for children taking these exams and measures to improve their grades have not been very successful. Given the widespread trend towards offering financial incentives to high school students for better grade performance, the authors wonder if financial incentives could work. They find that incentives are effective in the case of girls but not boys. Furthermore, incentives work only for those girls whose predicted grades are higher relative to the average. These marginal students would seem to have the most to gain from putting in extra effort or adjust their test-taking strategy. Five years after the intervention, these girls were also more likely to enroll in higher education, suggesting that incentives may have longer term effects.

Charitable donations may be publicly revealed or not. Under private information, donations are anonymous and carry no signal about the goodness or the altruism of the donor. Public information can take several forms, such as publicly revealing the list of donors, or giving donors special privileges, or simply giving tokens such as wristbands that publicly identify the donors. Ariely et al. (2009b) conjecture that in the private information case, incentives for donations (e.g., tax exempt donations) may enhance donations. However, in the public information case, if donations are made to signal one's image to others (or to oneself), then incentives deteriorate such signals. In this case, incentives may be counterproductive.

This conjecture is verified in their empirical results. Figure 8.23 shows donations to either a good cause (as determined by an individual) or to the Red Cross, which was determined to be a good cause by a majority of the subjects. Hence, the latter is particularly revealing for the signaling value of one's donations in the public information case. The vertical axis is the number of presses; subjects were asked to press buttons and the experimenter made donations to the chosen charity that were directly proportional to the number of presses. In each case, incentives reduce prosocial behavior in the public information case but increased such behavior in the private information case.

Figure 8.23 The effect of incentives on prosocial behavior in different treatments. Vertical bars are standard errors of means.

Source: Ariely et al. (2009b) with permission from the European Economic Association.

Carpenter and Myers (2010) consider the decision to volunteer as a firefighter and the decision to respond to a call. They find that subjects who are more altruistic, as identified by their performance in a dictator game, are more likely to be volunteer firefighters and also put in more training hours. However, altruism is not necessarily associated with the decision to respond to calls. The decision to respond to calls is more strongly correlated with incentives that boost one's public image such as a vanity license plate. For decision makers who are motivated by such reputational concerns, extrinsic motivation in the form of monetary incentives are ineffective.

Gneezy et al. (2012) conduct three field experiments to examine the effect of incentives on the degree of self-regarding behavior in markets. These experiments are similar in nature to the Prucker and Sausgruber (2013) experiments that we considered in Chapter 7. In the first experiment, an amusement park sells photos taken during a ride to potential customers. Potential customers can *pay the price that they want* (PWYW pricing). Under purely self-regarding preferences they should not pay at all. However, 8.39% of the customers choose to buy under PWYW pricing. In a second treatment (PWYW + charity), customers are told that half of the sales proceeds will go towards charitable contributions. In this case 4.49% buy their photos but they pay a price \$5.33 relative to a price of \$0.92 in under PWYW pricing. Indeed, the PWYW and PWYW + charity pricing scheme are profitable to the amusement park. The data supports the hypothesis that people buy less under PWYW + charity because they avoid the possibility that they will pay too little and harm their self-image.²⁸

In another field experiment, customers in a restaurant in Vienna could directly, and publicly, pay the owner or, under PWYW pricing, pay privately in an envelope. Under self-regarding preferences, customers should not pay under PWYW pricing, at least in a static game. The direct payment to the restaurant owner rules out any prosocial signaling. However, under PWYW pricing, one may self-signal prosocial behavior, or other desirable human virtues, by paying-up. Indeed, under PWYW pricing, customers paid more relative to direct public payments to the owner. A major conclusion of this study is that the desire to maintain a favorable self-image induces departures from self-regarding outcomes in markets.

²⁸ For a similar experiment and results see also Gneezy et al. (2010).

8.6.5 *Economic environment, learning, and incentives*

We have reviewed the empirical evidence in Henrich et al. (2001) in Chapter 5, which showed that participation in a market environment enhanced sociality among individuals from diverse cultures. Perhaps individuals learn to alter their preferences in such environments because doing so is advantageous to them. Furthermore, the effects of incentives can be long lasting; some examples of this are as follows. The association between educational incentives and long-term enrollment in higher education (Angrist and Lavy, 2009); the link between fines and lateness in the arrival of parents in after care centers in Israel (Gneezy and Rustichini, 2000a). We now consider some additional, related results.

Bohnet et al. (2001) consider the effects of the legal environment on contracts. They consider a two-player game in which a principal decides whether to enter or not into a contract with an agent; this is a measure of the *trust* of the principal. The principal does not know if the agent will perform; the probability that the agent performs is a measure of his *trustworthiness*. If the agent does not perform, then he is penalized with some probability that depends on the strength of the law enforcement institutions. The agent may experience psychological costs (such as guilt, or aversion to lying) from not performing or he may be completely self-regarding. In classical enforcement theory, formulated under purely self-regarding preferences, there is a monotonic relation between the strength of law enforcement and the trustworthiness of the agent. However, in the presence of human virtues, and malleable preferences, this monotonic relation may not hold.

Clearly, when the enforcement institutions are weak, the principal will only offer a contract if his belief about the trustworthiness of the agent is high. A low belief in the trustworthiness of the agent protects the principal from being exploited under these circumstances. A high degree of belief in trustworthiness may ensure that, over time, more trustworthy agents are hired (the authors formalize this in terms of an evolutionary argument). Hence, in an environment with weak enforcement, trustworthiness may be crowded-in. With medium enforcement, the probability of law enforcement is high enough so that it is worthwhile for the principal to enter into a contract, based on expected utility calculations. In this case, the self-regarding agents will maximize their payoffs by not performing and the honest agents will maximize their payoff by performing. Thus, with medium enforcement, trustworthiness may be crowded-out. When the enforcement institutions are strong, then non-performance is always detected and all types of agents perform. The predictions on the relation between the strength of the legal institutions and the degree of trustworthiness are verified in the experiments conducted by the authors.

In a field study, Meier (2007) examines the effect of temporary incentives and the long-term effect on behavior once the incentives are removed. His subject pool is Swiss students who can contribute to one of two possible social funds. It is announced in a treatment group that the contributions of those who contribute to both funds will be matched to varying degrees (in one sub-treatment, the match is 25% and in another it is 50%). It is found that incentives in the form of matching contributions increase donations to the social funds. However, once the incentive is removed, (1) the average contributions in the treatment group are significantly lower than the control group in which no incentives were given, and (2) most of the subjects in the treatment group who had originally contributed to one of the two social funds, stop contributing altogether to any fund.

Reeson and Tisdell (2008) run three treatments of a public goods game without punishments, over 12 rounds. Rounds 1–4 comprise the initial stage, rounds 5–8 the middle stage, and rounds

Figure 8.24 Total public goods contributions over successive rounds when the incentives are varied.

Source: Reprinted from *Journal of Economic Behavior and Organization* 68(1), Andrew F. Reeson and John G. T. Sdell, "Institutions, motivations and public goods: an experiments test of motivational crowding," 273–81. Copyright (2008), with permission from Elsevier.

9–12 the final stage. The control treatment is the standard public goods game experiment run over 12 rounds. In the *moral suasion treatment*, a standard text is read out to the subjects, which says that everyone will be better off if they contributed to the public good. This text was read out at the beginning of each stage, i.e., in rounds 1, 5, and 9. Finally the *regulation treatment* is identical to the moral suasion treatment except that in the middle stage, i.e., rounds 5–8, in addition to moral suasion, the experimenter announces a minimum required contribution of 100 cents to the public good. The results are shown in Figure 8.24 that shows the average contributions to the public good in cents in the three treatments.

The Nash equilibrium that is consistent with free-riding is constructed in such a way that it is 600 cents. Contributions are significantly higher in the moral suasion treatment relative to the control treatment in the initial stage. Consistent with the dominant finding in public goods games, the level of contributions declines over successive rounds in the initial stage. Reading out the moral suasion text at the beginning of round 5 boosts contributions in the middle stage to a level similar to that of the initial stage (the authors call this the “ground-hog day” effect). In the middle stage, contributions are highest in the regulation treatment and these are significantly higher than the control treatment. However, once the regulations are removed in round 9, contributions in the regulation treatment drop below the level of the moral suasion treatment and are significantly lower relative to the initial stage. Thus, not only does moral suasion play an important role, it dominates incentives, in the form of regulation, in the long run.

Burks et al. (2009) consider the effect of economic incentives on Swiss and American bicycle couriers. When distinguished by their compensation, bicycle messengers belong to two main groups. (1) The first group receives performance based pay or commission payment in which

couriers typically receive 40–45% of the revenues they generate. (2) The second group is made up of two subgroups that do not receive performance-based pay. They either receive a fixed hourly wage or they are members of cooperatives that simply share the total revenues.

Members of both groups are asked to play a sequential prisoner's dilemma game, which really is a standard prisoner's dilemma game except that the first player makes a choice that is observed by the second player who then sequentially makes his choice. In this game, respondents are asked to choose their strategy (cooperate or defect) in the role of the first player and the second player.²⁹ They are also asked what percentage of the other players are likely to cooperate. Each respondent is then randomly paired with another, their roles as the first player and the second player are also randomly chosen. The stated responses of both players in their respective roles are then implemented.

The outcomes are used to classify respondents into one of three groups. *Egotists* always defect, *altruists* always cooperate, and *conditional cooperators* are second players who cooperate when the first player plays cooperate and defect when the first player plays defect.³⁰ The same game is also played with students. The results are as follows.

On average, player 1s who played the strategy “cooperate,” estimated that 67% of players 2 will also cooperate. This was an underestimate—the actual figure was 86%. Thus, players may have other-regarding preferences. Respondents who are exposed to performance-based pay, exhibit significantly lower levels of the strategy “cooperate” relative to those who are not exposed to performance-based pay. They also expect others to cooperate less. The experimental classification of respondents into egotists, altruists, and conditional cooperators is a good predictor of the answers to survey questions that further probe their behavior at work and off work. There are significantly more egotists in the student population relative to the population of bicycle couriers.

8.6.6 *Crowding-in effect of incentives*

It is possible that, in certain cases, there might be a synergy between incentives and other-regarding preferences. For instance, punishments by one's peers may trigger feelings of guilt and shame, thus pushing individuals towards a better social outcome. It can often, however, be difficult to isolate the channels that are involved. For instance, punishment in public goods games may contribute to achieving an outcome close to the first best; see Section 5.4.3 above. However, it is also found that non-monetary punishments such as social ostracization can enhance contributions in public goods games (Masclot et al., 2003). Do non-contributors contribute more in the presence of punishment simply because they anticipate being punished and so they contribute, or because the punishment activates feeling of guilt, shame, lower self-evaluation, or even stigma if punishments are publicly implemented?

Herrmann et al. (2008), which was considered in Section 5.4.6, show that in public goods games with punishments, cooperation is higher when there is already a strong social norm of cooperation. In the presence of such norms, punishments trigger feelings of shame rather than resentment against the punishers. When such social norms are absent, then there is a crowding-out effect of punishment. In the absence of social norms of contributing, non-contributors who

²⁹ The *strategy method* is used to enhance the number of observations. In this method, the second player is asked what choice they would make for each possible observed choice of the first player (cooperate or defect).

³⁰ There is a fourth category of players, who the authors term as “Wingnuts” who do not appear to have understood the game. Since these are only 3% of the total, they are excluded from the sample.

have been punished in the past turn on the contributors in subsequent rounds by engaging in antisocial punishments.³¹

Xiao and Houser (2011) ask if the negative effect of incentives arise because the punishments are privately implemented. They consider a public goods game in which the punishments are publicly announced. Yet the anonymity of the target of the punishment is maintained in order to rule out any effects arising from “naming and shaming” of the non-cooperators. They announce a probability with which any round of the public goods game is monitored. In the monitored round, the individual whose contribution is the lowest is punished in proportion to the difference between the average contribution and the lowest contribution. They conjecture that the transmission channel through which incentives work is that public punishments help establish the norm of “contribute at least as much as the average of one’s group members.” Contributions are found to be much higher in the treatment with public punishment relative to the baseline case of private punishment.

Carpenter et al. (2009) reconsider the public goods game with punishments. In the strangers treatment, subjects are randomly assigned to a new group at the beginning of each round. They find that being punished seems to trigger feelings of shame and guilt among non-contributors, who then contribute more. The efficacy of punishments depends on there being a high enough proportion of players who exhibit indirect reciprocity and a group size that is not too large.

Cappelen et al. (2015) consider if giving behavior in dictator games is motivated by intrinsic motivation or extrinsic motivation. In different treatments, the authors vary the morality associated with giving, for instance, by varying entitlements and needs; differences in giving between these treatments reflect changes in intrinsic morality in different moral frames. Extrinsic motivation is altered by varying the information given to the receiver about the dictator’s giving behavior. Such motivation is caused by factors such as shame and guilt that, however, are better captured using psychological game theory that we develop in Part 4. The two main experimental findings are as follows. First, intrinsic motivation, which reflects human virtues, is fundamentally important. Second, intrinsic motivation crowds-in extrinsic motivation; in the absence of intrinsic motivation, extrinsic motivation is irrelevant.

Tyran and Field (2006) consider two kinds of sanctions on non-contributors in a public goods game. Sanctions imposed by the experimenter and sanctions imposed by a referendum among group members. Although both kinds of sanctions raised the cost of free-riding, sanctions imposed by the experimenter were not effective, while those imposed by a referendum were effective. One possible explanation is that the referendum conveys a signal of the moral disapproval by one’s peers, so it is more effective in triggering feelings of guilt and shame.³²

Fryer (2011) conducted experiments in four school districts in the US in which an amount of USD 6.3 million was distributed as incentive payments in 261 schools. In Dallas and Columbia, incentives were given for “inputs” such as attendance, good behavior, and reading a book, followed by a quiz to test the understanding of students. In New York City and Chicago, incentive payments were made for “outputs” such as exam grades. If students understand the production

³¹ Evidence for antisocial punishments are also found in Hopfensitz and Reuben (2009) using a social dilemma game such as the sequential prisoners’ dilemma and the trust game. They find that punishment is effective only when it induces feelings of shame and guilt among the punished.

³² For a theoretical model of the formation of a sanctioning institution (e.g., a court, or an arbitration board) that enables punishment of non-cooperators in a public goods game see Kosfeld et al. (2009). Institutional punishments may also evoke feelings of guilt and shame.

function that links inputs to outputs and if behavioral factors such as self-control are absent, then incentives based on outputs may be superior. The reason is that incentives based on inputs may distort the use of inputs, while output-based incentives allow users to optimally combine inputs. The results of the study are not easy to interpret. However, no link is found between intrinsic motivation and incentives. An important finding of the experiments is that incentives for output are ineffective, while incentives for inputs are effective, in a statistical sense, for some measures of performance in some of the districts. This suggests that we need to reconsider the underlying model of incentives in neoclassical economics.

Levitt et al. (2012) consider the effect of short-term educational incentives that are not confounded by issues of time discounting. They find that the effects of financial incentives, framed as gains, are mixed. However, there are stronger effects of financial incentives framed as losses.³³ Among younger students, non-financial incentives such as awards and trophies are as effective as financial incentives. There are also significant treatment effects such as age-specific effects (older children respond more to financial incentives) and gender effects (boys are more responsive to short-term incentives).³⁴ When incentives are delayed in the experiments (e.g. students are paid a month later, then the beneficial effects of incentives are substantially curtailed. In actual practice the rewards to education, such as jobs, salaries, and perks (which are the corresponding incentives in the real world) follow with substantial delay, suggesting that there could be underinvestment in education.)

A regular exercise regime coupled with a healthy diet, taken in moderation, has well-known benefits. These include higher self-esteem, better body image, a lower likelihood of being depressed and a lower risk factor for several health problems such as cardiovascular disease. Hence, it may be argued that there are already high incentives in place to induce a regular exercise regime, yet such a regime is not universally observed. Charness and Gneezy (2009) ask if financial incentives can aid in developing a habit to exercise?

In Study 1, they first give a handout that describes the benefit of exercise. Then they distribute the subjects into three groups. In the first group, the control group, no financial incentives are given. In the second group, the *one time group*, \$25 are given for exercising once a week. The third group, the *eight time group*, starts off with a payment of \$25 for exercising once a week, followed by a payment of \$100 for exercising eight more times in the next four weeks. In study 2, subjects were given \$75 to show up, have biometric readings taken, and receive a handout that described the benefits from exercise. At this time, subjects were divided into three groups and invited to come back two more times with the promise of a payment of \$50 each time as well as the recording of biometric readings. In the first group, the control group, there was no requirement to exercise. In group 2, the one time group, participants were asked to attend the gym once in the intervening period, while in group 3, the eight time group, participants were asked to attend the gym eight times in the intervening period.

The results are shown in Figure 8.25. The vertical axis shows visits to the gym per week. The period “before” records gym visits in the eight weeks before the intervention and the period “after” records gym visits in the seven weeks after the intervention. There is no statistical difference

³³ The framing effect of incentives jives well with the importance of framing considered elsewhere in the book. For instance, in the context of social preferences, Liberman et al. (2004) find that the manner in which a prisoner’s dilemma game is framed (a cooperative or competitive game) significantly affects the prosocial behavior of participants.

³⁴ The gender specific effects of incentives were also found in some of the studies considered above that examine educational incentives, e.g., Fryer (2011) and Angrist and Lavy (2009).

Figure 8.25 Number of weekly visits to the gym. Error bars reflect one standard error.
Source: Charness and Gneezy (2009) with permission of The Econometric Society.

between the control group and the one-time group. However, the eight-times group, the high incentive group, reveals significantly higher gym attendance in the “after” period. There is also a significant improvement in the biometric measures for this group. The positive effect of incentives in this group is driven largely by people who did not attend the gym regularly in the “before” period.

Exercises for Part 2

1. Prove Lemma 6.4.
2. (Fehr and Schmidt, 1999) Consider the ultimatum game with responder competition when all agents are other-regarding. Suppose that there are n players. Player 1 is the proposer and the remaining players are the responders, whose Fehr–Schmidt preference parameters are commonly given by (α, β) . The proposer offers a share $s \in [0, 1]$ that is observed by all responders who simultaneously choose to accept or reject. If more than one responder accepts, then one among this set is chosen randomly as the winner. The winning responder gets s , the proposer gets $1 - s$, and all other responders get 0. Suppose that $\beta < \frac{n-1}{n}$. Show that there exists a subgame perfect equilibrium in which all responders accept any $s \geq 0$ and the proposer offers $s = 0$. Show also that the highest offer that can be sustained as a subgame perfect equilibrium is given by $s^* = \frac{\alpha}{(1-\beta)(n-1)+2\alpha+\beta} < \frac{1}{2}$.
3. (Fehr and Schmidt, 1999) Prove Proposition 6.5.
4. (Fehr and Schmidt, 1999) Consider the public goods game in Section 5.4. Suppose that all contributors have Fehr–Schmidt preferences. Show that:
 - (a) If $r + \beta_i < 1$ for player i , then it is a dominant strategy for that player to choose $g_i = 0$.
 - (b) Let k denote the number of players with $r + \beta_i < 1$, $k \in [1, n]$. If $\frac{k}{n-1} > \frac{r}{2}$, then there is a unique equilibrium with $g_i = 0$ for all i .
 - (c) If $\frac{k}{n-1} < \frac{r+\beta_j^{-1}}{\alpha_j+\beta_j}$ for all players $j = 1, 2, \dots, n$ and $r + \beta_j > 1$, then there exist other equilibria with positive contribution levels. In these equilibria, all players with $r + \beta_i < 1$ choose $g_i = 0$, while all other players contribute $g_j = [0, y]$. Further, $\frac{r+\beta_j^{-1}}{\alpha_j+\beta_j} < \frac{r}{2}$.
5. (Fehr and Schmidt, 1999) Prove Proposition 6.6.
6. In a public goods game experiment that is repeated over several rounds, contributions stabilize at a very low level. Does this provide support for self-regarding preferences?
7. Consider the three-player experiments by Güth and van Damme (1998), which combine a ultimatum and a dictator game. There is a single proposer (player 1) and two responders, an active responder (player 2), and a passive responder (player 3). The proposer makes an offer of the form (x_1, x_2, x_3) such that the proposer's share is x_1 , the active responder's share is x_2 , and the passive responder's share is x_3 . Player 2 can (as in ultimatum games) either accept or reject the offer. Player 3 does not have any actions. The main empirical finding is that the proposer allocates very low amounts to player 3 and the rejection decision of player 2 does not seem to be significantly influenced by the amount offered to player 3. What are the implications of these results for maximin preferences (as in Charness and Rabin, 2002) and for models of inequity aversion such as the Fehr–Schmidt model and the Bolton–Ockenfels model?
8. (al-Nowaihi and Dhami, 2015) Consider the prisoner's dilemma game.

	C	D
C	2, 2	0, x
D	x , 0	1, 1

Each player has two choices: cooperate (C) or defect (D). The payoff-matrix shows material payoffs of the two players and $x > 2$. In terms of the material payoffs, (C, C) is not a Nash equilibrium. Now suppose that players are inequity averse and have Fehr–Schmidt preferences.

- (a) Suppose that $x = 3$. What is the lower bound on β that achieves the cooperative outcome (C, C) ?
- (b) Now suppose that $x = 10$. How does your answer to (a) change? Is the lower bound on β consistent with the experimental evidence? What can you conclude about the ability of Fehr–Schmidt preferences to explain the empirical results that in the static prisoner’s dilemma games, we observe the outcome (C, C) about 50% of the time?
- (c) “It has been suggested that players achieve a higher degree of cooperation in prisoner’s dilemma games when the game is framed as a community game (cooperative frame) rather than as a Wall Street game (competitive frame). It has also been shown that preplay communication improves cooperation in the prisoner’s dilemma game.” Can models of inequity aversion explain these results? What additional features might you need to explain this finding?
9. There is a positive level of giving in dictator games. Which of the three main types of theories—inequity aversion, intention-based reciprocity, or type-based reciprocity—can explain this finding?
 10. Equal splits (50–50) are often observed in the ultimatum game. Can these equal splits be rationalized in terms of the Bolton–Ockenfels (2000), ERC model? What restrictions are needed on the parameters α, β in the Fehr and Schmidt (1999) model to account for the empirical finding of equal splits? Can the model of Rotemberg (2008) (see Section 6.8.2) account for the equal splits, and if so, what is the difference in the transmission channel relative to the Fehr–Schmidt model.
 11. Charness (2004) conducts two treatments in a gift exchange game. In the random choice condition, the proposer’s choice is randomly determined. In the human choice condition, a human proposer makes the choice. What is the prediction of intention-based theories? What is the prediction of type-based reciprocity theories about the relative correlation between wage and effort in the two different treatments? The empirical finding in these experiments was that there is a significant positive correlation between wages and effort in the random choice condition. This correlation was only slightly lower in the human choice condition. What are the implications of these experiments for the three main types of theories—inequity aversion, intention-based reciprocity, or type-based reciprocity?
 12. (a) Eckel and Gintis (2010, p. 3) make the following comment: “Binmore and Shaked’s defense of the neoclassical analysis on the grounds that ‘all possible divisions of the money in the ultimatum game are Nash equilibrium outcomes’ is transparently faulty.” Do you agree with the comment?
 (b) Evaluate the following quotes from Eckel and Gintis (2010):
 (b1) (p. 4) “Binmore and Shaked also argue that other-regarding behavior disappears or is greatly attenuated when the stakes are high. It is not clear why this is a criticism.”
 (b2) On p. 11–12, Eckel and Gintis quote Binmore and Shaked, thus: “Behavioral economists sometimes claim that neoclassical economists hold that people are self-regarding . . . But no such [selfishness] axiom appears in neoclassical economics textbooks . . . When utility functions of various kinds are fitted to data obtained in laboratory experiments, neoclassical economics is therefore in no danger of being refuted.” Evaluate this claim in the context of a general equilibrium neoclassical model.
 13. (Dhami and al-Nowaihi, 2013) Prove Proposition 6.10.
 14. (Dhami and al-Nowaihi, 2013) Prove Propositions 6.11, 6.12.
 15. (Dhami and al-Nowaihi, 2010a) Prove Proposition 6.13.
 16. (Dhami and al-Nowaihi, 2010a) Prove Lemmas 6.6 and 6.7.

17. (Dhami and al-Nowaihi, 2010a) Consider the model in Section 6.5. (a) Prove Proposition 6.14.
(b) Show that if utility is quasilinear

$$\tilde{u}(c, 1 - l) = c - \frac{1}{2}l^2,$$

then a majority prefers the tax rate that is optimal for the median-skill voter. In particular, show that assumption A1 holds and assumption A2 in Proposition 6.14 is not needed in this case.

18. (Dhami and al-Nowaihi, 2010a) Prove Proposition 6.15.
19. (Dhami and al-Nowaihi, 2010a) Prove Proposition 6.16.
20. (Bartling et al., 2013) Consider the model of vertical integration in Section 8.4.4. How does this model offer at least a partial justification of the role of trade unions and labor market legislation?
21. (Itoh, 2004) Prove Propositions 8.26 and 8.27.
22. (Englmaier and Leider, 2012) Prove Proposition 8.30.
23. (Fehr et al., 2007) Prove Lemma 8.11. [Hint: Use the same method that you used in Lemma 8.10].
24. (Fehr et al., 2007) Prove Proposition 8.32. [Hint: Set up the Kuhn–Tucker conditions for the other-regarding principal's optimization problem and consider the various combinations of the complementary slackness conditions.]
25. (Fehr et al., 2007) Prove Proposition 8.31. [Hint: For each of the contracts, solve, using backward induction, the two-stage game in which the principal first chooses the contractual parameters followed by the agent's choice of effort].
26. Prove Lemma 8.19. [Hint: Rewrite the MLRP in (8.75) as $g(\sigma_H | c_H)g(\sigma_L | c_L) < g(\sigma_L | c_H)g(\sigma_H | c_L)$. Then integrate both sides twice, first over σ_L from σ_L to 1 and then over σ_H from σ_H to 1.
27. (Bénabou and Tirole, 2003) (a) Show that the conclusions of Proposition 8.37 are unaltered if the outside option of the agent is $\bar{U} > 0$.
(b) Consider the setting of the Bénabou–Tirole (2003) model in Section 8.5.1. Suppose now that costs are public information but that the principal has private information about the agent's ability to perform the task, θ , that is drawn from the distribution $F(\theta)$. The principal observes θ perfectly. The agent observes an imperfect signal of θ given by $\sigma \in [0, 1]$ that has conditional distribution function $G(\sigma | \theta)$ and conditional density $g(\sigma | \theta)$ that satisfies the monotone likelihood ratio property (see (8.75)). In all other respects we have the model given in Section 8.5. The principal does not observe the agent's effort e but pays a performance contingent reward, b , in the event that the project is successful. Show that all the results in Proposition 8.37 continue to hold with appropriate changes in notation and terminology.
28. Can you explain the following empirical findings using standard models of neoclassical economics in a plausible manner using reasonable assumptions? If not, what assumptions might you need on human sociality or non-standard human motivations to explain them.
(a) (Restivo and van de Rijt, 2012) Contributors to Wikipedia were randomly chosen to be given Barnstar rewards, a form of status-reward that was publicly displayed. Over the next three months, the individuals who were given the reward were 60% more productive as compared to a control group that was not given the reward.

(b) (Kosfeld and Neckermann, 2011) In a single data entry task, subjects in a gift exchange experiment were told that the top two performers will receive a congratulatory card and a personal thank-you note from the managing director. This simple intervention increased performance by 12%, which is identical to the hypothetical effect of an increase in wage of 35–72%, based on output elasticity measured in previous gift exchange games.

(c) (Ashraf et al., 2014) In a field experiment in Zambia, barbers were recruited by the public health organization to sell condoms. Four treatments varied in their reward structure. In a control treatment, there were no rewards; in two treatments, the margins offered were 10% and 90% of sales; in the star treatment there was a non-pecuniary reward in the form of a star stamped on a publicly displayed chart. The star treatment was supposed to capture the esteem associated with a sense of public duty. After a year it was found that barbers in the star treatment had sold twice as many condoms as in any other treatment.

29. Use the material in this chapter to explain the interaction between other-regarding preferences and incentives in the following description of events from Bowles and Polanía-Reys (2012, p. 369). “On December 1, 2001, the Boston Fire Department terminated its policy of unlimited paid sick days, replacing it with a fifteen-day sick day limit; pay would be docked for firemen exceeding the limit. The firemen responded to the new incentives: those calling in sick on Christmas and New Year’s Day increased tenfold over the previous year. The Fire Commissioner retaliated by canceling their holiday bonus checks (Belkin 2002). The firemen were unimpressed: the year following they claimed 13,431 sick days; up from 6,432 the previous year (Greenberger 2003). Many of the firemen, apparently angered by the new system, abused it or abandoned their previous ethic of serving the public even when injured or not feeling well.”
30. (Ariely et al. 2009b) Consider the following example. “An individual is considering buying a new hybrid car. This car is more expensive than an equivalent car operating with a standard gasoline engine, but the hybrid car helps in preserving the environment. Driving a car which is clearly a hybrid automobile would probably add to one’s positive image, especially for those who live in a community that values environmentally friendly technologies. Suppose now that the government gives a large tax benefit to those who decide to purchase a hybrid car (and everybody knows about this). The tax incentive, of course, reduces the price of hybrid cars and therefore should make the hybrid car more attractive for the individual.” Will the tax incentive be necessarily successful in boosting sales of the hybrid car among all groups of individuals?
31. (Ellingsen and Johannesson, 2008) Prove Proposition 8.39.
