Conversely, the system of ODE in (5.A3) can be termed as *non-autonomous* or time dependent. The vector $\mathbf{x}(t)$ is called the *state* of the system. The set of all states is called the state space. We assume that the set of all time–state pairs $(t, \mathbf{x})$ forms a connected open subset, X , of $\mathbb{R}^{n+1}$. The function $\mathbf{f}$, which equals the column vector $(\dot{x}_1(t), \dot{x}_2(t), \dots, \dot{x}_n(t))$ at time t , is called a *vector field*. It specifies at any instant of time t , the *direction* and the *velocity* of the state of the system.

An ODE is said to be *linear* if the function $\mathbf{f}(\cdot)$ is linear. The majority of differential equations that we will consider are *linear, autonomous, first order differential equations*. In a *scalar* differential equation, $n = 1$, while $n \geq 2$ implies that we have a *system of differential equations*.

SOLUTION OF AN ODE

A *solution* to an ODE is a function $\mathbf{x}(t)$ that satisfies (5.A3). However, there is typically a whole family of solutions. For instance, consider the linear scalar autonomous first order differential equation, $\dot{x}(t) = ax$. This has the general solution $x^*(t, k) = ke^{at}$ where k is some constant; check that this is the solution by differentiating both sides of the solution with respect to t , to get the original ODE. Set $t = 0$ in the solution to get $x^*(0, k) = k$, hence, the solution is

$$x^*(t, k) = x^*(0, k)e^{at}.$$

More generally, we write a solution to the ordinary differential equation (5.A3) that passes through $\mathbf{x}$ at time 0 as:

$$\mathbf{x}^*(t, \mathbf{x}), \quad \text{where} \quad \mathbf{x}^*(0, \mathbf{x}) = \mathbf{x} \quad (5.A5)$$

$\mathbf{x} \times (0, \mathbf{x}) = \mathbf{x}$ is called the *initial condition*. We are interested in several aspects of the solution. Does it exist? Is it unique? Is it local or global? We begin with the last of these three questions.

Definition 16.35 (*Local and global solutions*): Consider the solution (5.A5) to the ordinary differential equation (5.A3), where $\mathbf{x}^*(t, \mathbf{x}) \in X$ for $t \in T$. If T is the entire real line, $\mathbb{R}$, then $\mathbf{x}^*(t, \mathbf{x})$ is a *global solution*. Otherwise, it is a *local solution*. T could be so short that the local solution defined on T might have little interest. On the other hand, if $T = [0, \text{infinity})$, then the local solution defined on T might be adequate for all practical purposes.

We will use the notation C^1 to indicate that a function has continuous first order partial derivatives. The next theorem provides the existence and uniqueness results for the solution to ODE.

Definition 16.36 (*Lipschitz continuity*): Let $f : X \rightarrow X$. Then $\mathbf{f}$ is said to be *Lipschitz continuous* if for all $\mathbf{x}, \mathbf{y} \in X$, there exists some $\lambda \in \mathbb{R}_+$ such that

$$d(f(\mathbf{x}), f(\mathbf{y})) \leq \lambda d(\mathbf{x}, \mathbf{y})$$

where $d(\mathbf{x}, \mathbf{y})$ is the distance between points $\mathbf{x}, \mathbf{y}$. An example is the Euclidean metric in $\mathbb{R}^n$:

$$d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\| = \sqrt{\sum_{i=1}^n (x_i - y_i)^2}.$$

Theorem 16.3 Consider the problem of solving the system of ODE in (5.A4), subject to the initial conditions in (5.A5). Suppose that each $f_i(\cdot)$, $i = 1, \dots, n$ is a continuous function at the point $(0, \mathbf{x}_i(0))$.

- (a) *Existence:* There exists some C^1 function $\mathbf{x}^*(t, \mathbf{x}(0))$ defined over some open time interval T containing $t = 0$ such that it satisfies (5.A4) for all $t \in T$ and $\mathbf{x}^*(0, \mathbf{x}(0)) = \mathbf{x}(0)$.
- (b) *Uniqueness:* Suppose in addition that each $f_i(\cdot)$, $i = 1, \dots, n$ is C^1 at the point $(0, \mathbf{x}_i(0))$, then $\mathbf{x}^*(t, \mathbf{x}(0))$ is unique.

In Theorem 16.3(b), the restriction on $f(\cdot)$ to be C^1 can be weakened to *Lipshitz continuity*. Any C^1 function is Lipshitz continuous and Lipshitz continuity in turn is stronger than the notion of continuity.

Consider a compact subset C of the state space X . Time is drawn from the real line $\mathbb{R}$. For some initial value $\mathbf{x}(0) \in C$, the solution to the ODE in (5.A4) is denoted by $\mathbf{x}^*(t, \mathbf{x}(0))$. This allows us to define a *dynamic system*.

Definition 16.37 (Dynamic system): A *dynamic system* is a pair $D = (X, \mathbf{x}^*)$, where $X \subset \mathbb{R}^{n+1}$ is open and connected with $(0, \mathbf{x}) \in X$ for some $\mathbf{x} \in \mathbb{R}^n$ and $\mathbf{x}^* : X \rightarrow \mathbb{R}^n$ is a *flow*, i.e., $\mathbf{x}^*$ satisfies:

1. *Initial value condition:* $\mathbf{x}^*(0, \mathbf{x}) = \mathbf{x}$ for all $\mathbf{x} \in \mathbb{R}^n$ such that $(0, \mathbf{x}) \in X$.
2. *Time additivity:* $\mathbf{x}^*(t, \mathbf{x}^*(s, \mathbf{x})) = \mathbf{x}^*(s + t, \mathbf{x})$ for all $s, t, \mathbf{x}$ such that $(s, \mathbf{x}), (s + t, \mathbf{x}), (t, \mathbf{x}^*(s, \mathbf{x})) \in X$.
3. *Differentiability:* $\mathbf{x}^*(t, \mathbf{x})$ is continuously differentiable in t for all $(t, \mathbf{x}) \in X$.

An important concept in gaining some geometric intuition about many problems, particularly those that cannot be explicitly solved, is the concept of a *trajectory*.

Definition 16.38 (Trajectory): A *trajectory*, $\varphi(s, \mathbf{x})$, is the graph of the solution that passes through $\mathbf{x}$ at time s , i.e.,

$$\varphi(s, \mathbf{x}) = \{(t, \mathbf{y}) \in X : \mathbf{y} = \mathbf{x}^*(t, \mathbf{x})\}.$$

We might only be interested in the path taken by the solution of a dynamic system, without reference to the time at which a particular state is reached. This leads to the concept of an *orbit*.

Definition 16.39 (Orbit): The *orbit*, $\gamma(s, \mathbf{x})$, of the trajectory, $\varphi(s, \mathbf{x})$, is the set of points (states) that the trajectory passes through, i.e.,

$$\gamma(s, \mathbf{x}) = \{\mathbf{y} : (t, \mathbf{y}) \in \varphi(s, \mathbf{x}) \text{ for some } t\}.$$

An important concept in dynamical systems is that of a *steady state*. One can define the steady state in terms of the induced solution mapping $\mathbf{x}^*(t, \mathbf{x}(0))$ as a state, $\bar{\mathbf{x}}$, such that

$$\mathbf{x}^*(t, \bar{\mathbf{x}}) = \bar{\mathbf{x}}.$$

Thus, in the steady state, if we begin at the state $\bar{\mathbf{x}}$, the dynamic system stays at $\bar{\mathbf{x}}$ over time, so evaluated at $\bar{\mathbf{x}}$, we have $\dot{\mathbf{x}}(t) = 0$.

It is not always possible to find an *explicit solution* to a differential equation. However, explicit solutions can be found in some special cases.

1. Suppose that

$$\dot{x}(t) = ax,$$

where a is some constant. We have already noted above, that the solution to this differential equation is $x^*(t, x(0)) = x(0)e^{at}$.

2. Suppose that

$$\dot{x}(t) = ax + b, \quad (5.A6)$$

where a, b are constants. The general solution is

$$x(t) = \frac{-b}{a} + ke^{at},$$

which can be differentiated to recover the differential equation in (5.A6). The steady state can be found by setting $\dot{x}(t) = 0$ in (5.A6) and solving out for $x = \bar{x}$, which gives $\bar{x} = \frac{-b}{a}$.

We also have $x(0) + \frac{b}{a} = k$ as the value of k .

Any differential equation of order 2 or above can be written as a system of first order differential equations. Consider, for instance, the second order differential equation.

$$\ddot{x}(t) = f(t, x(t), \dot{x}(t)) \quad (5.A7)$$

This can be converted into a system of two first order differential equations. Define

$$\dot{x}(t) = y(t). \quad (5.A8)$$

Then (5.A7) can be written as

$$\dot{y}(t) = f(t, x(t), y(t)). \quad (5.A9)$$

Equations (5.A8), (5.A9) give us a system of two first order ordinary differential equations. In general, any m th order differential equation can be converted into a system of m first order ordinary differential equations. Hence, there is no loss of generality in considering a system of first order ordinary differential equations.

SYSTEM OF LINEAR DIFFERENTIAL EQUATIONS

Often we would like to focus on a system of n linear first order differential equations, expressed in the compact matrix notation

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t), \quad (5.A10)$$

where $\mathbf{x}(t)$ is a $n \times 1$ column vector with the i th element given by $x_i(t)$. Similarly $\dot{\mathbf{x}}(t)$ is a $n \times 1$ column vector with i th element given by $\dot{x}_i(t)$. A is a $n \times n$ matrix with typical element given by a_{ij} . Denote the eigenvalues of the matrix A by $r_1, r_2, \dots, r_n$ and the eigenvectors by $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n$. Then the solution to (5.A10) for various cases is given by the following theorems. We omit the proofs; the reader can find these in Hirsch and Smale (1974).

Theorem 16.4 (*Distinct real eigenvalues*) Suppose that $r_1, r_2, \dots, r_n$ are distinct and real. Then the solution to (5.A10) is given by

$$\mathbf{x}(t) = \sum_{i=1}^n c_i e^{r_i t} \mathbf{v}_i. \quad (5.A11)$$

The constants $c_1, \dots, c_n$ are determined from n initial conditions, such as the one given in (5.A5).

Theorem 16.4 is valid even if we have multiple eigenvalues, so long as any eigenvalue with multiplicity k has k linearly independent eigenvectors. If not, then we have the following case, which we give for the case of a 2×2 matrix A .

Theorem 16.5 (*Multiple eigenvalues, $n = 2$*) Suppose that the two eigenvalues of the 2×2 matrix A are equal, i.e., $r_1 = r_2 = r$. Let $\mathbf{v}$ be the one independent eigenvector corresponding to the eigenvalue, r . Let $\mathbf{u}$ be the generalized eigenvector of A .¹ Then the general solution to (5.A10) is given by

$$\mathbf{x}(t) = e^{rt} (c_1 \mathbf{v} + c_2 \mathbf{u}) + t e^{rt} c_2 \mathbf{v}, \quad (5.A12)$$

where the two constants c_1, c_2 are determined by using the initial conditions.

Theorem 16.6 (*Complex eigenvalues, $n = 2$*) Suppose that the two eigenvalues of the 2×2 matrix A are complex, i.e., $\alpha \pm i\beta$, where $\alpha, \beta \in \mathbb{R}$. The corresponding eigenvectors are also complex, i.e., $\mathbf{u} \pm i\mathbf{v}$. Then the general solution to (5.A10) is given by

$$\mathbf{x}(t) = e^{\alpha t} \cos \beta t (c_1 \mathbf{u} - c_2 \mathbf{v}) - e^{\alpha t} \sin \beta t (c_2 \mathbf{u} + c_1 \mathbf{v}), \quad (5.A13)$$

and the two constants c_1, c_2 are determined by using the initial conditions.

STEADY STATES AND STABILITY

Consider the system of n ODE in (5.A3), $\dot{\mathbf{x}}(t) = \mathbf{f}(t, \mathbf{x}(t))$. The *steady state*, also known as a *stationary point* or an *equilibrium*, of an ODE, is a state $\bar{\mathbf{x}}$, that satisfies

$$\mathbf{f}(\bar{\mathbf{x}}, t) = 0.$$

Thus, in a steady state, $\dot{\mathbf{x}}(t) = 0$.

Definition 16.40 (*Liapunov stability or neutral stability*): Let $\mathbf{x}^*(t, \mathbf{x}(0))$ be the solution to (5.A3). A steady state $\bar{\mathbf{x}}$ is *Liapunov stable* if for some neighborhood U of $\bar{\mathbf{x}}$, there exists a neighborhood V of $\bar{\mathbf{x}}$ such that for all $t \geq 0$, and for any $\mathbf{x}(0) \in V$, $\mathbf{x}^*(t, \mathbf{x}(0))$ stays in U .

¹ The generalized eigenvector, $\mathbf{u}$, solves $(A - rI)\mathbf{u} = \mathbf{v}$, where I is the 2×2 identity matrix and $\mathbf{v}$ is the one independent eigenvector corresponding to the eigenvalue, r .

Definition 16.41 (Dynamic or asymptotic stability): Let U, V be as defined in Definition 16.40. A steady state $\bar{x}$ is asymptotically stable if (i) it is Liapunov stable, and (ii) for any $x(0) \in V$

$$\lim_{t \rightarrow \infty} x^*(t, x(0)) = \bar{x}. \quad (5.A14)$$

Definition 16.42 (Unstable steady states): If $\bar{x}$ is neither asymptotically stable nor neutrally stable, then it is said to be unstable.

The two concepts of stability and asymptotic stability are shown in Figure 5.A1, which is self-explanatory in light of the definitions. Asymptotic stability is the more stringent of the two stability conditions, but it does not necessarily imply Liapunov stability. The intuition is that a trajectory might have to stray outside the set U before it eventually converges to $\bar{x}$, but that would contradict Liapunov stability.

Another useful concept is that of a *basin of attraction* and an *attractor*. Heuristically, a basin of attraction of some set A is the set of all initial states such that the trajectory of the dynamic system stays in A for large enough values of t .

Definition 16.43 (Basin of attraction): Let X be a compact set of states and let $x \in X$. The basin of attraction of a closed set $A \subset X$ is the following set:

$$\{x(0) \in X : \lim_{t \rightarrow \infty} x^*(t, x(0)) \in A\}.$$

Definition 16.44 (Attractors) A set $A \subset X$ is an attractor if its basin of attraction is a neighborhood of A .

The analysis of stability is substantially simplified by examining the size and sign of the eigenvalues corresponding to the matrix A . We will use the solutions for the various cases in (5.A11), (5.A12), (5.A13). We only state the results that we need for this appendix, some for the 2×2 case; the interested reader can consult Hirsch and Smale (1974) for the more general case.

Theorem 16.7 (Stability of linear systems): Consider the system of n linear first order differential equations in (5.A10), $\dot{x}(t) = Ax(t)$.

Figure 5.A1 Stability of steady states.

- (a) Suppose that all eigenvalues $r_1, r_2, \dots, r_n$ are distinct and real. If each $r_i < 0$, $i = 1, 2, \dots, n$, then the steady state $\bar{x} = 0$ is globally asymptotically stable.
- (b) Suppose that in the 2×2 case, the eigenvalues are complex, i.e. $\alpha \pm i\beta$. If $\alpha < 0$, then $\bar{x} = 0$ is globally asymptotically stable. If $\alpha = 0$, i.e., the eigenvalues are imaginary numbers and a complete set of independent eigenvectors does not exist, then $\bar{x} = 0$ is asymptotically unstable.
- (c) Suppose that in the 2×2 case, the eigenvalues are equal, i.e., $r_1 = r_2 = r$. Then if $r < 0$, $\bar{x} = 0$ is asymptotically stable. If $r \geq 0$, then $\bar{x} = 0$ is asymptotically unstable.

Now let us focus on the stability of non-linear systems. Consider an ODE in one variable.

$$\dot{x}(t) = f(x). \quad (5.A15)$$

Suppose that the graph of this function is given in Figure 5.A2. In the Figure, the steady state is shown at $\bar{x}$. When $x > \bar{x}$, then $f(x) < 0$, so $\dot{x}(t) < 0$, thus, x decreases. On the other hand, when $x < \bar{x}$, then $f(x) > 0$, so $\dot{x}(t) > 0$, thus, x increases. In other words, any trajectory of the system converges to $\bar{x}$ as $t \rightarrow \infty$. Hence, $\bar{x}$ is asymptotically stable. Notice that $f'(\bar{x}) < 0$; this turns out to be a crucial condition for asymptotic stability.

Theorem 16.8 (Stability of non-linear systems, $n = 1$): Let $f(x)$ be a C^1 function and let $\bar{x}$ be a steady state of the system, so $f(\bar{x}) = 0$. If $f'(\bar{x}) < 0$, then $\bar{x}$ is an asymptotically stable equilibrium. If $f'(\bar{x}) > 0$, then $\bar{x}$ is an asymptotically unstable equilibrium.

Suppose that we have a system of $n > 1$ non-linear differential equations, $\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t))$. The extension of Theorem 16.8 to this case is straightforward with the derivative $f'(\bar{x})$ replaced by the Jacobian matrix of partial derivatives, $D\mathbf{f}(\bar{\mathbf{x}})$.

$$D\mathbf{f}(\bar{\mathbf{x}}) = \begin{bmatrix} \frac{\partial f_1(\bar{\mathbf{x}})}{\partial x_1} & \frac{\partial f_1(\bar{\mathbf{x}})}{\partial x_2} & \cdot & \cdot & \frac{\partial f_1(\bar{\mathbf{x}})}{\partial x_n} \\ \frac{\partial f_2(\bar{\mathbf{x}})}{\partial x_1} & \frac{\partial f_2(\bar{\mathbf{x}})}{\partial x_2} & \cdot & \cdot & \frac{\partial f_2(\bar{\mathbf{x}})}{\partial x_n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \frac{\partial f_n(\bar{\mathbf{x}})}{\partial x_1} & \frac{\partial f_n(\bar{\mathbf{x}})}{\partial x_2} & \cdot & \cdot & \frac{\partial f_n(\bar{\mathbf{x}})}{\partial x_n} \end{bmatrix}$$

Figure 5.A2 Stability of the steady state in a first order non-linear differential equation.

Theorem 16.9 (Stability of non-linear systems, $n > 1$): Consider the system of $n > 1$ non-linear autonomous differential equations, $\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t))$, where $\mathbf{f}(\cdot)$ is C^1 . Denote the steady state of the system by $\bar{\mathbf{x}}$.

- (a) If all eigenvalues of the matrix $D\mathbf{f}(\bar{\mathbf{x}})$ are negative, or have a negative real part in the case of complex numbers, then $\bar{\mathbf{x}}$ is an asymptotically stable steady state.
- (b) If at least one eigenvalue of $D\mathbf{f}(\bar{\mathbf{x}})$ is positive, or has a positive real part in the case of complex numbers, then $\bar{\mathbf{x}}$ is an asymptotically unstable steady state.
- (c) If some of the eigenvalues are zero, or some have purely imaginary parts in the case of complex numbers, then the Jacobian matrix cannot be used to determine the stability of the steady state. In this case more information is needed about the state of the system.

In many cases, we cannot find the solution to an ODE. In this case, we have to construct a *phase diagram* of the system. Essentially, this is a plot of the vector field of the system (described above). Often it helps to plot the vector field by fixing the value of $\dot{\mathbf{x}}$, e.g., $\dot{\mathbf{x}} = 0$. The vector field corresponding to a particular value of $\dot{\mathbf{x}}$ is called an *isocline*. The stability of the system can then be inferred from a plot of the isoclines for $\dot{\mathbf{x}} = 0$ and the point of intersection of the isoclines.

Appendix B: A note on choice under stochastic utility

In most learning models that we shall consider, individuals choose among their pure strategies in a probabilistic manner that is consistent with either the conditional logit model, or the multinomial logit model.² The foundation for this behavior lies in models of stochastic utility, as we now explain.

Suppose that $N = \{1, \dots, n\}$ is the set of players. The pure strategy set of player $i \in N$ is given by $S_i = \{s_{i1}, s_{i2}, \dots, s_{in_i}\}$ and the pure strategy profile is given by $s = (s_1, s_2, \dots, s_n) \in S = S_1 \times \dots \times S_n$. From the perspective of player i we may write the strategy profile as (s_i, s_{-i}) where s_{-i} is the strategy profile of all players other than player i . Let ε_i be a random variable, specific to player i . The utility function of player i is given by $u_i : S \times \varepsilon_i \rightarrow \mathbb{R}$. In particular suppose that

$$u_i(s_i, s_{-i}, \varepsilon_i) = v_i(s_i, s_{-i}) + \varepsilon_i(s_i, s_{-i}). \quad (5.A16)$$

This is the general formulation of a stochastic utility model. Suppose that any two random variables ε_i and ε_j for two different players are independent. We assume that ε_i is an Extreme Value Type I random variable (sometimes referred to as a Weibull distribution). The distribution function of ε_i is given by

$$F(c) = \Pr(\varepsilon_i < c) = e^{-e^{-(c+\alpha_i)}}, \quad (5.A17)$$

where α_i is the single parameter of the distribution, sometimes also called the *location parameter*. The next proposition gives some important results about Extreme Value Type I distribution as well as about the utility function, u_i , in (5.A16).

Proposition 16.34

- (a) The density of an Extreme Value Type I random variable, ε_i , is given by

$$f(\varepsilon_i) = e^{-(\varepsilon_i + \alpha_i)} \left(e^{-e^{-(\varepsilon_i + \alpha_i)}} \right).$$

² See Amemiya (1981), McFadden (1981), and Maddala (1986) for this framework.

- (b) *Independently distributed Extreme Value Type I random variables, $\varepsilon_1, \dots, \varepsilon_n$ are closed under maximization, i.e., the distribution function $\Pr(\max_i \{\varepsilon_i\} \leq \varepsilon)$ belongs to an Extreme Value Type I random variable.*
- (c) *u_i defined in (5.A16) is an Extreme Value Type I random variable.*

Proof: (a) From (5.A17), $F(\varepsilon_i) = e^{-e^{-(\varepsilon_i + \alpha_i)}}$, hence, the density is given by $f(\varepsilon_i) = \frac{\partial F(\varepsilon_i)}{\partial \varepsilon_i}$. Let $x = e^{-e^{-(\varepsilon_i + \alpha_i)}}$, so $\log x = -e^{-(\varepsilon_i + \alpha_i)}$ and $\frac{\partial x}{\partial \varepsilon_i} = x \frac{\partial}{\partial \varepsilon_i} (-e^{-(\varepsilon_i + \alpha_i)}) = x e^{-(\varepsilon_i + \alpha_i)}$, thus,

$$f(\varepsilon_i) = e^{-(\varepsilon_i + \alpha_i)} \left(e^{-e^{-(\varepsilon_i + \alpha_i)}} \right). \quad (5.A18)$$

(b) Suppose that $\varepsilon_1, \dots, \varepsilon_n$ are independently distributed Extreme Value Type I random variables. Then

$$\begin{aligned} \Pr(\max_i \{\varepsilon_i\} \leq \varepsilon) &= \prod_{i=1}^n \Pr(\varepsilon_i \leq \varepsilon) \text{ [By definition]} \\ &= \prod_{i=1}^n e^{-e^{-(\varepsilon + \alpha_i)}} \text{ [Using (5.A17)]} \\ &= e^{-e^{-\varepsilon} \sum_{i=1}^n e^{-\alpha_i}} \text{ [By simplification]}. \end{aligned} \quad (5.A19)$$

Let $\sum_{i=1}^n e^{-\alpha_i} = e^{-\alpha}$. Taking logs on both sides, we get $-\alpha = \log \sum_{i=1}^n e^{-\alpha_i}$. Substituting in (5.A19) we get

$$\Pr(\max_i \{\varepsilon_i\} \leq \varepsilon) = e^{-e^{-\varepsilon} e^{-\alpha}} = e^{-e^{-(\varepsilon + \alpha)}}. \quad (5.A20)$$

Comparing (5.A17) and (5.A20) it follows that the random variable $\max_i \{\varepsilon_i\}$ also has an Extreme Value Type I distribution.

(c) Denote the distribution function of u_i by F_{u_i} , then

$$\begin{aligned} F_{u_i}(\varepsilon) &= \Pr(u_i \leq \varepsilon) \\ &= \Pr(v_i + \varepsilon_i \leq \varepsilon) \text{ [Using (5.A16)]} \\ &= \Pr(\varepsilon_i \leq \varepsilon - v_i) \\ &= e^{-e^{-(\varepsilon - v_i + \alpha_i)}} \text{ [Using (5.A17)]}. \end{aligned} \quad (5.A21)$$

Thus, u_i has an Extreme Value Type I distribution. ■

We can now use Proposition 16.34 to show that player $i \in N$ chooses his pure strategies with probabilities using the conditional logit, or multinomial model.

Suppose first that $S_i = \{s_{i1}, s_{i2}\}$. When does player i choose his first strategy over the second? Since the RHS of (5.A16) is a random variable, we can compute the probability of this event. Denote $u_i(s_{ij}, s_{-i}, \varepsilon_i)$ by u_{ij} , $v_i(s_{ij}, s_{-i})$ by v_{ij} , $\varepsilon_i(s_{ij}, s_{-i})$ by ε_{ij} , and $\Pr(s_{i1} \text{ is chosen})$ by P_{i1} , then

$$\begin{aligned} P_{i1} &= \Pr(u_{i1} > u_{i2}) \\ &= \Pr(v_{i1} + \varepsilon_{i1} > v_{i2} + \varepsilon_{i2}) \\ &= \Pr(\varepsilon_{i2} < v_{i1} - v_{i2} + \varepsilon_{i1}). \end{aligned} \quad (5.A22)$$

Since ε_{ij} has an Extreme Value Type I distribution, thus

$$\Pr(\varepsilon_{i2} < v_{i1} - v_{i2} + \varepsilon_{i1}) = \int_{-\infty}^{\infty} f(\varepsilon_{i1}) \left[\int_{-\infty}^{v_{i1} - v_{i2} + \varepsilon_{i1}} f(\varepsilon_{i2}) d\varepsilon_{i2} \right] d\varepsilon_{i1}. \quad (5.A23)$$

Using (5.A21), (5.A22), (5.A23) and we get

$$\Pr(s_{i1} \text{ is chosen}) = \int_{-\infty}^{\infty} e^{-e^{-(v_{i1} - v_{i2} + \varepsilon_{i1} + \alpha_2)}} f(\varepsilon_{i1}) d\varepsilon_{i1}. \quad (5.A24)$$

Substituting the value of f from (5.A18), $e^{-(\varepsilon_i + \alpha_i)} \left(e^{-e^{-(\varepsilon_i + \alpha_i)}} \right)$, into (5.A24)

$$\begin{aligned} P_{i1} &= \int_{-\infty}^{\infty} e^{-e^{-(v_{i1} - v_{i2} + \varepsilon_{i1} + \alpha_2)}} e^{-(\varepsilon_{i1} + \alpha_1)} \left(e^{-e^{-(\varepsilon_{i1} + \alpha_1)}} \right) d\varepsilon_{i1} \\ &= e^{-\alpha_1} \int_{-\infty}^{\infty} e^{-\varepsilon_{i1}} e^{-e^{-(v_{i1} - v_{i2} + \varepsilon_{i1} + \alpha_2)}} \left(e^{-e^{-(\varepsilon_{i1} + \alpha_1)}} \right) d\varepsilon_{i1} \\ &= e^{-\alpha_1} \int_{-\infty}^{\infty} e^{-\varepsilon_{i1}} e^{-(e^{-\varepsilon_{i1}})(e^{-\alpha_1 - e^{-(v_{i1} - v_{i2} + \alpha_2)}})} d\varepsilon_{i1}. \end{aligned}$$

Let $\mu = (e^{-\alpha_1} - e^{-(v_{i1} - v_{i2} + \alpha_2)})$, which is independent of ε_{i1} , then

$$P_{i1} = \frac{e^{-\alpha_1}}{\mu} \int_{-\infty}^{\infty} e^{-(e^{-\varepsilon_{i1}})\mu} (e^{-\varepsilon_{i1}}\mu) d\varepsilon_{i1}. \quad (5.A25)$$

Using the result that $\int_{-\infty}^{\infty} e^{g(x)} g'(x) dx = |e^{g(x)}|_{-\infty}^{\infty}$, we can rewrite (5.A25) as

$$P_{i1} = \frac{e^{-\alpha_1}}{\mu} \left| e^{-(e^{-\varepsilon_{i1}})\mu} \right|_{-\infty}^{\infty}.$$

Simplifying this expression gives

$$P_{i1} = \frac{e^{-\alpha_1}}{e^{-\alpha_1} + e^{-(v_{i1} - v_{i2} + \alpha_2)}}.$$

Multiplying and dividing the denominator by $e^{v_{i1}}$ we get the desired result

$$P_{i1} = \frac{e^{v_{i1} - \alpha_1}}{e^{v_{i1} - \alpha_1} + e^{v_{i2} - \alpha_2}}.$$

Such a probabilistic choice is called a conditional or multinomial logit model.

We can now use Proposition 16.34(b) to generalize this result to any finite strategy set $S_i = \{s_{i1}, s_{i2}, \dots, s_{in_i}\}$.

$$\begin{aligned} P_{i1} &= \Pr(u_{i1} > u_{i2}, u_{i1} > u_{i3}, \dots, u_{i1} > u_{in_i}) \\ &= \Pr\left(u_{i1} > \max_{2 \leq j \leq n_i} u_{ij}\right) \\ &= \Pr\left(v_{i1} + \varepsilon_{i1} > \max_{2 \leq j \leq n_i} (v_{ij} + \varepsilon_{ij})\right) \\ &= \frac{e^{v_{i1} - \alpha_1}}{e^{v_{i1} - \alpha_1} + e^{v_{i2} - \alpha_2} + \dots + e^{v_{in_i} - \alpha_{n_i}}}, \end{aligned} \quad (5.A26)$$

which is the result we were seeking to prove.

A special case arises by setting the location parameter $\alpha_1 = 0$. This case is the most commonly used in applied experimental work. In this case we can rewrite (5.A26) as

$$P_{ij} = \frac{e^{v_{ij}}}{\sum_{k=1}^{n_i} e^{v_{ik}}}.$$

Appendix C: A brief user's guide to Markov Chains

This section gives a brief, informal, cookbook guide to using Markov chains for Part 5 of the book. Readers interested in an introduction to the field may consult Karlin and Taylor (1998).

Suppose that time t is discrete, so $t = 0, 1, 2, \dots$. A discrete *random variable* x_t at time t takes possible realizations from a finite set, $S = \{s_1, s_2, \dots, s_n\}$. The set S is said to be the *state-space*.

Definition 16.45 (*Stochastic process*): A stochastic process $\{x_t\}_{t=0}^{\infty}$ is a sequence of random variables.

Definition 16.46 (*Markov property*): A stochastic process is said to have the Markov property if³

$$p(x_{t+k} \mid x_{t+k-1}, x_{t+k-2}, \dots, x_0) = p(x_{t+k} \mid x_{t+k-1}); \forall t, k \geq 2.$$

Thus, under the Markov property, in predicting the future, only the immediate past matters. Denote by $\Delta(S)$ the set of all probability vectors on the state space S . The typical probability vector at time t is denoted by the row vector $\lambda_t = [\lambda_t(s_1), \lambda_t(s_2), \dots, \lambda_t(s_n)]$, where $\lambda_t(s_i)$ is the probability that the random variable x_t takes the value s_i at time t , $s_i \in S$.

Definition 16.47 (*Transition matrix*): The transition matrix, P , is given by

$$P = \begin{bmatrix} p_{11} & p_{12} & \cdot & \cdot & p_{1n} \\ p_{21} & p_{22} & \cdot & \cdot & p_{2n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ p_{n1} & p_{n2} & \cdot & \cdot & p_{nn} \end{bmatrix}$$

The typical element of the transition matrix is denoted by

$$p_{ij} = P(s_i, s_j); i, j = 1, \dots, n,$$

where p_{ij} denotes the probability of being in state $s_j \in S$ at time $t+1$, conditional on being in state $s_i \in S$ at time t . For any row in P , the sum of all entries in any row is 1, i.e.,

$$\sum_{j=1}^n p_{ij} = 1; \forall i = 1, \dots, n.$$

For instance, starting from the state s_1 at time t , the first row of P gives the probability of transiting to all the n states in S at time $t+1$. The typical element in the first row, p_{1j} gives the probability of transiting to state $s_j \in S$ at time $t+1$. The transition matrix is a *stochastic matrix* because all entries are non-negative and all rows sum to 1.

³ We use the standard notation, $p(x \mid y)$, for the probability of x conditional on y .

Definition 16.48 (*Markov chain*): A Markov chain is given by the pair (S, P) , where S is the set of states, and P is the transition matrix, given the initial probability vector λ_0 , such that $\sum_{j=1}^n \lambda_0(s_j) = 1$. We will focus on finite Markov chains in which there is a finite number of elements in S .

The unconditional probability vector at time t , λ_t , can be found as follows

$$\lambda_t = \lambda_{t-1}P. \quad (5.A27)$$

From (5.A27), the probability of being in state s_i at time $t + 1$ is given by

$$\lambda_t(s_i) = \sum_{j=1}^n \lambda_{t-1}(s_j) p_{ji}. \quad (5.A28)$$

Iteratively substituting backwards, using (5.A27), we get $\lambda_t = (\lambda_{t-2}P)P = \dots = \lambda_0P^t$. Given

$$\lambda_t = \lambda_0P^t, \quad (5.A29)$$

we are usually interested in the limiting unconditional probability distribution

$$\bar{\lambda} = \lim_{t \rightarrow \infty} \lambda_0P^t. \quad (5.A30)$$

The limit in (5.A30) exists under some mild regularity conditions; see Karlin and Taylor (1998). If probabilities converge to the limiting distribution $\bar{\lambda}$, (5.A27) implies that $\bar{\lambda} = \bar{\lambda}P$, so

$$\bar{\lambda}(I - P) = 0. \quad (5.A31)$$

where $I, 0$ are, respectively, the identity matrix and the row vector of zeros. Taking the transpose on both sides of (5.A31) we get that:

$$(I - P^T)\bar{\lambda}^T = 0.$$

Hence, $\bar{\lambda}^T$ is the eigenvector corresponding to the matrix P^T whose columns each sum to unity. Since P is a stochastic matrix (all elements positive and rows summing to 1) there is at least one unit eigenvalue. This is easily seen by noting that $Pe = e$ where e is the unit column vector.

A question of particular interest is: does $\bar{\lambda}$ depends on the initial probability vector λ_0 ?

Definition 16.49 (*Unique invariant distribution*) If $\bar{\lambda}$ does not depend on the initial probability vector λ_0 , then it is said to be a unique invariant distribution of the underlying stochastic process (S, P) .

Definition 16.50 (*Asymptotic stationarity*): If the stochastic process (S, P) has a unique invariant distribution, it is said to be asymptotically stationary.

An example where a unique invariant distribution does not exist is when $P = I$, the identity matrix. In this case, $\bar{\lambda} = \lambda_0$, so there is a clear dependence of the limiting distribution on the initial conditions. On the other hand, suppose that $P = [0, 0, \dots, 1, \dots, 0]$, i.e., the i th column has all entries equal to 1, while all other entries in the matrix are 0. In this case, using (5.A28),

$\bar{\lambda} = (0, 0, \dots, 1, \dots, 0)$ for any initial probability vector λ_0 , whose entries sum up to 1. Hence, $\bar{\lambda}$ is a *unique invariant distribution*.

Definition 16.51 (Ergodicity): When the limit in (5.A30) exists and $\bar{\lambda}$ is independent of λ_0 , then the stochastic process (S, P) is said to be *ergodic*.

Definition 16.52 (Empirical frequency of play): Suppose that we begin with some state $s_j \in S$. Suppose we let the system evolve for t time periods and note down the frequency with which each of the n states, $s_1, s_2, \dots, s_n$, is visited. Then the empirical frequency with which the i th state is visited (in t time periods), conditional on the initial state being s_j is denoted by $f^t(s_i | s_j)$.

Theorem 16.10 (Convergence of the empirical frequency): Suppose that the stochastic process (S, P) is ergodic and the unique invariant distribution is given by $\bar{\lambda}$. Then, the empirical frequency distribution converges almost surely to $\bar{\lambda}$, independently of the initial state $s_j \in S$, i.e., for all $s_i \in S$

$$\lim_{t \rightarrow \infty} f^t(s_i | s_j) = \bar{\lambda}(s_i),$$

where $\bar{\lambda}(s_i)$ is the probability of being in state s_i in the unique invariant distribution.

Theorem 16.11 The stochastic process (S, P) is asymptotically stationary with a unique invariant distribution if $p_{ij} > 0$ for all $i, j = 1, 2, \dots, n$.

For the case of a stochastic matrix P^t with typical element p_{ij}^t (where t denotes time) this theorem requires that $p_{ij}^t > 0$ for all $i, j = 1, 2, \dots, n$ and for some $t \geq 1$.

Definition 16.53 (Basin of attraction): The basin of attraction of a state s_i , denoted by $B(s_i)$, is the set of all states such that there is a positive probability of moving from those states to the state s_i in a finite number of periods.

We now provide an alternative motivation of ergodicity, which will be useful in the analysis of perturbed Markov chains.

Definition 16.54 (Accessibility): State s_i is “accessible” from state s_j if starting from state s_j there is a positive probability of moving to state s_i in a finite number of periods. We write this as $s_j \rightarrow s_i$. The symbol $\nrightarrow$ denotes “not accessible.”

Definition 16.55 (Communication): If $s_j \rightarrow s_i$ and $s_i \rightarrow s_j$, then both states are accessible from each other. In this case, we say that states s_i, s_j “communicate” and we write this as $s_i \sim s_j$. A communication class is a set such that for any s_i, s_j in the class, we have $s_i \sim s_j$.

Being an equivalence relation, $\sim$, partitions the state space, S , into equivalence classes, or communication classes.⁴

⁴ Suppose that the equivalence relation, $\sim$, is defined over some set A and $a, b, c \in A$. Then the equivalence relation is reflexive ($a \sim a$), symmetric ($a \sim b \Leftrightarrow b \sim a$), and transitive ($a \sim b, b \sim c \Rightarrow a \sim c$). For example, let the set A be the set of birthdays for each individual in a city. Let $\sim$ be the binary relation “has the same birthday as.” Then the equivalence relation partitions the set A into disjoint equivalence classes and each class has all those individuals who share their birthday.

Definition 16.56 (Recurrence classes): A communication class is said to be a recurrence class if for any s_j in that class, $s_j \rightarrow s_i$, for any s_i outside that class.

Recalling the definition of accessibility, a recurrence class only requires that starting within it we cannot reach a state outside it in finite time. Furthermore, since the recurrence class is a communication class we can, in finite time, move between elements of the recurrence class.

Definition 16.57 (Recurrent and transient states): A state is said to be a recurrent state if it belongs to some recurrent class; otherwise it is said to be a transient state.

Definition 16.58 (Absorbing state): If a recurrent class has a single state in it, then the single state is called an absorbing state. In other words, for an absorbing state s_i , $p_{ii} = 1$.

Definition 16.59 (Irreducible Markov process): If a Markov process has a single recurrent class and it constitutes the entire state space, then the Markov process is said to be irreducible. Alternatively, a Markov process is irreducible if for the entire state space, there is a positive probability of moving from any state to any other in finite time.

Theorem 16.12 (Ergodicity): A finite Markov chain (S, P) is ergodic if it has a unique recurrence class.

Suppose that there is not a unique recurrent class. Then, there are several limiting distributions, each depending not only on the initial conditions (non-ergodic), but also on what happens along the path.

Theorem 16.13 (Alternative method for checking ergodicity): Consider a finite Markov chain (S, P) . Suppose that we can partition the set of states S into two disjoint subsets S_1, S_2 , such that the following hold.

- (1) There is a positive probability of moving in finite time from (a) a state in S_1 to a state in S_2 , (b) a state in S_2 to a state in S_1 .
- (2) There is a zero probability of moving in finite time from a state in S_2 to a state in S_1 .
Then ergodicity holds.

Definition 16.60 (Aperiodic Markov chain): Choose some $s_i \in S$. Let N_i be the set of positive integers $\{1, 2, \dots, n_i\}$ such that there is a positive probability that $s_i \rightarrow s_i$ in exactly n_i periods. If the greatest common divisor of N_i is unity for all $s_i \in S$, then the Markov chain is said to be aperiodic.

The next theorem makes even sharper predictions about asymptotic behavior.

Theorem 16.14 (Average and probabilistic behavior): Suppose that a finite Markov chain is aperiodic and ergodic (i.e., has a unique invariant distribution, $\bar{\lambda}$). Then,

- (i) The frequency of play of the pure strategies (or the average behavior) converges to $\bar{\lambda}$, i.e.,

$$\lim_{t \rightarrow \infty} f^t(s_i | s_j) = \bar{\lambda}(s_i); \forall s_i, s_j \in S.$$

- (ii) The probabilistic behavior also converges to $\bar{\lambda}$, i.e.,

$$\lim_{t \rightarrow \infty} p_{ij}^t = \bar{\lambda}(s_j),$$

where p_{ij}^t is an element of the matrix P^t .

PERTURBED MARKOV CHAINS

We now consider the basics of *perturbed Markov chains*; see, for instance, Kandori et al. (1993), Young (1993a, 1998), and Ellison (2000). Consider a family of Markov chains indexed by the parameter ε and denoted by $(S, P_\varepsilon)_{\varepsilon \in [0,1]}$. As before, S contains a finite number of states.

Definition 16.61 For each $\varepsilon \in [0,1]$, P_ε is a transition matrix and it is called the *perturbed transition matrix*. For $\varepsilon = 0$, P_0 is called the *unperturbed transition matrix*. All elements of P_ε are continuous in ε for all $\varepsilon \in [0,1]$.

For each $\varepsilon \in (0,1)$, the stochastic process (S, P_ε) is assumed to be ergodic with a unique invariant distribution given by $\bar{\lambda}_\varepsilon$. We do not assume ergodicity for the unperturbed transition matrix, P_0 .

Definition 16.62 (*Resistance or transition cost function*): The “resistance” or “transition cost function,” $c(s_i, s_j)$, captures the difficulty of moving from state s_i to s_j in finite time. One may think of $c(s_i, s_j)$ as the minimum number of steps required to make the transition from state s_i to state s_j .

Definition 16.63 (*Regular perturbed Markov process*): The Markov chain (S, P_ε) is said to be a regular perturbed Markov process if it satisfies two conditions.

- (i) P_ε is ergodic for all small enough $\varepsilon > 0$.
- (ii) The rate at which P_ε approaches P_0 is exponentially smooth. This requires two conditions. First, there is an element by element convergence of the perturbed matrix to the unperturbed matrix, as the noise in the system dies out, i.e.,

$$\lim_{\varepsilon \rightarrow 0^+} P_\varepsilon(s_i, s_j) = P_0(s_i, s_j); i, j = 1, 2, \dots, n.$$

Second, it requires that if for some $\varepsilon > 0$

$$P_\varepsilon(s_i, s_j) > 0, \text{ then } 0 < \lim_{\varepsilon \rightarrow 0^+} \frac{P_\varepsilon(s_i, s_j)}{\varepsilon^{c(s_i, s_j)}} < \infty.$$

For regular perturbed Markov processes, $\lim_{\varepsilon \rightarrow 0} \bar{\lambda}_\varepsilon$ always exists.

Definition 16.64 (*Limit invariant distribution*): Define the limit invariant distribution, λ^* , as one when the noise, ε , in the dynamical system goes to zero, i.e.,

$$\lambda^* = \lim_{\varepsilon \rightarrow 0} \bar{\lambda}_\varepsilon. \quad (5.A32)$$

Definition 16.65 (*Stochastically stable states*): The set of stochastically stable states, $S^* \subset S$, are those which are in the support of the limit invariant distribution, i.e.,

$$S^* = \{s \in S : \lambda^*(s) > 0\}. \quad (5.A33)$$

Thus, the stochastically stable states are those that are most likely to be observed in the long run as the noise in the system becomes very small. The concept was introduced by Foster and Young (1990).

Theorem 16.15 Every stochastically stable state lies in the invariant distribution of the unperturbed dynamics.

Proof: By definition, $\bar{\lambda}_\varepsilon$ is the unique invariant distribution of the stochastic process (S, P_ε) , hence, $\bar{\lambda}_\varepsilon = \bar{\lambda}_\varepsilon P_\varepsilon$.

Using (5.A32) we get $\lambda^* = \lim_{\varepsilon \rightarrow 0} \bar{\lambda}_\varepsilon = \lim_{\varepsilon \rightarrow 0} \bar{\lambda}_\varepsilon P_\varepsilon$, or

$$\lambda^* = \lim_{\varepsilon \rightarrow 0} \bar{\lambda}_\varepsilon \lim_{\varepsilon \rightarrow 0} P_\varepsilon.$$

Using (5.A32) and continuity of P_ε in ε we have

$$\lambda^* = \lambda^* P_0.$$

Thus λ^* (which is the *limit invariant distribution*) is the *unique invariant distribution* of the unperturbed transition matrix P_0 .

Remark 16.1 Suppose that we start with some initial state of the unperturbed system, which coincides with the stochastically stable state, λ^* . Then, the long-run probability of any state s_i in the support of λ^* is positive. This can be easily shown:

$$\left[\lim_{t \rightarrow \infty} \lambda^* P_0^t \right] (s_i) = \lambda^* (s_i) > 0.$$

Recall that the *transition cost function* $c(s_i, s_j)$ gives the minimum number of steps required to make the transition from state s_i to state s_j . The point of introducing perturbed Markov chains was to analyze cases where it is difficult or cumbersome to directly compute the unique invariant distribution. In this sense, Theorem 16.15 gives only limited help because it does not tell us how to compute $\bar{\lambda}_0$. The following methods are useful in this regard.

THE METHOD OF YOUNG (1993A)

Let the recurrence classes for the unperturbed process, $\{S, P_0\}$, be given by $C_1, C_2, \dots, C_M$. If we focus just on the unperturbed process, then, by definition of the recurrence classes, we can never move to a state outside a recurrence class once we are in it. However, if the process is perturbed, $\{S, P_\varepsilon\}$, then we can move from a state inside a recurrence class of $\{S, P_0\}$ to a state outside the recurrence class. The next theorem tells us how to find the recurrence classes of the unperturbed process.

Theorem 16.16 (*Recurrence classes of the unperturbed process*): Suppose that all players in the game play an identical strategy $s_i \in S$. This is called a *monomorphic equilibrium*. The recurrence classes of the unperturbed process are the singletons $s_i \in S$, $i = 1, 2, \dots, n$. Thus, the recurrence classes of the unperturbed processes are the *monomorphic equilibria*.

The central concept in Young's method is that of the *stochastic potential of a directed graph*. We give a series of definitions that lead to this concept.

Definition 16.66 (*ij-path*): For any two distinct recurrence classes, C_i, C_j , an *ij-path*, denoted by κ_{ij} , is a sequence of states $s_i \rightarrow s_{i+1} \rightarrow \dots \rightarrow s_{j-1} \rightarrow s_j$ where $s_i \in C_i$ and $s_j \in C_j$.

Definition 16.67 (*Resistance of an ij-path*): Given an *ij path*, κ_{ij} , and a transition cost function $c(s_i, s_j)$, the *resistance of κ_{ij}* , denoted by $R(\kappa_{ij})$, is defined as

$$R(\kappa_{ij}) = c(s_i, s_{i+1}) + c(s_{i+1}, s_{i+2}) + \dots + c(s_{j-1}, s_j).$$

Definition 16.68 (Minimum resistance of an ij -path): For all possible ij -paths that take us from a state in C_i to a state in C_j , define the minimum resistance of an ij -path, denoted by ρ_{ij} by

$$\rho_{ij} = \min R(\kappa_{ij}) \text{ over all } ij\text{-paths.}$$

Recall that we have M recurrence classes, $C_1, C_2, \dots, C_M$. We now construct a *directed graph* or *tree* over the set of M nodes, one for each of the M recurrence classes. A tree that is rooted at a node corresponding to the j th recurrence class is called a j -tree. So, for instance, a tree that is rooted at a node that corresponds to C_1 is called a 1-tree, and at a node that corresponds to C_6 , a 6-tree and so on. The shapes of some basic trees are shown in Figures 5.A3, 5.A4, below.

Definition 16.69 (j -tree): A j -tree is rooted at the j th node and it comprises a set of $M - 1$ directed edges such that (i) every node is the initial point of one and only one directed edge, and (ii) from every node different from j , there is a unique directed path to the root of the tree (that comprises a node corresponding to the C_j recurrence class). The weight on the directed edge $i \rightarrow j$ is the minimum resistance of the path, ρ_{ij} .

Example 16.11 (Two recurrence classes): Suppose that there are two recurrence classes C_1, C_2 and each class has exactly one state, respectively s_1, s_2 . Then there are two trees, a 1-tree (which is rooted at the first recurrence class) and a 2-tree (which is rooted at the second recurrence class). This is shown in Figure 5.A3.

Example 16.12 (Three recurrence classes): Suppose that there are three recurrence classes, C_1, C_2, C_3 and each class has exactly one state, respectively, s_1, s_2, s_3 . There are three trees in this case, a 1-tree, a 2-tree, and a 3-tree. These trees are shown, respectively, as the first, second, and third rows in Figure 5.A4. For instance, the 1-tree shows the root at the unique element, s_1 , of the recurrence class, C_1 . There are three possible ways of reaching this root, each shown by the first row in Figure 5.A4. These are: (i) $s_3 \rightarrow s_2 \rightarrow s_1$, (ii) $s_3 \rightarrow s_1$ and $s_2 \rightarrow s_1$, and (iii) $s_2 \rightarrow s_3 \rightarrow s_1$. The 2-trees and the 3-trees can be similarly read off from the second and third rows of the figure.

Figure 5.A3 j -trees for two recurrence classes with one state each.

Figure 5.A4 1-tree (first row), 2-tree (second row), 3-tree (third row) for the case of three recurrence classes with one state each.

Definition 16.70 (*Resistance of a j -tree*): The resistance of a j -tree is the sum across all $M - 1$ directed edges of ρ_{ij} .

Definition 16.71 (*Stochastic potential*): The stochastic potential of the j th recurrence class, C_j , denoted by ϕ_j , is the minimum value of resistance across all possible j -trees for the states in C_j .

Theorem 16.17 (*Stochastically stable states*): The stochastically stable states are those which are contained in the recurrence classes with the minimum stochastic potential (this includes the possibility that there might be more than one recurrence classes, which has the minimum stochastic potential). So essentially, the root of the tree with the minimum stochastic potential is a stochastically stable steady state.

Example 16.13 Consider Figure 5.A3. Using Definition 16.71, the stochastic potential of C_1 is ρ_{21} , while that of C_2 is ρ_{12} . We can now use Theorem 16.17. C_1 is the stochastically stable state if $\rho_{21} < \rho_{12}$, while C_2 is the stochastically stable state if $\rho_{21} > \rho_{12}$.

Example 16.14 Consider Figure 5.A4. We can find the resistance of any tree by adding together the two resistances along its two edges. For instance, for the leftmost tree in the first row, the resistance is $\rho_{32} + \rho_{21}$. The resistance of the 1-tree is given by the minimum of the resistance across the three trees in the first row. We can likewise compute the resistance of the 2-tree and the 3-tree (by taking, respectively, the minimum across the second and third rows). Finally, we can take the minimum resistance across the three trees. The corresponding recurrence class is the stochastically stable steady state.

THE METHOD OF ELLISON (2000)

Definition 16.72 (*Radius and co-radius*): Suppose $s_i \in S$. Then the radius of s_i , $R(s_i)$ is given by

$$R(s_i) = \min_{s_j \in S} c(s_i, s_j), s_i \neq s_j.$$

The co-radius $CR(s_i)$ is given by

$$CR(s_i) = \max_{s_j \in S} c(s_i, s_j), s_i \neq s_j.$$

Theorem 16.18 (Ellison, 2000): If $R(s_i) > CR(s_i)$, then s_i is the only stochastically stable state.

Exercises for Part 5

- Recall from Figure 14.2 that ESS is a subset of the set of Nash equilibria of a game. Consider the normal form game in Figure 5.E1. There are two pure strategy Nash equilibria (A, A) and (B, B). Show that A is not an ESS, but B is.
- (Gintis, 2009a, Theorems 10.1, 10.2): Consider the game $G(2, S, \pi)$ and $S = (s_1, s_2)$.
 - Suppose that $a_{11} \neq a_{21}$ and $a_{12} \neq a_{22}$ (see Section 14.2 for this notation; a_{ij} is the payoff of player i when he follows the strategy s_i and the opponent follows the strategy s_j). Then show that $G(2, S, \pi)$ has an evolutionarily stable strategy.
 - Show that $G(2, S, \pi)$ has a mixed strategy Nash equilibrium if $a_{11} < a_{21}$ and $a_{22} < a_{12}$. Show that this equilibrium is an ESS.
- Consider the stag-hunt game in Figure 5.E2.

Each player has two pure strategies. Hunt hare (H) or stag (S). Hunting stag requires a cooperative effort that is only successful if both parties engage in it; a successful stag hunt gives each player a payoff of $s > 0$. Hunting hare gives each player a payoff of $0 < h < s$, irrespective of what the other player does. Finally, hunting stag gives a payoff of 0 if the other player hunts hare.

 - Show that there are three Nash equilibria: (H,H), (S,S) and a mixed strategy equilibrium in which $\sigma(H) = \frac{s-h}{s}$ and $\sigma(S) = \frac{h}{s}$.
 - Show that each pure strategy Nash equilibrium is an ESS, but the mixed strategy Nash equilibrium is not an ESS.
- Consider the hawk-dove game in Figure 5.E3.

The strategies in this game are dove (D) and hawk (H), which are, respectively, the non-aggressive and aggressive strategies. Two players fight for a fixed prize that has value v . If both play aggressively, each shares the prize v , but each player also incurs a fixed cost $c > v$. If a dove meets a hawk, then the dove backs down and the hawk gets the prize.

 - Show that there are no pure strategy Nash equilibria, and in the unique mixed strategy equilibrium, $\sigma(D) = \frac{c-v}{c}$ and $\sigma(S) = \frac{v}{c}$.
 - Show that the mixed strategy Nash equilibrium is an ESS.
 - (Smith, 1982) How might this simple example account for ritualized fighting in animals?

5. (Multiple mutations: Gintis, 2009a, Section 10.10) Consider the normal form game shown in Figure 5.E4.
 - (a) Show that the pure strategy A is an ESS.
 - (b) Starting from the established strategy A, consider two simultaneous mutations. A fraction $0 < \lambda_B < 1$ of the players play B (type-B mutants) and a fraction $\lambda_C > \lambda_B$ of players play C (type-C mutants). In the face of these simultaneous mutations, show that the type-B mutants have a higher payoff than players who play A. This is the sense in which the ESS, A, is not “unbeatable.”¹
6. Consider the following coordination game in Section 14.6.4:

	A	D
A	1, 1	0, 0
D	0, 0	1, 1

Suppose now that this game is played by players who are randomly matched from the same population. Show that the equilibrium in which one half of the population plays A, while the other half plays D is asymptotically stable.

7. Consider the following coordination game played between two populations of players who are randomly matched.

1\2	A	D
A	0, 0	2, 1
D	1, 2	0, 0

¹ As to the usefulness of this concept, Gintis (2009a, p. 240) writes: “But unbeatability is not a very important concept, because it has no interesting dynamic properties.”

Show that the polymorphic equilibrium in which each population plays strategy A with probability $\frac{2}{3}$ is unstable and that it is a saddle path. What are the stable equilibria of this game in replicator dynamics?

8. Consider the rock–scissors–paper game that we considered above in Section 14.6.3. Suppose that the payoffs are instead given by the payoff matrix:

	R	S	P
R	ε, ε	$1, -1$	$-1, 1$
S	$-1, 1$	ε, ε	$1, -1$
P	$1, -1$	$-1, 1$	ε, ε

- (i) Let $\varepsilon > 0$ be small. Show that the unique Nash equilibrium is still $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$.
 (ii) Show that the Nash equilibrium is an unstable steady state of the replicator dynamics such that the trajectories spiral outwards from $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ without ever touching the boundaries of the simplex.
 (iii) Suppose that $\varepsilon < 0$ is small. Show that the Nash equilibrium in this case is an asymptotically stable steady state.
9. (van Damme, 1987) For many examples in the text, ESS coincided with the asymptotically stable states of replicator dynamics. From Figure 14.2, we know that the latter set is larger. To illustrate this point, consider the payoff matrix.

	A	B	C
A	$0, 0$	$1, -2$	$1, 1$
B	$-2, 1$	$0, 0$	$4, 1$
C	$1, 1$	$1, 4$	$0, 0$

- (i) Show that the game has a unique symmetric equilibrium $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$.
 (ii) Show that $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ is not an ESS and it can be successfully invaded by the strategy $(0, \frac{1}{2}, \frac{1}{2})$.
 (iii) Show that $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ is asymptotically stable in the replicator dynamics.
10. Prove Proposition 14.18.
 11. Prove Proposition 14.19.
 12. (Gintis, 2011): Let g, c, e be, respectively, vectors of genetic variables, cultural variables, and environmental variables. Suppose that in an evolutionary model we have the following system of first order differential equations.

$$\begin{cases} \dot{g} = F(g, c, e) \\ \dot{c} = G(g, c, e) \\ \dot{e} = H(e) \end{cases} \quad (5.E1)$$

An argument is sometimes made that culture is an “effect of genes that can be factored out in the long run.” This is equivalent to the assertion that c can be eliminated from the equations in (5.E1). Based on the statement given, derive a contradiction using (5.E1).

13. Consider the following statement in Gintis et al. (2014, p.19): “Fire and cooking thus co-evolved with the emergence of a normative order and social organization based on ethical behavior.” Can you think of arguments to support this statement?
14. (Bowles and Gintis, 2011, pp. 6, 8) Consider the following influential views that strongly advocate that humans are essentially selfish.
- (i) In his celebrated book, Richard Dawkins (2006) writes:² “Let us try to teach generosity and altruism, because we are born selfish.”
 - (ii) Richard Alexander (1987) writes: “ethics, morality, human conduct, and the human psyche are to be understood only if societies are seen as collections of individuals seeking their own self-interest.”
 - (iii) Garrett Hardin (1968) gave an account of the tragedy of the commons and the importance of self-interest in the depletion of common property resources. He writes (p. 1246): “The tragedy cannot be solved by an appeal to conscience, for those who heeded the appeal would have fewer children, and by the heritability of the capacity of the conscience, this would lead to a less moral population.”

In light of these views how can we explain the central theme in Part 2 of the book that most humans have other-regarding preferences and possess character virtues?

15. Consider a technology adoption game in which there is a choice of two technologies s_1 , s_2 . There is a large population, and in every period a single player gets the opportunity to make a technology choice (perhaps the technology becomes obsolete). Before making the technology choice, the player samples m individuals about their choice of technology, who report back honestly. The payoff matrix is shown below.

	s_1	s_2
s_1	a, a	$0, 0$
s_2	$0, 0$	b, b

Consider a perturbed Markov process in which the individual plays a best response with probability $1 - \varepsilon$ ($\varepsilon > 0$ is small) and randomizes equally between the two technologies with equal probability (i.e., $\frac{\varepsilon}{2}$ each). Show that if $a > b$ then the stochastically stable choice is to invest in technology a , while if $a < b$, then the stochastically stable choice is b . Show that such a choice also satisfies the criterion of risk dominance.

16. (Young, 2006) Consider again a technology adoption game. The setup is as in Exercise 15. Suppose that the payoff from a technology arises from two sources. The first source is *networking* which arises from interaction between different technologies. The second source is *payoff from own use* which arises independently of networking effects. The payoff matrix is shown below.

	s_1	s_2
s_1	$a + a', a + a'$	$c + a', c + b'$
s_2	$c + b', c + a'$	$b + b', b + b'$

² This is a much caricatured view. See Dawkin’s clarification in the introduction to the anniversary edition (2006, p. ix).

The payoffs without primes arise from networking effects, while the payoffs with primes arise from own use. We assume that $a + a' > c + b'$ and $b + b' > c + a'$, so we have a symmetric coordination game. Consider the special case of $a = 4$, $b = 1$, $c = 1$, $a' = 1$, $b' = 3$. Show that the stochastically stable outcome is for everyone to adopt s_2 , but that this is not a Pareto optimal outcome.

17. (Young, 2006) Consider the same setup as in Exercise 15, but now there is a choice between three competing technologies, s_1 , s_2 , s_3 . The payoff matrix is given by

	s_1	s_2	s_3
s_1	5, 5	0, 0	0, 0
s_2	0, 0	4, 4	0, 0
s_3	0, 0	0, 0	3, 3

Show that in the stochastically stable state, technology s_1 is chosen.

18. (Young, 1998) Several different commodities have historically been used as a medium of exchange. Young (1998) gives a fascinating account. Consider the following stylized example in which there are two possible commodities, gold and silver, that can be used as a medium of exchange. There is a single population. Individuals are matched each period to engage in a transaction. Each period, one individual is drawn at random (the experimenter). He chooses either to carry gold or silver. Consider the Markov process, $P^{T,\tau,\varepsilon}$; thus, the selected individual takes a sample of size $\tau \leq T$ and plays with some noise ε . The payoff matrix is given by:

	Gold	Silver
Gold	3, 3	0, 0
Silver	0, 0	2, 2

Thus, of the individuals sampled, if a proportion p holds gold, then the payoff to the experimenter from holding gold is $3p$, while that from holding silver is $2(1-p)$. With probability, $1 - \varepsilon$ the experimenter plays a best response to these frequencies and with probability ε (noise) he chooses each of the two actions with equal probability. Show that the stochastically stable equilibrium is (Gold, Gold).

19. (Young, 1998) Along the lines of the discussion in Section 16.3.3, consider the following 2×2 game of chicken.

	Defensive	Aggressive
Defensive	10, 5	0, 0
Aggressive	7, 7	5, 10

Suppose that the row and the column players use different sample sizes. Greater information corresponds to a larger sample size. Show that more information is advantageous.

PART 6

Emotions

INTRODUCTION TO PART 6

In economics, the standard practice is to focus on *emotionless deliberation* and assume that economic agents make cool, calculated, decisions in constructing trade-offs between alternative choices. In contrast, evidence suggests that humans operate along the entire range of the emotional spectrum, rather than at the cool end only. Emotions are central to human behavior and affect economic outcomes in a fundamental way. Until fairly recently, economic theorists had little to say about emotions, and researchers working in the area of emotions, little to say about the effect of emotions on economic variables. However, in recent years, there has been an impressive spurt of research activity in this area.

One may give the following useful taxonomy of emotions (Elster, 1998). *Social emotions* include anger, hatred, guilt, shame, pride, admiration, and liking. *Counterfactual emotions* are generated by thinking about unrealized possibilities, e.g., regret, rejoicing, disappointment, and elation. *Anticipatory emotions* are caused by anxiety about what may happen, e.g., fear and hope. *Realized emotions* are caused by events that have already been realized in the past, e.g., grief and joy. *Material emotions* are caused by the possession of material or non-material objects by others, e.g., envy, malice, indignation, and jealousy. There are other kinds of emotions that may not fall into any of these categories, e.g., contempt, disgust, and romantic love.

In this part, we are mainly interested in the study of a limited number of emotions and their impact on economic behavior.¹ We also consider the interaction between emotions and cognition in shaping economic decisions. Indeed, as Elster (1998, p. 73) writes: “The more urgent task is to understand how emotions interact with other motivations to produce behavior.”

There is a range of interesting questions that we either omit, or which offer a limited discussion; however, these questions are well discussed in other sources.² For instance, are emotions culture-specific or universal? What hormonal or physiological changes are associated with emotions? What is the valence, or location on a pleasure–pain scale, of different emotional states? Can emotions be called upon/avoided by individuals in a deliberate and rational manner, or are they passively undergone? Can we learn to avoid cues that trigger different emotional states? Can individuals successfully induce emotions in others?

We have already considered, elsewhere in the book, material that could have also been well situated in this chapter. This includes (i) formal models of emotions such as guilt, anger, and disappointment using *psychological game theory* (Part 4 of the book),³ (ii) models of *disappointment aversion* and *regret* (Part 1 of the book), and, (iii) issues of *self-control* that arise from *present-*

¹ There is a corresponding realization among emotion theorists about the importance of economic models. For instance, Rolls (2014) devotes a major part of his Chapter 9 to economic models, albeit the main focus is on neuroeconomics.

² The interested reader may consult Frank (1988), Elster (1998), Loewenstein (2000), Goldie (2009), Winter (2014), and Rolls (2014).

³ For a discussion of guilt inculcation in children by parents that does not rely on the machinery of psychological game theory, see Becker (1996) and Frank (1988), although they invoke very different mechanisms to each other.

biased preferences (Part 3 of the book). In order to avoid repetition, we omit a discussion of these issues here, and focus on the remaining issues in the role of emotions in economics.⁴

Chapter 17 gives an introduction to some components of emotions and physiological states (moods, physical pain, hunger, thirst) that are of interest in economic models; collectively these are known as *visceral factors*. We briefly consider the question of the rationality of emotions. In Part 1, we considered the role of *anticipated emotions* such as regret and disappointment that might be experienced at some future time, on account of decisions made today. Here, in Chapter 17, we introduce *anticipatory emotions* experienced at the time of making decisions, such as anxiety and dread. Part 1 also considered various theories of risk. However, risk may also bring about feelings of dread, anxiety, and apprehension. Thus, it would appear that emotions ought to be inextricably linked to explanations of human behavior under risk. We explain the *risk as feelings hypothesis*, that ought to be taken more seriously by economists.

Visceral factors are typically activated by external cues. We develop a model of *habit formation* in the presence of *stochastic cues* and discuss the role of active cue management. Anticipation of future pain or rewards can create anxiety or elation, thus, we also incorporate the role of *anticipal utility* into a simple life-cycle model. We develop a *preference representation of anxiety* and apply it to a problem of portfolio choice in a life-cycle model of consumption. It turns out that risky assets, whose uncertain returns create anxiety, may command an *anxiety premium* that could also potentially explain the equity-premium puzzle.

When predicted future tastes differ from their actual realization, individuals are said to suffer from *projection bias*. In this case, individuals might make time-inconsistent choices, and may end up making decisions in a hot state that they regret later. This explains the role of public policy and legal provisions that provide for various cooling-off periods, be they for the purchase of consumer durables or applying for marriage/divorce.

We discuss the Gul–Pesendorfer framework of *temptation preferences* that explains temptation and self-control problems in the classical revealed preference framework. In this framework, one response to temptation is to remove a tempting option from the menu of choices. However, in the presence of uncertainty about the future, there are costs and benefits from this option. For instance, removing a currently tempting option from the menu may improve current savings, yet an adverse shock to marginal utility in the future may reduce the future enjoyment of these savings.

In the final section of this chapter we discuss the emerging literature on *happiness economics*. Unlike many other areas in economics, the evidence relies on self-reported measures of well-being, health, and life satisfaction. However, there is a strong correlation between various measures of well-being and these, in turn, successfully predict job quits, suicides, productivity, and probability of a divorce among couples. We examine a celebrated result in this literature, the *Easterlin paradox*. The cross-sectional evidence in any country shows that richer people are happier. However, the time series evidence shows that growth in income is not associated with higher self-reported measures of well-being. A leading explanation is that as incomes increase over time, the reference point of individuals, as captured by their aspiration levels, moves upwards. Thus, an increase in income over time is not associated with greater happiness. In recent years, the data behind the Easterlin paradox has been increasingly questioned based on a longer time series and a more representative sample of poor countries.

⁴ Instructors who wish to teach a specialized course in emotions in economics or a behavioral course with special emphasis on emotions may wish to combine these topics from different parts of the book.

Chapter 18 considers the interaction between emotions and cognition. This interaction has evolutionary origins. The cognitive system is associated with the development of the prefrontal cortex, 150,000 years ago. However, the cognitive system was built on top of an already existing emotional system that we share with other mammals. The result is that the objectives of the emotional and the cognitive systems can sometimes be in conflict, and at other times, in harmony. We also employ a System 1 (quick, reactive emotional system) and System 2 (slow, deliberative cognitive system) distinction in Part 7. However, here we are interested in examining a different set of issues.

We begin by presenting a promising model of the interaction between the two systems that can serve as a template for the development of future models. This model has the advantage of endogenously deriving several behavioral features of interest to economists such as reference dependence, loss aversion, social preferences, and hyperbolic discounting.

In a formal model of *dual selves*, we show how the cognitive system can control the emotional system through the exercise of costly willpower. We derive the optimal solution in the presence and in the absence of a commitment technology.

People often try to discover themselves through their actions. For instance, charitable giving may be a self-signal that the individual has empathy and compassion for others. Withstanding extreme stress and successfully completing a timed task may self-signal willpower to an individual. These issues can be modeled in several ways. A radical proposal is to model the interaction between the dual systems using classical game theoretic asymmetric information models. However, this leaves open the question of how contracts are enforced between the emotional and the cognitive systems, and what does a participation constraint imply in this special case?

In the final two sections, we consider the *strategic transmission of information* in a multiple-selves model. In these models, if the current self chooses to acquire some information, it immediately becomes available to all future selves, who can use this information to the detriment of the current self. In this case, the current self may choose to be strategically uninformed. For instance, individuals vastly overestimate the effects of smoking on lung cancer, yet typically are not proactive in accessing easily available information. There can be other equally plausible explanations for this phenomenon. For instance, individuals may procrastinate in the presence of hyperbolic discounting. However, here we study a different set of explanations that are based on *imperfect willpower*, *imperfect recall*, and *motivated cognition* (i.e., managing the degree to which subsequent selves can recall past events).

CHAPTER 17

Emotions and Human Behavior

17.1 Introduction

In this chapter, we motivate the use of emotions to explain human behavior. In contrast to the cold, emotionless, deliberations undertaken by Homo economicus, the introduction of emotions provides a more satisfactory explanation of many economic phenomena. A wealth of empirical evidence provides a compelling case for taking emotions more seriously in all areas of economics.

In Section 17.2, we focus on intense physiological states such as hunger, moods, thirst, physical pain that are collectively referred to as *visceral influences* (Loewenstein, 1996). Visceral influences can induce individuals to take actions that are often contrary to their own self-interests. Yet individuals often underestimate the effect of visceral influences on their past, current, and future behavior. The usual practice in economics is to consider emotions arising in the future on account of current decisions, as in regret theory and disappointment aversion; these are *anticipated emotions*. A strong case has been made for considering the role of emotions at the time of making decisions, i.e., *anticipatory emotions*, such as anxiety and dread (Loewenstein, 2000).

The issue of the rationality of emotions is an interesting one (Damasio, 1994). Individuals who have suffered damage to the emotional centres of their brains are unable to experience emotional states associated with fear. When faced with risky situations that entail occasional large losses and overall negative expected values, these individuals make extremely risky decisions. Damasio and several others have argued that the absence of emotions is detrimental to sound cognitive decisions, hence, on net, emotions must be rational. Emotions need not always enable us to take socially optimal actions although emotions such as compassion and empathy often do lead to prosocial actions at an individual level. For instance, our insensitivity to many global problems such as global warming, and poverty and hunger in poor countries may be caused by a problem of insufficient emotions (Loewenstein, 2010).

In the final part of Section 17.2, we consider the role of anticipatory emotions in decisions under risk based on the idea of *risk as feelings* (Loewenstein et al., 2001). In many risky situations, individuals do not behave in an entirely consequentialist manner (i.e., they do not pay sufficient attention to probabilities and outcomes). We consider how emotional states may influence the types of decisions made under risky environments. This gives an alternative, affective, account of decision making under risk that deserves to be taken more seriously by economists of all persuasions.

Visceral influences are often activated by external stimuli, which we refer to as *cues*. Traditional habit formation models do not consider the role of cues (Becker and Murphy, 1988). In Section 17.3, we consider the role of stochastic cues in models of habit formation (Laibson, 2001;

Bernheim and Rangel, 2004). The nature of the solution under the cues and the no-cues models is very similar. If the stock of habits exceeds a threshold, then the individual optimally engages in the harmful activity, otherwise not. In traditional habit formation models, the main upshot of this feature is that once rationally addicted, individuals stay addicted. However, in the cues model, the harmful activity is dictated by the observation of a cue. In order to wean themselves off addiction, individuals may then engage in active cue-management, while self-interested firms may try to counter this by making consumption-inducing cues more salient. Models of addiction are also considered in subsequent Sections 17.6, 17.7, and in applications of present-biased preferences in Part 3 of the book that readers interested in a fuller treatment should consult.

We often feel anxious about an uncertain future. Will my pension contributions be sufficient for my retired life? Will early retirement turn out to be a good decision? Should I buy or sell stocks in the current economic environment? Anticipation of a stressful event can create anxiety that in some cases is worse than the event itself, e.g., an impending visit to a dentist. Such feelings of anxiety are caused by *anticipation* of future events, and they are *aversive*. Future events need not, however, always be unpleasant. We might savor a pleasurable experience such as waiting for a dessert at the end of a meal. Or, we might be excited about a forthcoming pleasurable vacation.

For both pleasant and unpleasant events, individuals often exhibit a negative discount rate. This typically takes the form of postponing a pleasant experience (dessert at the end of a meal) and preponing an unpleasant one (taking out an aching and doomed tooth sooner rather than later). This evidence is contrary to the predictions of the discounted utility model, which does not take account of anticipatory utility and anticipatory disutility from future events. Section 17.4 shows how such anticipatory feelings can be incorporated into a formal model (Loewenstein, 1987).

It is natural to suppose that anxiety about future events may be associated with uncertainty about the future. In Section 17.5, we consider a utility representation of preferences under anxiety (Caplin and Leahy, 2001). We use this preference representation to derive equilibrium prices of assets whose returns are ex-ante random. The randomness of returns creates feelings of anxiety. When investors exhibit anxiety, risky stocks are priced even higher relative to the case of no-anxiety. This provides one possible explanation for the *equity premium puzzle* that does not rely on loss-aversion. Furthermore, the price of riskless assets in the presence of anxiety is relatively higher because they provide a “peace of mind function” for the investor that stocks with fluctuating returns cannot.

In the absence of any random shocks, the typical assumption in economics is that individuals are fully aware of their future tastes. When the predictions of future tastes differ from their actual realization, despite no inherent randomness in the model, then the individual is said to make a *projection bias*. Section 17.6 considers issues of projection bias (Loewenstein et al., 2003). For instance, among patients who await kidney transplants, those who are successful (unsuccessful) in getting a transplant overestimate (underestimate) their future quality of life (Smith et al., 2008). A distinguishing feature of projection bias is that individuals use their current state disproportionately to predict their future states. Hungry shoppers choose far more groceries for future consumption, relative to satiated shoppers, even when they have the same future needs (Read and van Leeuwen, 1998).

Individuals who have projection bias make *time inconsistent choices*, without being aware of it. Under the influence of projection bias, in a *hot state*, individuals might, for instance, (i) end up buying goods that they regret later, and (ii) end up marrying/divorcing without sufficient deliberation. In response to these concerns, (i) consumer regulation provides a 21 day cooling-off period during which goods can be returned, provided they are in a satisfactory state, and (ii)

the law typically requires a cooling-off period before which applications for marriage and divorce cannot be filed. Projection bias also provides an alternative explanation for why individuals may get addicted. First, they might underestimate the (negative) effect of current consumption on future utility. Second, they might under-appreciate the formation of habit, i.e., addiction to the harmful product. We give two formal applications of projection bias. The first is to a two-period model of habit formation, and the second is to purchase of consumer durables.

What does it mean to say that one alternative is more tempting relative to another? Can one provide an axiomatization of preferences that incorporates some plausible notion of *temptation*? Consider a two-period model. In the first period, the individual chooses between a set of *menus*. In the second period, the individual chooses an element from the menu that was chosen in the first period. Preferences exhibit *temptation* if the individual prefers to exclude certain menus from first period choice; under the typical preferences specified in neoclassical economics, more options never hurt. If exclusion of the temptation is not possible, then the individual may either be able to exercise self-control in the second period or succumb to the temptation. We give a utility representation of temptation preferences in Section 17.7 (Gul and Pesendorfer, 2001; Dekel et al., 2001). We also show that temptation preferences can also arise in a model of competing dual selves, when there is some uncertainty about the eventual winner in a contest between them (Bénabou and Pycia, 2002).

When individuals have self-control problems, such as those arising from temptations, the standard prescription in a range of models is to commit to eliminate options that lead to such temptations. Section 17.8 considers an important trade-off associated with the removal of temptations in a model of multiple-selves (Amador et al., 2006). Eliminating a subset of the options has the benefit of reducing/eliminating temptations, but at the cost of reduced flexibility, especially when new information is likely to arrive in the future. For instance, in the context of intertemporal choice, a reduction in temptations might improve the savings rate of an individual. However, if the future marginal utility turns out to be unexpectedly low, then the improvement in savings might not have been as worthwhile. In the context of this framework, we derive the justification for a minimum savings rule when current selves have asymmetric information about the subsequent selves. Within the two type case, we also derive conditions under which the first best can be implemented.

Modern economics typically relies on the notion of *decision utility*—the utility experienced at the time of the decision. An older tradition in economics emphasizes *experienced utility*—the hedonic experience associated with an outcome (Bentham, 1798). The modern approach is based on checking if preferences are consistent with the axioms of rational choice—this is encapsulated in the revealed preference approach. However, in many cases, the well-being of individuals is influenced by outcomes that they cannot directly choose. Examples include inflation, unemployment, income inequality, environmental degradation, crime, health shocks, accidents, and exogenous income shocks. In these cases, revealed preference arguments cannot be used to infer the well-being of individuals. It would be bizarre, if one is willing to take experienced utility seriously, to argue that the subject matter of economics should restrict itself to those economic outcomes that can be handled via the revealed preference approach only.

Section 17.9 considers an alternative approach to well-being, based on *experienced utility*. In this approach, individuals are asked directly to report their well-being, life satisfaction, and health status. Clearly, self-reported survey questions that report experienced utility are subjected to biases, such as *duration neglect*, and *peak-end evaluation* (Kahneman et al., 1997). However, subjective measures of well-being are consistent with the actual choices for the vast majority of subjects and these measures are the best predictors of choices (Benjamin et al., 2012). Such

subjective measures successfully predict a range of phenomena such as job quits, probability of suicides, productivity and probability of a future divorce among couples. Despite the drawbacks of self-reported measures of well-being, it may be still preferable to use them rather than have experts guess the well-being of individuals. Furthermore, survey questions may catch people in a deliberative mood rather than an emotional state, hence, self-reported measures may have normative value (Benjamin et al., 2014).

Evidence from many countries showed that at any point in time, richer individuals are happier. However, over time, while GDP growth takes place, mean self-reported happiness stays almost unchanged. This has come to be known as the *Easterlin paradox* (Easterlin, 1974). The main explanation offered for the paradox is that individuals adapt to the higher level of income, and simply raise their aspiration levels. In this view, self-reported happiness is a measure of the difference between actual incomes and aspiration incomes (Easterlin 1974, 1995).

This evidence has been contested in recent years in a series of papers, which argue that mean happiness is increasing in the levels of income over time, hence, there is no Easterlin paradox (Deaton, 2008; Stevenson and Wolfers, 2008, 2013). The main reasons for the difference in conclusions is newer datasets (Gallup World Poll rather than the World Values Survey, which formed the basis of earlier results) that provide data on a more inclusive set of poorer countries, and use a more representative sample. Easterlin has responded with the argument that while the paradox might not hold in the short run, it does hold in the long run (Easterlin et al., 2010). We end Section 17.9 with a brief note on the correlates of self-reported well-being, such as inflation, unemployment, health, income inequality, and democracy.

17.2 Visceral influences and the rationality of emotions

17.2.1 *Visceral influences*

One manifestation of emotions that has an important influence on human decision making is intense physiological states that are lumped under the term *visceral factors/influences*. Examples include hunger, thirst, moods, physical pain, and craving for a drug. So, for instance, consider the visceral factor of sleep deprivation in its extreme form. Individuals do not make a rational decision to fall asleep behind the wheel of their car, but some people do, with disastrous consequences. Overeating, compulsive shopping, and drug addiction are other examples where strong visceral influences can lead to suboptimal behavior.

Loewenstein (1996) has drawn attention to the role of visceral influences in influencing choices. Two important features of visceral influences are the following.

1. *Current visceral factors can have a “disproportionate” influence on current behavior:* When visceral influences are weak, individuals can control them better. However, when they are “intense,” the individual gives almost exclusive attention to these influences at the expense of other possible objectives. Under extreme visceral influences, the individual may behave as if the discount factor were zero. Hence, such factors might drive a wedge between the self-interested optimum of an individual and actual behavior.
Under the influence of visceral factors, individuals can often be aware of the wedge between their actions and best interests. However, they nevertheless persist in taking actions that are contrary to their self-interest. For instance, in a visceral state of anger, an individual, in the heat of the moment, could say something that is deeply regretted later, and lead to a poor outcome.

An extreme example of visceral influences is the behavior of individuals who have various *phobias* that they fully know are non-threatening but are still unable to use rational judgment to counter them. Police and military interrogators use extreme visceral influences such as pain, hunger, or sleep deprivation to elicit confessions. Or, as a strike deadline approaches, labor negotiations often go “round the clock,” evoking the extreme visceral influence of sleep deprivation that is more likely to elicit concessions. Both sides, perhaps due to mutual awareness of a potential bargaining impasse, agree to this bargaining structure.

In conclusion, unlike the assumptions of neoclassical economic theory, on many occasions individuals do not operate at the *cool end* of the spectrum of human emotions. Despite a degree of self-awareness of the problem, they can operate at the *hot end* of the spectrum, with detrimental consequences to their self-interest.

2. *Individuals typically underestimate the importance of visceral factors in determining their past, current, and future behavior:* Loewenstein (1996) reports the following empirical result. Prior to the onset of labor, pregnant women were asked to make a non-binding decision on whether they will require an anaesthetic during labor. A majority were optimistic that they would not need an anaesthetic. However, acute pain is often an extreme visceral influence. Once labor set in, a high proportion of the women reversed their earlier decision. Hence, individuals can underestimate the effect of visceral influences on future behavior.

The “endowment effect” can also be thought of as evoking the visceral factor of attachment. Individuals underpredict the future endowment effect. Individuals also often forget or underreport the visceral influence of pain in the past; memories of pain seem qualitatively different from other sorts of memories.

These concerns are contrary to the behavior of individuals in models where they *rationally decide* to be addicts, in full knowledge of all future consequences, as in Becker and Murphy (1988). By contrast, visceral influences explain drug addiction by a serious error of judgment on the part of individuals, who underestimate the pain of withdrawal and craving for the drug, caused by the visceral activity of addiction.

Visceral factors are not *tastes* or *preferences*, as understood in conventional economic theory. Visceral influences arise from external stimulation or deprivation, hence, they may be more volatile than tastes. As Loewenstein (1996, p. 273) puts it: “In contrast, changes in preferences are caused by slow experience and reflection, are typically not anticipated, and do not imply a permanent change in behavior.” Furthermore, Loewenstein cites evidence to show that tastes and visceral factors draw on different neurophysiological mechanisms. Visceral factors are likely to have a common neurophysiological mechanism. Evidence for this assertion comes from the observation that behavior contrary to one’s self-interest, arising from a range of visceral influences, can be mitigated by using a single drug, Fluoxetine.

The origin of visceral factors are most likely evolutionary. For instance, the fitness of animals who respond to hunger by focusing exclusively on the search for food, might have been higher. However, such behavior could also be a double edged sword. For instance, moderate fear may lead to actions that are conducive for survival, but extreme fear can petrify an individual and hinder rational action.

Under the influence of visceral factors, individuals focus more on their needs and less on others. Interrogators have long known that under appropriate visceral influences, e.g., extreme torture, otherwise sincere individuals are likely to betray collaborators, friends, and family.

17.2.2 *Rationality and emotions*

Is it rational to have emotions? One possibility is that our judgment may be clouded in the presence of emotions, hence, we may make suboptimal decisions (Baumeister et al., 1994; Baumeister et al., 2007; Frijda and Mesquita, 1994). For instance, one may make a reckless purchase in a hot state of mind and regret it later, once the initial emotion subsides. The presence of cooling-off periods, enshrined in law in many countries, appear to be a regulatory response to this possibility.

On the other hand, using data from neurobiological studies, Damasio (1994) argues that emotions aid us in taking better decisions. For supporting findings and the evidence, see Bechara et al., (1994, 1996, 1997, 1999) and Damasio (1996). Using data from individuals who had suffered damage to the emotional regions of their brains, e.g., damage to the ventromedial prefrontal region,¹ Damasio draws several conclusions from the behavior of individuals who suffer such kind of brain damage; we summarize some of these conclusions, below.

1. These individuals are less likely to conform to social norms, which might lead them to suffer social sanctions.
2. These individuals may procrastinate more in social situations because they are less likely to suffer from the guilt and embarrassment of letting others down.
3. These individuals may do worse in decision tasks. For instance, in one experiment, individuals had to choose from four possible decks of cards, A, B, C, and D. Decks A and B contained high payments and occasional large losses, so that the expected temporal pay-offs were negative. Decks C and D contained low payments but positive expected temporal payoffs. Observing the data over time, it was possible to learn that it is a dominated strategy to choose decks A and B. Yet, those with damage to the emotional regions of the brain continued to choose decks A and B, while those who did not suffer from the damage learned to pick decks C and D. A possible interpretation of these findings is that individuals with brain damage did know that decks A and B are associated with occasional large losses, but they lack a fear response that would have led to the avoidance of decks A and B. Indeed, over time, such individuals could go bankrupt. Similar results are expected from psychopathic criminals, who are insensitive to the future consequences of their actions.

These results, however, cut both ways. For instance, one could design an experiment such that, while decks A and B have large occasional losses, the expected temporal value of choosing these decks is higher as compared to choosing decks C and D. In this case, those with a damaged ventromedial prefrontal region may earn a higher long-run return.

Smith and Dickhaut (2005) find that they can make better predictions of prices in English and Dutch auctions when they take account of the heart rates of participants, just prior to making choices. An interesting finding is that emotions play a role in price determination in Dutch auctions but not in English auctions. Hence, there might be important complementarities between emotions and the determination of economic outcomes under some institutions, but not others.

When choices are cognitively challenging, individuals may often make choices based on physiological signals, or emotional states, associated with outcomes. This is also sometimes known as the *somatic markers* hypothesis. For instance, a coiled object on the side of the street may initiate immediate fear, and the fight-or-flight response, bypassing the cognitive

¹ This region of the brain is found to be active when individuals make choices; see Glimcher et al. (2009). Individuals with damage to the ventromedial prefrontal region otherwise appear to be normal in respect of memory, intelligence, and language comprehension.

system. Avoidance of decks A and B after a period of learning may also be based on the fear of losing a large amount, while patients with ventromedial prefrontal damage exhibit no such fear.

The debate on the rationality of emotions, despite the influential work of Damasio and his colleagues, is not a settled one. For instance, anger may be a suitable emotion to get a larger share of the cake when aggression is required to determine the division of the cake. However, more irascible individuals may be shunned by others in subsequent divisions of the cake and may lose out in the long run. The economic models that we consider in subsequent sections, allow for a more explicit consideration of these opposing forces.

Are emotional states induced voluntarily or involuntarily? The somatic markers hypothesis is based on the assumption that emotional states are induced involuntarily. Sinaceur and Tiedens (2006) provide evidence to show that individuals may also make use of emotional states in a strategic manner to gain advantage in bargaining situations. Meshulam et al. (2012) provide evidence that suggests many individuals can induce emotional states at will. In their experiments, players play a modified dictator game in which they play the role of recipients who receive low, medium, and high offers. Their emotional response, in terms of skin conductance response (SCR) and heart rates, is measured, while they receive the different offers. These measurements can determine if their emotional state is angry, calm, or happy.

Subjects are given incentives to exhibit various emotional states, depending on the offers received. For instance, when they receive a low offer, they are given a bonus if their emotional response is angry. Likewise they are given a bonus to demonstrate a happy state in the case of a high offer. In addition, at the end of the experiment, subjects fill in a questionnaire in which they are given two vignettes in which an individual suffers harm from another's negligence. Subjects were then asked to rate their punitiveness towards the negligent individual on a 1–7 scale. This is used to classify individuals into those who are naturally angry, calm, and happy.

Figure 17.1 shows the main results. More angry subjects (as measured by scores on the 1–7 response to the two vignettes) are also angrier when they receive low offers (as measured by SCR

Figure 17.1 Skin conductance response (SCR) amplitude and heart rate (HR), 0–12 s after offer presentation onset. Bars represent mean amplitude of SCR for high and low offers of participants in each condition. Lines represent mean HR during the presentation of high and low offers. Error bars: $\pm$ SEM.

and the heart rate). Since individuals are responding to the incentive effect of bonuses, if they demonstrate the required emotional state, the authors conclude that emotions are voluntary and rational. There is an asymmetry between angry and happy individuals; the latter are not able to fully muster the necessary emotions to take advantage of the bonus on offer. This finding could be a useful candidate for further exploration; the authors speculate that prospect theory may be a possible explanation.

Formal theoretical models of the rationality of emotions are in their infancy. Winter et al. (2014) propose that players choose their strategies and their mental states simultaneously. They define the notion of a *mental equilibrium* in which roughly, (i) the chosen strategies of the players are a Nash equilibrium for a given mental state, and (ii) the mental state of each player is a best response to the mental states of other players. The epistemic foundations of a Nash equilibrium show just how strong the underlying conditions are and the outcomes of many games are not consistent with equilibrium concepts (see Part 4). The cognitive requirements for a mental equilibrium are likely to be even stronger. Ultimately, the usefulness of this line of research, particularly for experimental results, is an open question. Perhaps the framework of a mental equilibrium may have greater usefulness in understanding the development of emotions in certain contexts over a longer, evolutionary, time period. Winter (2014) makes a case for the rationality of emotions that follows in large part from the notion of a mental equilibrium. In the mental equilibrium framework, being angry is necessarily a rational response that is codified as a part of the equilibrium. For an alternative approach that is able to distinguish between anger caused by the intentionality (or lack of it) of the behavior of others using a psychological game theory approach, see the interesting paper by Battigalli et al. (2015).

Loewenstein (2010) proposes that many global problems may be caused by the problem of insufficient emotion. For instance, we may not feel sufficiently emotionally distressed about global warming, or hunger, poverty, and disease in the poorer countries, hence, we react inadequately. Even during wars and genocides, humans appear to feel inadequate emotions for the victims who are often dehumanized through propaganda that paints them as outsiders or dangerous to one's own world view. Statistics of lives lost through wars and genocides often move us insufficiently. Insufficient emotions could be an evolutionary adaptation. For instance, they prevent us from being immobilized by the large number of emotionally disturbing events around us. Perhaps for this reason, we are emotionally more sensitive to next of kin or close members of our own social group, a phenomenon known as *parochial altruism*.

Vividness of events plays an important role in our emotional arousal. For instance, we are less moved by statistics of accidents, poverty, child labor, and disease, but more moved by graphic stories of individuals who have suffered, particularly women and children. Good storytellers often weave personal, individual narratives within complex social situations, for greater effect. For similar reasons, simple cost–benefit analyses, say, associated with global warming, or the cost of saving a life in a poor country, can sometimes be an inadequate impetus for many of us to be proactive.

There is a contrast between the work of economists and psychologists in terms of the role played by emotions in guiding human behavior. Economists have traditionally incorporated *anticipated emotions*, such as regret and disappointment (see Part I of the book). These are emotions that are not experienced at the time of making decisions, but are experienced in the future when the outcomes of current decisions materialize. In contrast, psychologists have stressed the role of *anticipatory emotions*. These are emotions such as fear, dread, and anxiety that are experienced at the time of decision making. Loewenstein (2000) and Loewenstein et al. (2001)

make a compelling case for incorporating anticipatory emotions into economics. While the ideas apply quite generally, the thrust of our discussion below is to consider the effects on decisions under risk.

We now outline some of the main ideas from the seminal work of Loewenstein et al. (2001). Each of the assertions below are backed by good evidence; the interested reader should consult Loewenstein et al. (2001) for an exhaustive list of about 200 references that we omit.

Classical decision theories such as expected utility, rank dependent utility, and prospect theory are *consequentialist* in the sense that decision makers are assumed to be solely influenced by the probabilities and outcomes. In a series of papers, Paul Slovic and co-authors (see, e.g., Slovic et al., 2002) have highlighted anticipatory emotions such as dread and risk of the unknown in determining the outcomes of decisions under risk. By contrast, consequentialist factors such as probabilities and outcomes play little role in the outcomes. For instance, some individuals may experience dread and anxiety at the mere thought of air travel, while being perfectly comfortable with travel by car. However, the probability of car accidents, per mile travelled, is much higher. Phobias are an extreme form of these kinds of anxieties. High-risk activities, even if associated with a positive expected value, may be associated with negative emotions, hence, they may be avoided, which is consistent with the somatic markers hypothesis.

Empirical evidence suggests that jurors often make decisions based on their gut feelings. The difficulty in making decisions can evoke negative emotions even when all possible consequences are positive. People in good moods often make optimistic choices, while people in bad moods make pessimistic choices. When people are exposed to “sad” newspaper articles, their estimates of risk for a range of potential causes of death are higher, relative to people who read “happy” newspaper articles. Under induced anxiety, people choose low risk and low reward options.

The emotional and cognitive pathways in the brain are different, hence, it is not surprising that decisions made in the presence of emotional factors are different from the decisions made under purely cognitive considerations. Loewenstein et al. (2001) highlight the transmission channels behind these differences as well as the differences in outcomes under the two. Their approach to decision making under risk, which they term as *risk as feelings theory*, is a mixture of consequentialist and non-consequentialist reasoning. The outcomes under this theory can differ substantially from the predictions of standard decision theory in economics, particularly when anticipatory emotional reactions are strong, relative to the cognitive evaluations.

A schematic outline of the risk as feelings thesis is shown in Figure 17.2. Following the bottom row of arrows from left to right in the figure, behavior under risk can manifest independently of the associated probabilities and outcomes. Indeed the top two channels in the figure show that behavior can arise under a combination of outcomes and emotions (ignoring probabilities) or probabilities and emotions (ignoring outcomes). Each of these channels makes a prediction that cannot be made under traditional models of risk in economics.

The ability of individuals to form vivid images associated with risky outcomes, an ability that differs among individuals, can affect risky choices. For instance, individuals could underinsure themselves from risks that cannot be vividly imagined. Vividness may be enhanced by knowing someone who has suffered from the negative consequences of a risky situation. Thus, as noted above, individuals are less affected by statistics associated with risk and more affected by personal human stories of suffering that evoke greater emotion. However, inducing too much anxiety by, say, public information, may lead to avoidance of the relevant public information, forgoing the necessary risk mitigation activities, by some individuals. For instance, public information on the importance of self-examination to allow for early detection of breast cancer has led many women

to avoid the necessary self-examination, on account of the presence of anticipatory anxiety. Many empirical studies show that women are more risk averse than men. Women are also known to engage in better and more vivid imagery as compared to men. Perhaps women can feel more negative emotions associated with losses, hence, they appear to be relatively more risk averse.

Decision makers are often not very sensitive to variations in probabilities within a broad set of values. Hence, contrary to consequentialist models of risk, they typically do not react as much to changes in probability from, say, 1 in 100,000, to 1 in 1,000,000. In a large number of experiments in psychology, the probability of receiving an impending shock had little effect on anticipatory anxiety. By contrast, in the presence of pallid outcomes, say, losing \$20, the degree of sensitivity to probabilities is relatively higher. These sorts of considerations might explain why the *probability weighting function* (see Part 1 of the book) is relatively flat for mid-range probabilities and why the degree of flatness may depend on anticipatory anxiety.

One explanation for the high take-up rates of expensive warranties is that people do not pay adequate attention to the probability of breakdowns. They appear to think immediately of the “peace of mind” associated with the warranty, which is an anticipatory emotion. Indeed, salesmen rarely highlight probabilities of breakdown, and emphasize the convenience and peace of mind aspects of owning the warranty. Lottery sellers similarly appeal to anticipatory emotions when they use slogans such as “buy a dream.” We did not consider any of these issues in Part 1, neither has the economics profession given adequate attention to this line of research; clearly, it deserves more attention and respect.

17.3 Cue-conditioned behavior and habit formation

Visceral influences are typically activated by external stimuli or *cues* that heighten certain desires. The desire for consumption, in particular, can be enhanced by a number of cues; we will refer

to this as *cue-conditioned consumption*. For instance, the smell of freshly made cookies might create a craving for them. Cue-conditioned consumption, like visceral influences, is not specific to humans. In a famous experiment, conducted more than a century ago, Pavlov (1904) found that if bells are rung at the same time as food is given to a dog, after some period of conditioning, the ringing of bells alone is sufficient to produce salivation in the dog.

Cues can be individual-specific, for instance, the desire for a particular food might be conditioned on the cue being a rainy day. But some cues apply to most of us, perhaps because these have been acquired through a common evolutionary history. For instance, the desire for immediate consumption is heightened by the smell and sight of food. This *current-bias* for consumption does not arise through time discounting (e.g., hyperbolic discounting) but through the proximity of a cue that acts as an external stimulus.

Furthermore, cues often increase the marginal utility from consumption. So, for instance, the smell of baking cookies whets the appetite for them. Cues might also trigger physiological compensatory mechanisms in the body. So, for instance, cues might offset the harmful effects of a drug. For that reason, addicts often need increasingly larger amounts of a drug to get the same “kick.”

Laibson (2001) formalizes the effect of cues on habit forming behavior. This model is also useful to illustrate the rational addiction model of Becker and Murphy (1988, 1993). Laibson describes the central premise of his theory as follows. “The cues model in the current paper captures these patterns by assuming that habit formation effects are turned on and off by the presence of cues (i.e. sensory inputs) that have been associated with past consumption of habit-forming goods.” Unlike the second premise of the visceral influences model in Section 17.2.1, it is assumed here (as also in Becker and Murphy, 1988) that individuals make a rational decision to be addicted to, or abstain from, a particular habit forming activity. Thus, the cues model can be thought of as one formalization of the first premise of the visceral influences model in Section 17.2.1.

Suppose that time is discrete, so $t = 0, 1, 2, \dots$. The individual lives infinitely and uses exponential discounting. In each period, the individual chooses one from two possible activities. A *primary activity*, or activity 1, that is potentially habit forming, and a *secondary activity*, or activity 0, that is not habit forming; the activity set is denoted by $a = \{0, 1\}$.

Before choosing the activity, the individual observes a *cue* that has no economic significance; i.e., the cues are neutral. Ex-ante, the cue is random and takes on one of two discrete values, Red or Green. The probability distribution of the cues is given by:

$$\Pr(\text{Red}) = \mu^R \geq 0, \Pr(\text{Green}) = \mu^G \geq 0, \text{ and } \mu^G + \mu^R = 1. \quad (17.1)$$

In any period t , the individual observes the cue and then makes a choice from the set a . Denote the cue-conditioned choice by $a_t^j = \{0, 1\}$ when the individual observes the cue $j = \text{Red, Green}$. So, for instance, the pair of choices $(a_t^R = 1, a_t^G = 0)$ means that in period t , the individual undertakes the primary activity only when the cue is Red. We wish to determine the optimal temporal sequence of actions $(a_0^R, a_0^G), (a_1^R, a_1^G), (a_2^R, a_2^G), \dots$

The utility function is influenced by two *stock variables*, or *compensatory processes*, each activated in any given period by the realization of the cue. Denote these compensatory processes in period t by x_t^R, x_t^G ; these variables are of the nature of stocks. The Red cue only activates the x_t^R process, while the green cue only activates the x_t^G process. An unactivated process, in any period, experiences no change in value. In particular, the evolution of the two processes is given by the following two equations:

$$\begin{cases} x_{t+1}^R = \theta x_t^R + (1 - \theta) a_t^R; & x_{t+1}^G = x_t^G, & \text{if period } t \text{ cue is Red} \\ x_{t+1}^G = \theta x_t^G + (1 - \theta) a_t^G; & x_{t+1}^R = x_t^R, & \text{if period } t \text{ cue is Green} \end{cases}, 0 < \theta < 1. \quad (17.2)$$

Hence, the activated process at time $t + 1$ is a convex combination of the time t stock and the decision. The initial values of the stock variables are denoted by $x_0^R \in [0, 1]$, $x_0^G \in [0, 1]$, and are given exogenously. Since $a_t^j = \{0, 1\}$, $x_{t+1}^j \in [0, 1]$ for all t .

Like the stock variables, the instantaneous utility is also cue-contingent. The utility of the alternative activity, activity 0, is normalized at $\bar{u}$. The stochastic cues trigger a change in preferences. The instantaneous utility in period t , following the two cues is given by

$$U_t(a_t^j, x_t^j) = u(a_t^j - \gamma x_t^j) + (1 - a_t^j) \bar{u}; j = R, G, 0 < \gamma < 1. \quad (17.3)$$

Since $a_t^j = \{0, 1\}$, the utility from the alternative activity, $\bar{u}$, kicks in only when the individual chooses the alternative activity, i.e., $a_t^j = 0$. The function $u(a_t^j - \gamma x_t^j)$ is increasing, $u' > 0$, and strictly concave, $u'' < 0$; it reflects the instantaneous utility from the current decision, a_t^j , and from the stock of the primary activity, x_t^j .

To understand the nature of instantaneous utility, suppose that the primary activity is drug addiction.

1. A decision to consume drugs in the current period, $a_t^j = 1$, increases current utility, but at an opportunity cost of $\bar{u}$. If the individual has been consuming high levels of drugs in the past, then the stock variable x_t^j is high. Thus, current utility from consuming drugs is low, i.e.,

$$\frac{d}{dx_t^j} u(a_t^j - \gamma x_t^j) = -\gamma u' < 0. \quad (17.4)$$

2. Higher drug consumption in the past, reflected in an increase in the stock variable, x_t^j , increases the current marginal utility of consumption, i.e.,

$$\frac{d^2}{dx_t^j da_t^j} u(a_t^j - \gamma x_t^j) = -\gamma u'' > 0. \quad (17.5)$$

These features are standard in habit formation models. The individual chooses the time path of actions $(a_0^R, a_0^G), (a_1^R, a_1^G), (a_2^R, a_2^G), \dots$, where $a_t^j \in \{0, 1\}$, to maximize

$$\sum_{t=0}^{\infty} \delta^t [\mu^R [u(a_t^R - \gamma x_t^R) + (1 - a_t^R) \bar{u}] + \mu^G [u(a_t^G - \gamma x_t^G) + (1 - a_t^G) \bar{u}]],$$

subject to the evolution of the stock variables in (17.2); $\delta \in (0, 1]$ is the discount factor.

An early discussion of habit formation can be found in Duesenberry (1949) and a formalization is given in Pollack (1970). Becker and Murphy (1988) provided an additional impetus to this class of models. A discrete time version of the Becker–Murphy model can be recovered from the cues model in which the cue takes only one possible value, i.e., one of μ^R, μ^G is zero. This *no-cues*

model, and its solution, also helps gain insights into the solution to the cues model. For this reason, we turn to the no-cues model, next.

17.3.1 *Solution to the no-cues model*

Suppose that the cue takes only one possible value. Thus, we can omit the superscript $j = R, G$ that we used to distinguish between different values of the cues. The problem for an individual in the no-cues model is to choose the time path of cue-independent actions $(a_1, a_2, \dots)$, where $a_i \in \{0, 1\}$, in order to maximize

$$\sum_{t=0}^{\infty} \delta^t [u(a_t - \gamma x_t) + (1 - a_t) \bar{u}], \quad (17.6)$$

subject to the constraint

$$x_{t+1} = \theta x_t + (1 - \theta) a_t.$$

This is a standard problem in dynamic programming. The Bellman equation is written as

$$V(x | \delta) = \underset{a \in \{0,1\}}{\text{Max}} [u(a - \gamma x) + (1 - a) \bar{u} + \delta V(\theta x + (1 - \theta) a) | \delta]. \quad (17.7)$$

Let us motivate the solution through the following intuition. As the stock of habits increases, it has two opposing effects. (i) From (17.4), it reduces current and future utility. (ii) From (17.5), the marginal utility from undertaking the primary activity increases. From (i) and (ii) it follows intuitively that if the stock of habits is large enough, say, greater than some threshold value $\tilde{x}$, the second effect dominates in a marginal utility based calculation, so it is optimal to choose the primary activity $a = 1$. Otherwise, the secondary activity is chosen. We summarize this result in Proposition 17.1, below. The proof is not difficult but it is lengthy; an exercise asks for a proof of the problem and gives hints to solve it.

Proposition 17.1 (*Laibson; 2001*): *In the no-cues problem, there exists some threshold value of the stock variable, $\tilde{x}$, such that the optimal decision rule of the individual is*

$$a = \begin{cases} 1 & \text{if } x > \tilde{x} \\ 0 & \text{if } x < \tilde{x} \end{cases}.$$

When $x = \tilde{x}$, some sort of tie breaking rule can be used. Several comparative static results can be derived. The threshold value, $\tilde{x}$, is increasing in $\bar{u}$ and δ . An increase in the primary activity increases the future stock of habits, hence, it reduces future utility. An increase in δ makes this reduction of future utility more salient. Hence, the threshold $\tilde{x}$ must be larger for the primary activity to be undertaken. A higher value of $\bar{u}$ increases the relative utility of the alternative good, hence, the marginal utility of the primary good must be correspondingly higher. From (17.5) this occurs if the stock of habits is higher, hence, we need a higher threshold, $\tilde{x}$.

Example 17.1 (*The dynamic programming solution in a two-period model*): *Given the importance of the no-cues model for forming intuition about the solution of the cues model, consider a two-period example. Using (17.6), the individual wishes to maximize the intertemporal utility $U_1(a_1, x_1) + \delta U_2(a_2, x_2)$, or*

$$[u(a_1 - \gamma x_1) + (1 - a_1)\bar{u}] + \delta [u(a_2 - \gamma x_2) + (1 - a_2)\bar{u}] \quad (17.8)$$

subject to the constraint

$$x_2 = \theta x_1 + (1 - \theta)a_1, \text{ and } x_1 \text{ given.} \quad (17.9)$$

The problem of the decision maker is to choose $a_1 \in \{0, 1\}$ and $a_2 \in \{0, 1\}$. Let the utility function take the CARA form, so $u(c) = \frac{-b}{\alpha} e^{-\alpha c}$, $\alpha, b > 0$; since we are not fundamentally interested in the degree of curvature of the utility function, suppose $\alpha = 1$. Check that $u' > 0$ and $u'' < 0$ are satisfied. For pedagogical simplicity, let $\delta = 1$ so the individual does not discount future utility. Denote the optimal value of the action in any period by a_t^* , $t = 1, 2$. In the second period, the decision maker chooses a_2 , given x_2 . It is optimal to choose $a_2^* = 1$ if

$$-be^{-(1-\gamma x_2)} > -be^{\gamma x_2} + \bar{u}$$

or

$$x_2 > \tilde{x} = \frac{1}{\gamma} \ln \left(\frac{\bar{u}/b}{1 - e^{-1}} \right). \quad (17.10)$$

If the inequality in (17.10) is reversed, then $a_2^* = 0$. Clearly the threshold value $\tilde{x}$ is increasing in the outside option, $\bar{u}$, as claimed earlier. Suppose that the parameter values are

$$\gamma = 0.7, \bar{u} = 1, b = 1.25, \text{ and } \theta = 0.5. \quad (17.11)$$

Then (to three decimal places) $\tilde{x} = 0.423$, which gives the decision rule

$$a_2^* = \begin{cases} 1 & \text{if } x_2 > 0.423 \\ 0 & \text{if } x_2 < 0.423 \end{cases}. \quad (17.12)$$

The second period utility is $U_2(a_2^*, x_2) = -be^{-(a_2^* - \gamma x_2)} + (1 - a_2^*)\bar{u}$. Substituting x_2 from (17.9) in U_2 we get

$$U_2(a_2^*, \theta x_1 + (1 - \theta)a_1) = \begin{cases} -be^{-(1-\gamma(\theta x_1 + (1-\theta)a_1))} & \text{if } x_2 > 0.423 \\ -be^{\gamma(\theta x_1 + (1-\theta)a_1)} + \bar{u} & \text{if } x_2 < 0.423 \end{cases}. \quad (17.13)$$

The unconstrained first period optimization problem of the individual is

$$a_1^* \in \arg \max_{a_1 \in \{0, 1\}} -be^{-(a_1 - \gamma x_1)} + (1 - a_1)\bar{u} + U_2(a_2^*, \theta x_1 + (1 - \theta)a_1), \quad (17.14)$$

where x_1 is given exogenously, U_2 is given in (17.13), and the parameter values are given in (17.11).

I. The simplest case arises when the initial stock of habits is $x_1 = 0$. Using (17.9),

$$x_2 = \begin{cases} 0.5 & \text{if } a_1 = 1 \\ 0 & \text{if } a_1 = 0 \end{cases}. \quad (17.15)$$

From (17.12) and (17.15), if the individual chooses $a_1 = 1$, then it is optimal to choose $a_2^* = 1$, otherwise if $a_1 = 0$, then the optimal second period choice is $a_2^* = 0$.

If the individual chooses $a_1 = 1$, then, using the parameter values in (17.11), his utility is $-(1.25)e^{-1} - (1.25)e^{-(1-0.7(0.5))} = -1.1124$. If he chooses $a_1 = 0$, his utility is $-(1.25)e^{-0} +$

$1 - (1.25)e^0 + 1 = -0.5$. Hence, $a_1^* = 0$. In summary, when $x_1 = 0$ and given the parameters values in (17.11), the optimal dynamic programming solution is $(a_1^*, a_2^*) = (0, 0)$.

II. Suppose at the other extreme that the initial stock of habits is high, $x_1 = 1$. In this case, for any of the two choices, $a_1 \in \{0, 1\}$, we have $x_2 \geq 0.5$, so, from (17.12), $a_2^* = 1$. Thus, irrespective of the first period choice of the individual, the second period action is identical. By choosing $a_1 = 1$, the decision maker's utility is

$$- (1.25)e^{-(1-0.7)} - (1.25)e^{-(1-0.7)} = -1.852, \quad (17.16)$$

while if he chooses $a_1 = 0$, the utility is

$$- (1.25)e^{-(0.7)} + 1 - (1.25)e^{-(1-0.7(0.5))} = -2.1697. \quad (17.17)$$

Hence, $a_1^* = 1$.

Thus, starting from a high enough stock of habits, the individual is more likely to undertake the action, say, drug consumption, in each period. However, starting from a low stock of habits, the individual is likely to refrain from drug consumption. In the case of smoking, the initial stock of drugs may well be determined by factors such as smoking in the peer group, or exposure to smoking at home. Hence, addiction to smoking may become an accident of history rather than a rational choice. ■

17.3.2 Solution to the cues model

The solutions to the model with and without cues are very similar because a given cue only activates one of the two compensatory processes or stock variables. The Bellman equation for the cues model is given by

$$W(x^R, x^G) = \frac{\mu^R}{1 - \delta\mu^G} V\left(x^R \mid \tilde{\delta} = \frac{\delta\mu^R}{1 - \delta\mu^G}\right) + \frac{\mu^G}{1 - \delta\mu^R} V\left(x^G \mid \tilde{\delta} = \frac{\delta\mu^G}{1 - \delta\mu^R}\right),$$

where $V(x \mid \tilde{\delta} = z)$ is the solution to the no-cues Bellman equation when the discount factor $\tilde{\delta}$ takes the value z and μ^R, μ^G are defined in (17.1). The solution in the presence of cues turns out to be a simple generalization of Proposition 17.1. We state this result in Proposition 17.2.

Proposition 17.2 (Laibson, 2001): *In the presence of cues, there exist threshold values $\tilde{x}^R$ and $\tilde{x}^G$ such that the optimal decision of the individual is given by*

$$a^R = \begin{cases} 1 & \text{if } x^R > \tilde{x}^R \\ 0 & \text{if } x^R < \tilde{x}^R \end{cases}$$

$$a^G = \begin{cases} 1 & \text{if } x^G > \tilde{x}^G \\ 0 & \text{if } x^G < \tilde{x}^G \end{cases}$$

As in Proposition 17.1, when $x^R = \tilde{x}^R$ or $x^G = \tilde{x}^G$, then some tie breaking rule can be used to determine the optimal action. As in the no-cues model, the threshold values are increasing in δ and $\bar{u}$. Figure 17.3, drawn in (x^R, x^G) space, shows the direction of evolution of the state variables for each possible value of the states.² The figure shows the threshold values $\tilde{x}^R, \tilde{x}^G$ that partition

² Despite the presence of discrete time, we have shown continuously differentiable phaselines for a clearer diagram.

Figure 17.3 Dynamics in the cue-dependent model.

the diagram into four quadrants, labeled, I–IV; arrows indicate the direction of motion in each quadrant. We also show the four steady states of the model, $(0, 0)$, $(1, 1)$, $(0, 1)$, $(1, 0)$, and one trajectory in each quadrant that converges to a steady state. The adjustment processes in (17.2) imply a gradual adjustment path, unless θ is close to its extreme values of zero or one.

The steady states $(0, 0)$ and $(1, 1)$ can be used to illustrate the dynamics in the no-cues Becker–Murphy model. At the steady state $(0, 0)$, the individual always undertakes the secondary activity ($a = 0$, no-addiction) because $x^R < \tilde{x}^R$ and $x^G < \tilde{x}^G$. At the steady state $(1, 1)$, the individual always undertakes the primary activity ($a = 1$, addiction), irrespective of the realization of the cue. These are the cue-independent history-dependent states, as shown in Example 17.1.

The other two steady states, $(0, 1)$, $(1, 0)$, are the cue-dependent states and illustrate the additional steady states that can arise once we allow for the introduction of cues. Consider quadrant I where $x^G < \tilde{x}^G$ and $x^R > \tilde{x}^R$; here the individual chooses the secondary activity ($a = 0$, no-addiction) if the cue is Green, and the primary activity ($a = 1$, addiction) when the cue is Red (see Proposition 17.2). The intuition follows from Example 17.1. If the stock of the primary activity is high enough, then the marginal utility from the primary activity is greater than the secondary activity, so the primary activity is preferred. At the steady state $(0, 1)$ the individual's action is also cue-dependent; choose the alternative activity if the cue is Red and the primary activity when the cue is Green.

The cues, however, are completely neutral and have no economic significance in the model. The theory, therefore, explains how neutral cues can come to form the basis of behavior, provided that the individual believes in them. One prediction of the model is that since the stochastic cues trigger a change in preferences (see (17.3)) individuals may check themselves into rehab centres in order to avoid the cravings associated with the cues. For this, one needs to invoke models of multiple selves or planner–doer models, in which the current self is more patient about future choices relative to the future selves.

In the Becker–Murphy model, once addicted, the individual rationally stays addicted forever. However, in the model with cues, the individual's consumption of a harmful good depends on the observed cues. In actual practice, we do observe that people engage in cue-management that

sometimes successfully controls consumption of the harmful good. At the same time, firms may wish to sell more by highlighting the salience of certain cues that induce individuals to consume their products, even if they are harmful.

Laibson (2001, pp. 107–8) gives examples of *cue-management behaviors* that include: hiding cigarettes, avoiding parties where alcohol will be served, and using the candy-free checkout lane. However, counter practices by firms include: installing hotel minibars in which snacks and alcohol are visible, even if the minibar has not been opened; generating artificial appetite-arousing food smells in supermarkets; packaging snack food in see-through containers; visually displaying dessert options in restaurants; and placing candy and gum in all checkout lanes to take advantage of impulse buying. Thus, an emotions-augmented account of the Becker–Murphy model gives a better explanation of several important aspects of human behavior.

This is not the only place in the book where we treat issues of addiction. Addiction can be explained through several channels. We explain it using present-biased preferences in Part 3 of the book (e.g., Gruber and Köszegi, 2001); using projection bias in Section 17.6; and using models of temptation utility in Section 17.7. Other than models of projection bias, individuals do not make mistakes; they simply make rational choices at each instant in time.

The possibility of mistakes in the presence of stochastic cues is considered by Bernheim and Rangel (2004). Stochastic cues are also a feature of the Laibson model, but the possibility of mistakes is not. An important difference in predictions between the Bernheim–Rangel model and the Laibson model is that in the former, individuals who wish to check into rehab centres fully appreciate that they will experience cravings for harmful goods. However, they hope that by checking into the rehab centres they will be able to control their actions in response to the cravings. In the Laibson model, individuals check in because they think they will be able to control their cravings by, say, avoiding the cues that give rise to the cravings.

None of the other models of addiction that we consider in this book, except for projection bias, allow for mistakes. In the presence of a projection bias, individuals might currently underappreciate the difficulty of kicking a future habit. Indeed, models of present-biased preferences and temptation utility assign no role to the empirically important phenomenon of cues either. Present-biased preferences, in addition, do not differentiate between addictive and non-addictive goods.

17.4 Anticipation and delay under certainty

The idea that anticipation about future outcomes gives rise to current utility, or *anticipal utility*, is not new in economics. It goes back to Bentham (1789) who placed anticipation of consumption on a footing similar to physical consumption in that they potentially impart pleasure and pain. These Benthamite ideas were applied further by Jevons (1905) who gave particular emphasis to the “memory of past events” and “anticipations of future events” in causing pleasure and pain. Anticipations may take the form of *anticipal pleasure* and *anticipal pain*, depending on whether the events cause *savoring* or *dread*. Anticipations may lead us to postpone consumption, as for instance, a dessert at the end of a meal. Indeed, we may exhibit negative discount rates for such cases.

Loewenstein (1987) provides a theoretical framework for anticipal utility under certainty that we now outline. Issues arising from uncertainty are considered in Section 17.5 below. Loewenstein reports the following experiment. Among other options (not reported here) students were asked how much they would pay now to (1) obtain a kiss from a movie star of their choice, and (2) avoid

Figure 17.4 Maximum payment as a proportion of current value to obtain/avoid outcomes at selected time delays.

receiving a non-lethal 110 volt shock. These events occurred at various time delays: 0, 3 hours, 24 hours, 3 days, 1 year, and 10 years. The results are shown in Figure 17.4.

The outcomes in Figure 17.4 are at odds with the prediction of the discounted utility (DU) model. Under positive discounting, the DU model predicts that the immediate occurrence of the pleasant event (kiss) would be most valued because the discounted value of the event occurring in the future is lower. However, subjects were willing to pay the most for the kiss to be delayed by three days, in line with the prediction of anticipatory utility. Anticipatory utility for a kiss exhibits a hump shaped pattern, peaking at three days.

Similarly, DU predicts that an unpleasant event (shock) should be delayed because the discounted value of a negative event is lower. In contrast, subjects found the unpleasant event more painful the longer the delay, hence, they were willing to pay more now to avoid shocks the later they were supposed to occur. The analogy is with the common preference of getting an aching tooth out earlier rather than later. Hence, individuals appear to prefer the unpleasant event to occur immediately to avoid the anticipatory pain of the event.

We now incorporate Jevon's *anticipatory pleasure* and *anticipatory pain* in a standard DU model. Consider an individual who, at some initial time t_0 , must decide to engage in a single act of consumption of one unit of a good at time $T > 0$. There are two kinds of utilities. The act of consumption at time T confers a utility v per period over periods $[T, T + L]$, $L > 0$, which occurs, for instance, for consumer durables. Thus, denoting the consumption utility experienced at time t by u_t^c we have

$$u_t^c = \begin{cases} v & T \leq t \leq T + L \\ 0 & \text{otherwise} \end{cases}. \quad (17.18)$$

We consider here the case of *anticipatory pleasure* and indicate later the implications arising from *anticipatory pain*. The consumer derives anticipatory utility, u_t^a , at time $t \in [t_0, T]$ from the *entire stream of consumption between time periods $T \leq t \leq T + L$* . Anticipatory utility arises prior to

the act of consumption, while consumption utility arises during the act of consumption. Hence, for times $T \leq t \leq T+L$ when the individual derives consumption utility, anticipal utility is zero. Conversely, during times $t_0 \leq t \leq T$ the individual derives anticipal utility but no consumption utility. Let $\alpha > 0$ be a measure of the anticipation or vividness of the consumption experience to follow, then

$$\begin{aligned} u_t^a &= \alpha \int_T^{T+L} e^{-\sigma(\tau-t)} v d\tau, \quad t_0 \leq t \leq T, \\ &= \frac{\alpha v}{\delta} e^{-\sigma(T-t)} (1 - e^{-\sigma L}). \end{aligned} \quad (17.19)$$

In (17.19), σ is the discount rate applicable to anticipated consumption; it need not equal the traditional discount rate r that applies to actual consumption (see (17.20)). From (17.19), we can make the following inferences that were noted by Jevons (1905).

$$\frac{\partial u_t^a}{\partial L} > 0, \quad \frac{\partial u_t^a}{\partial v} > 0, \quad \frac{\partial u_t^a}{\partial t} > 0, \quad \frac{\partial^2 u_t^a}{\partial t^2} > 0; \quad 0 \leq t \leq T.$$

Hence, instantaneous anticipal utility over $t \in [t_0, T]$ increases as one approaches the date of actual consumption. Moreover, it increases at an increasing rate. Think, for instance, about the approaching date of a long anticipated holiday. The future per-period enjoyment from the holiday, v , and the length of the holiday, L , also increase anticipal utility.

We can now combine the instantaneous consumption and anticipal utilities over the time interval $[t_0, T+L]$ into total intertemporal utility from the one-off consumption decision:

$$U = \int_{t_0}^T u_t^a e^{-rt} dt + \int_T^{T+L} u_t^c e^{-rt} dt, \quad (17.20)$$

where $r > 0$ is the conventional discount rate used in exponential discounting functions. Substituting (17.18) and (17.19) in (17.20) we get

$$U = \int_{t_0}^T \frac{\alpha v}{\delta} e^{-\sigma(T-t)} (1 - e^{-\sigma L}) e^{-rt} dt + \int_T^{T+L} v e^{-rt} dt. \quad (17.21)$$

Simplifying (17.21), we get

$$U = v \left[\frac{\alpha}{\sigma(\sigma - r)} (e^{-rT} - e^{-\sigma T}) (1 - e^{-\sigma L}) + \frac{1}{r} e^{-rT} (1 - e^{-rL}) \right]. \quad (17.22)$$

Will the consumer ever want to delay consumption, i.e., is the optimal starting date of consumption, T^* , greater than t_0 ? To answer this question, differentiate (17.22) with respect to T

$$\frac{\partial U}{\partial T} = v \left[\frac{\alpha (1 - e^{-\sigma L})}{\sigma(\sigma - r)} (\sigma e^{-\sigma T} - r e^{-rT}) - (1 - e^{-rL}) e^{-rT} \right]. \quad (17.23)$$

The first term in (17.23) gives the marginal benefit of anticipal utility (or savoring), while the second term captures the delay costs. In the absence of the first term, we get the classical outcome

under discounted utility, namely, that the individual should engage in immediate consumption of goods that give anticipal pleasure.

Suppose that $t_0 = 0$. If $\frac{\partial U}{\partial T}\big|_{T=0} > 0$, then the individual will like to defer consumption from the present date. Using (17.23), we have

$$\frac{\partial U}{\partial T}\bigg|_{T=0} = v \left[\frac{\alpha}{\sigma} (1 - e^{-\sigma L}) - (1 - e^{-rL}) \right],$$

thus,

$$\frac{\partial U}{\partial T}\bigg|_{T=0} > 0 \Leftrightarrow \frac{\alpha}{\sigma} (1 - e^{-\sigma L}) > (1 - e^{-rL}). \quad (17.24)$$

From (17.24), factors conducive to delaying are: high α (greater salience of anticipal utility), and low σ (lower discounting of future anticipated outcomes). If condition (17.24) is met, then it can be shown that there is an optimal time for consumption $T^* > 0$ that maximizes the individual's utility. At this point, $\frac{\partial U}{\partial T}\big|_{T^*} = 0$ and $\frac{\partial^2 U}{\partial T^2}\big|_{T^*} < 0$. The outcome $T^* > 0$ immediately contradicts the predictions of the discounted utility model without anticipal considerations.

We leave the reader to derive the corresponding conditions in the case of unpleasant outcomes. Discounted utility theory predicts delayed consumption in this case, while the incorporation of anticipal utility opens up the possibility that the individual would like to speed up consumption.

17.5 Fear and anxiety under uncertainty

Several models consider ex-post disappointment in static models (Bell, 1985; Loomes and Sugden, 1986). Ex-post disappointment presupposes, however, that there must have been ex-ante hopefulness or anxiety about an event. Hence, the appropriate scope of such models would appear to be dynamic. The model in Section 17.4 considered feelings of anxiety under certainty. However, since anxiety is often caused by uncertainty about future events, we need a model that considers uncertainty explicitly. Caplin and Leahy (2001) provide one such model, within an expected utility framework, which they call *psychological expected utility*.

17.5.1 An outline of the framework

Consider a two-period model. We first present a brief outline of Caplin and Leahy's general framework and then deal with a concrete life-cycle example. Suppose that the set of psychological states in the two periods are vectors of real numbers $X_t \subseteq R^n$, $t = 1, 2$. Let $X = X_1 \times X_2$ be the Cartesian product of the two psychological states, and let $P(X)$ be the space of all probability distributions over X .

Example 17.2 Suppose that the emotional states are happiness, elation, and disappointment, denoted respectively by h , e , d . Let $X_1 = \{h\}$ and $X_2 = \{e, d\}$. The model requires us to put numerical values on these psychological states that are real numbers, so $h, e, d \in R$. Then we have $X = X_1 \times X_2 = \{(h, e), (h, d)\}$. Consider two illustrative probability distributions over X , $p, q \in P(X)$ such that $p = (p_1, p_2) = (0.3, 0.7)$ and $q = (q_1, q_2) = (0.5, 0.5)$.

Definition 17.1 We assume that $P(X)$ is a mixture space. Thus, for any $\lambda \in [0, 1]$ and any $p, q \in P(X)$ there exists an element $p\lambda q \in P(X)$ such that for any $x \in X$ we have $p\lambda q(x) = \lambda p(x) + (1 - \lambda)q(x)$.

The individual has preferences $\succeq$ that are defined directly over $P(X)$. We make the following standard assumptions on preferences that readers familiar with expected utility theory will easily relate to.

A1: $\succeq$ is complete and transitive.

A2: (Substitution axiom) For all $p, q, r \in P(X)$ and $\lambda \in [0, 1]$, $p \succeq q$ implies $p\lambda r \succeq q\lambda r$.

A3: Let $p, q, r \in P(X)$ such that $p \succeq q$ and $q \succeq r$. Then there exists numbers $\lambda_1, \lambda_2 \in [0, 1]$ such that $p\lambda_1 r \succeq q$ and $q \succeq p\lambda_2 r$.

A4: (Indifference) Let $p, q \in P(X)$ such that for any $x = (x_1, x_2)$, $p(x) = (p_1(x_1), p_2(x_1))$, and $q(x) = (q_1(x_1), q_2(x_1))$, where $p_t(x_t)$ and $q_t(x_t)$ are respective probabilities of the vector of psychological state x at time t (see Example 17.2). If $(p_1(x_1), p_2(x_1)) = (q_1(x_1), q_2(x_1))$ then $p \sim q$.

A5: (Continuity) Let $\lambda \in [0, 1]$ and $p, q \in P(X)$. Then, the sets $\{z : p\lambda q \succeq z\}$ and $\{z : z \succeq p\lambda q\}$ are closed.

Since preferences are defined directly on probability distributions over X , assumption A1 alone ensures that a utility representation exists.

Proposition 17.3 (Expected utility representation) Suppose that only assumption A1 holds. Then there exists a utility function $U: X \rightarrow \mathbb{R}$ such that for any $p, q \in P(X)$, if $p \succeq q$, then $E_p U \geq E_q U$, where $E_r U$ is the expected utility under the probability density $r \in P(X)$.

Example 17.3 In Example 17.2 suppose that $p \succeq q$. Then Proposition 17.3 implies that

$$E_p U \geq E_q U \Leftrightarrow 0.3u(h, e) + 0.7u(h, d) \geq 0.5u(h, e) + 0.5u(h, d). \quad (17.25)$$

Proposition 17.4 (Additive separability of the representation; Caplin and Leahy, 2001) Suppose that assumptions A1–A5 hold. Let $p, q \in P(X)$. Then the utility function in Proposition 17.3, U , takes an additive form, such that $U(x) = u_1(x_1) + u_2(x_2)$, where $u_t: X_t \rightarrow \mathbb{R}$ for $t = 1, 2$.

Example 17.4 Continuing with Example 17.3, the function u in (17.25) can be specialized to the form, $u(x_1, x_2) = u_1(x_1) + u_2(x_2)$.

The set of possible consumption levels (or prizes) in the two periods are monetary and given by $Z_t \subseteq \mathbb{R}^{n_t}$, $t = 1, 2$. In any period $t = 1, 2$ the psychological state X_t is realized immediately after a choice is made from the consumption set Z_t . Hence, there is no within-period anticipatory utility. Anxiety is caused by anticipation of future events, hence, there is no anxiety in the second period of a two-period model. To simplify the exposition, let the psychological and physical states coincide in period 2, i.e., $Z_2 = X_2$. However, in the first period, the realization of the psychological state $x_1 \in X_1$ depends on two factors.

1. The draw from the consumption set $z_1 \in Z_1$.
2. Uncertainty about the outcomes in the second period, Z_2 . In order to formalize the second effect, let l_2 be a probability distribution over Z_2 .

We can now use the framework of Kreps and Porteus (1978) to deal with *evolving uncertainty* that is implicit in this formulation. Let $Y_1 = Z_1 \times l_2$ and denote a typical element of Y_1 by

$y_1 = (z_1, l_2)$. Let l_1 be the space of all probability distributions over Y_1 . Following Kreps–Porteus, elements of l_1 are called *temporal lotteries*. Define a function $\phi : Y_1 \rightarrow Z_1 \times X_1$ that specifies how elements of the set Y_1 translate into first period consumption levels and psychological states at time $t = 1$.

Recalling that $Z_2 = X_2$, Caplin and Leahy then define the following utility function over temporal lotteries

$$V(y_1) = u_1[\phi(y_1)] + E_{l_2} u_2[x_2], y_1 \in Y_1, x_2 \in X_2. \quad (17.26)$$

Equation (17.26) looks like the standard time separable functional form. However, the innovation here is that the distribution, l_2 , over second period outcomes is included in the first period utility function. Hence, the anxiety created by anticipation of future uncertainty affects current utility. We now look at a specific example using (17.26).

17.5.2 *Life-cycle consumption, portfolio choice, and asset prices under anxiety*

As an application of the Caplin–Leahy framework, we now consider a two-period model of consumption-portfolio choice. In the first period, a representative consumer is endowed with e_1 units of a non-storable consumption good, and 1 unit each of N productive assets. A unit of each asset yields a random output equal to $s_i \in S_i$, $i = 1, \dots, N$ in terms of the second period consumption good. There are competitive markets and the competitively determined price of the i th asset in period 1, in terms of the consumption good, is p_i . The representative-agent nature of the model implies that the aggregate supply of each asset in the economy is unity as well.

The portfolio allocation problem in the first period is to choose the amount θ_i of the i th asset to buy, $i = 1, \dots, N$. The consumer's first period budget constraint is given by

$$c_1 + \sum_{i=1}^N \theta_i p_i = e_1 + \sum_{i=1}^N p_i. \quad (17.27)$$

The RHS of (17.27) is the representative consumer's first period income. It is the sum of income from the non-storable consumption good and income from ownership of the assets. The LHS is the total expenditure, which can be split into first period consumption c_1 and investment in a portfolio of N assets. Given the definition of p_i , the units on both sides of (17.27) are in terms of the first period consumption good.

Second period income is the sum of incomes from investments in each of the N assets made in period 1. Income from the i th asset in the second period is $\theta_i s_i$, which is a random variable because s_i is random. Hence, second period consumption, c_2 , is bounded above by the random second period income $\sum_{i=1}^N \theta_i s_i$.

In terms of the notation in Section 17.5.1, we proceed as follows. Define the physical prizes in each period to be identical to the consumption in that period, so $Z_1, Z_2 \subseteq R$ and $c_t \in Z_t$, $t = 1, 2$. Thus, a typical element of Z_2 , depending on the realization of the random terms $s_i \in S_i$, is given by

$$c_2 \equiv z_2 = \sum_{i=1}^N \theta_i s_i. \quad (17.28)$$

On account of the randomness in returns, s_i , from the perspective of period 1, c_2 is random. Furthermore, each portfolio choice, $\theta = (\theta_1, \theta_2, \dots, \theta_N)$, assumed to belong to a compact set, Θ , alters the moments of this random variable. Insofar as uncertainty about the second period creates anxiety in the first, each portfolio choice is associated with a possibly different level of anxiety.

Define l_2 as the probability distribution over Z_2 . From (17.28), second period outcomes depend on θ , so it is more illustrative to write $l_2 = l_2(\theta)$. The space of *temporal lotteries* is the set of pairs $y_1 = (c_1, l_2)$. The psychological state in period 1 can now be found by using the function $\phi : Y_1 \rightarrow Z_1 \times X_1$. Let us assume a particular function, $\phi(y_1) = (c_1, a(l_2))$, where $a(l_2)$ is assumed to be a differentiable function of l_2 that captures the anxiety associated with a distribution l_2 over second period outcomes and $c_1 \in Z_1$. Noting the dependence of l_2 on θ we may write $\tilde{a}(\theta) = a(l_2(\theta))$. The temporal expected utility in (17.26) now takes the form

$$V(c_1, l_2) = u_1(c_1, \tilde{a}(\theta)) + \beta E_{l_2} u_2(c_2). \quad (17.29)$$

Substituting (17.27), (17.28) in (17.29), the unconstrained problem of the consumer is

$$\theta^* \in \arg \max_{\theta \in \Theta} u_1 \left(e_1 + \sum_{i=1}^N p_i - \sum_{i=1}^N \theta_i p_i, \tilde{a}(\theta) \right) + \beta E_{l_2} u_2 \left(\sum_{i=1}^N \theta_i s_i \right). \quad (17.30)$$

The first order condition for an interior solution is

$$-p_i \frac{\partial u_1}{\partial c_1} + \frac{\partial u_1}{\partial \tilde{a}} \frac{\partial \tilde{a}}{\partial \theta_i} + \beta E_{l_2} s_i \frac{\partial u_2}{\partial c_2} = 0; i = 1, 2, \dots, N. \quad (17.31)$$

The condition (17.31) is a standard Euler equation with the addition of an extra term (the second term) to account for anxiety. This is an arbitrage condition that illustrates the trade-off from reducing first period consumption by a unit (first term) and purchasing an extra unit of the i th asset that gives a random return s_i in the second period (third term). The second term captures the marginal effect of anxiety on first period utility that arises from the purchase of an extra unit of the i th asset.

Each asset is in fixed supply of one unit. Competitive market clearing ensures that the price of the i th asset, p_i , adjusts so as to clear the market for the asset. Given that we have a representative agent model, market clearing of the one unit implies

$$\theta_i^* = 1, i = 1, 2, \dots, N, \quad (17.32)$$

or $\theta^* = \mathbf{1}$, where $\mathbf{1}$ is a vector of ones, so $\tilde{a}(\theta^*) = \tilde{a}(\mathbf{1})$. Substituting $\theta_i^* = 1$ in (17.27) we get the optimal consumption as

$$c_1^* = e_1. \quad (17.33)$$

Substituting $\theta_i^* = 1$ in (17.28), we get

$$c_2 = \sum_{i=1}^N s_i. \quad (17.34)$$

Substituting (17.32), (17.33), (17.34) in (17.31), the price of the i th asset can be solved out as

$$p_i^* = \frac{1}{\frac{\partial u_1(e_1, \tilde{a}(1))}{\partial c_1}} \left[\frac{\partial u_1(e_1, \tilde{a}(1))}{\partial \tilde{a}} \frac{\partial \tilde{a}(1)}{\partial \theta_i} + \beta E_{l_2} s_i \frac{\partial u_2\left(\sum_{i=1}^N s_i\right)}{\partial c_2} \right]. \quad (17.35)$$

Anxiety is *aversive*, so $\frac{\partial u_1(e_1, \tilde{a}(1))}{\partial \tilde{a}} < 0$. Note that in the absence of anxiety we get $\frac{\partial u_1(e_1, \tilde{a}(1))}{\partial \tilde{a}} = 0$. Since $\frac{\partial u_1}{\partial c_1} > 0$, we immediately get our first result.

Proposition 17.5 *Anxiety alters the price of assets. If (i) $\frac{\partial \tilde{a}(1)}{\partial \theta_i} > 0$, then the price of the asset is relatively lower as compared to the no-anxiety case and the expected rate of return is higher, and if (ii) $\frac{\partial \tilde{a}(1)}{\partial \theta_i} < 0$, then the price of the asset is relatively higher as compared to the no-anxiety case and the expected rate of return is lower.*

The formula in (17.35) depends on $\frac{\partial \tilde{a}(1)}{\partial \theta_i}$. Consider the following mean-variance functional form for anxiety,

$$a(l_2) = -\alpha E_{l_2} c_2 + \gamma \text{Var}_{l_2}(c_2), \alpha > 0, \gamma > 0. \quad (17.36)$$

Hence, anxiety from investment in any vector of assets is increasing in the variance of second period consumption and decreasing in the average level of second period consumption. Using (17.28) we get

$$\text{Var}_{l_2}(c_2) = \sum_{i=1}^N \theta_i^2 \text{Var}(s_i) + \sum_{i=1}^N \sum_{j=1, j \neq i}^N \theta_i \theta_j \text{Cov}(s_i, s_j). \quad (17.37)$$

$$E_{l_2}(c_2) = \sum_{i=1}^N \theta_i E_{l_2}(s_i).$$

Hence, it follows that

$$\frac{\partial \text{Var}_{l_2}(c_2)}{\partial \theta_i} = 2 \left(\theta_i \text{Var}(s_i) + \sum_{j=1, j \neq i}^N \theta_j \text{Cov}(s_i, s_j) \right) = 2 \text{Cov}(c_2, s_i). \quad (17.38)$$

$$\frac{\partial E_{l_2}(c_2)}{\partial \theta_i} = E_{l_2}(s_i). \quad (17.39)$$

Using (17.36), (17.38), (17.39) we get

$$\frac{\partial \tilde{a}(1)}{\partial \theta_i} = -\alpha E_{l_2}(s_i) + 2\gamma \text{Cov}(c_2, s_i). \quad (17.40)$$

Substituting (17.40) in (17.35), we can now derive the prices of the N assets in terms of the fundamentals. For $i = 1, \dots, N$, the optimal asset price is

$$p_i^* = \frac{1}{\frac{\partial u_1(e_1, \tilde{a}(1))}{\partial c_1}} \left[\frac{\partial u_1(e_1, \tilde{a}(1))}{\partial \tilde{a}} \left[-\alpha E_{l_2}(s_i) + 2\gamma \text{Cov}(c_2, s_i) \right] + \beta E_{l_2} s_i \frac{\partial u_2\left(\sum_{i=1}^N s_i\right)}{\partial c_2} \right]. \quad (17.41)$$

Suppose that the i th asset is riskless, so $\text{Cov}(c_2, s_i) = 0$, hence, $\frac{\partial \tilde{a}(1)}{\partial \theta_i} = -\alpha E_{l_2}(s_i) < 0$ because a riskless asset would be held in the portfolio only if its expected return, $E_{l_2}(s_i)$, is positive. The next proposition directly follows from Proposition 17.5.

Proposition 17.6 *For a riskless asset, the price of the asset under anxiety is relatively higher and so the expected rate of return is relatively lower.*

In the presence of anxiety, by investing in a riskless asset, the investor is purchasing “peace of mind” so he is prepared to pay a relatively higher price as compared to the no-anxiety case. On the other hand, stocks are risky and the fluctuations in their returns causes anxiety. So their purchase is likely to (i) increase the expected value, which is anxiety reducing, and (ii) increase the variance of second period consumption, which is anxiety enhancing. From (17.40), the trade-off between risk and return on the level of anxiety depends on the relative magnitudes of α and γ and the underlying probabilistic structure. The next result directly follows from these observations and Proposition 17.5.

Proposition 17.7 *Suppose that γ is relatively large as compared to α .*

- (i) *If $\text{Cov}(c_2, s_i) < 0$, then $\frac{\partial \tilde{a}(1)}{\partial \theta_i} < 0$, so the price of the asset under anxiety is relatively higher and the expected rate of return is lower*
- (ii) *If $\text{Cov}(c_2, s_i) > 0$, then $\frac{\partial \tilde{a}(1)}{\partial \theta_i} > 0$. In this case, the price of the risky asset under anxiety is relatively lower and so the expected rate of return is relatively higher.*

Proposition 17.7(ii), which is the psychologically more interesting case, shows that the ownership of a risky stock creates anxiety, which reduces its price and increases its return relative to the no-anxiety case. This provides one possible explanation for the *equity premium puzzle* that we consider in more detail in Parts 1 and 7 of the book. The equity premium puzzle refers to the gap between returns on equities and bonds that cannot be explained by differences in the risk characteristics of the two financial assets.

One may distinguish between anxiety and risk aversion. Anxiety is an anticipatory feeling that arises before the resolution of an event, while under expected utility, risk aversion is a property of the curvature of the utility function. By considering risk aversion in the absence of anxiety, traditional measures of risk aversion might be partially capturing anxiety.

There are several other applications of the Caplin–Leahy framework. For an application to the revelation of information by a concerned party to an uninformed party, see Caplin and Leahy (2004). An example of this setting is a doctor who considers revealing information about a life threatening condition to two kinds of patients. An information-avoiding patient who avoids anxiety by shunning new information and an information-seeking patient who seeks information to lower anxiety (e.g., to rule out potentially worse possibilities). The natural vehicle of analysis for such a model is psychological game theory that we develop in Part 4 of the book. Caplin and Eliaz (2003) consider the possibility that individuals may be put off by the anxiety of a positive test result and, therefore, avoid AIDS testing. They embed the Kreps–Porteus preferences used above, into a mechanism design approach to propose an optimal mechanism that encourages testing and reducing the incidence of the disease.

17.6 Projection bias

Projection bias arises when individuals make predictions of their future tastes that are disproportionately influenced by their current tastes and are typically not realized in equilibrium. Consider the following examples.

Example 17.5 *Smith et al. (2008) asked patients awaiting a kidney transplant to predict their quality of life in a year’s time if they did or did not receive the transplant. The subjects*

were then followed up a year later and asked to report on their actual quality of life. The predictions failed systematically. The quality of life predicted by patients who received (did not receive) the transplant was lower (higher) relative to the actual quality of life.

Example 17.6 When ordering food at the beginning of a meal, we must predict how hungry we will be at the end of the meal. We often overestimate our future hunger and order more than we can eat. Furthermore, shopping on an empty stomach leads people to buy more (Gilbert et al., 2002). When making the decision to smoke, an individual must predict how the future desire for smoking will be affected. An underappreciation of the future desire by smokers often leads to greater current overconsumption.

Example 17.7 Read and van Leeuwen (1998) asked office workers to choose among healthy and unhealthy snacks to be received in a week's time. When asked to make this decision, office workers were in one of two possible states. In the hungry state, the question was posed just before lunchtime, and subjects were more likely to choose the unhealthy snack. However, in the satiated state, the question was posed just after lunchtime, and subjects were more likely to choose the healthy snack. The authors conclude that subjects in a currently hungry state overestimate their future hunger; in contrast, satiated subjects underestimate future hunger. In other words, people project their current tastes onto future tastes.

What accounts for projection bias? Loewenstein et al. (2003) argue that the reason is twofold. First, the ability of humans to adapt to changes is remarkably good. Second, individuals underestimate the extent of their adaptation. The two main stylized facts about projection bias that we need for the moment are:

1. Individuals are able to predict the *direction* of taste changes.
2. Individuals under-appreciate the true *magnitude* (or absolute value) of the change.

Suppose that we measure the current hunger-state of an individual on a scale of 1 (very satiated) to 10 (very hungry). Assume that normally the individual experiences a hunger-state of about 5. Suppose that we consider individuals who are currently at the two extremes, 1 and 10, and ask them to predict their hunger-state in the future. The first stylized fact implies that both individuals will report future hunger-states in the direction of 5. However, the second stylized fact implies that they will underappreciate the full extent of the movement to 5. For instance, the very satiated individual may predict a future hunger-state of 3, while the very hungry individual may predict a hunger-state of 7.

The two stylized facts also provide a plausible explanation of the endowment effect. Before obtaining a mug, individuals are not adapted to owning the mug and underappreciate the satisfaction derived from its ownership, hence, they undervalue it. After obtaining the mug, individuals adapt to ownership but underappreciate how well they will adapt if they were to be deprived of it, hence, they overvalue it.

17.6.1 Preferences under projection bias

Suppose that an individual lives for T periods, $t = 1, 2, \dots, T$. The instantaneous utility in period t is given by $u(c_t, s_t)$, where c_t is consumption at time t and s_t is the state of the world at time t that reflects tastes of the individual. The set of possible states is $S \subset \mathbb{R}^n$. Given the current state, s_t , the individual's prediction of utility from consumption c and state $s_{t'}$ is given by $\tilde{u}(c, s_{t'} \mid s_t)$.

We now give a definition of projection bias that incorporates stylized facts 1 and 2.

Definition 17.2 (Loewenstein et al., 2003): An individual exhibits projection bias if for all c, s_t and $s_{t'}$ there exists $\alpha \in [0, 1]$ such that

$$\tilde{u}(c, s_{t'} | s_t) = \alpha u(c, s_t) + (1 - \alpha)u(c, s_{t'}); \alpha \in [0, 1]. \quad (17.42)$$

In Definition 17.2, the prediction of future utility is a linear combination of the current instantaneous utility and the actual instantaneous utility in the relevant state. The central feature is that current tastes, as reflected in s_t , affect one's prediction of future tastes. If $\alpha = 0$, then we have the classical case of no projection bias. When $\alpha = 1$, the individual has extreme projection bias and equates current tastes fully with future tastes. Intermediate values of α capture varying degrees of projection bias. In particular, for $0 < \alpha < 1$, the individual accurately predicts the direction of change in tastes but underpredicts their magnitude.

Example 17.8 Consider two states of the world, hungry (state h), and not hungry (state n). Suppose that we have only one consumption good c and an identical consumption level in each period. Then we have the following four cases.

$$\tilde{u}(c, h | h) = \alpha u(c, h) + (1 - \alpha)u(c, h) = u(c, h). \quad (17.43)$$

$$\tilde{u}(c, n | h) = \alpha u(c, h) + (1 - \alpha)u(c, n). \quad (17.44)$$

$$\tilde{u}(c, n | n) = \alpha u(c, n) + (1 - \alpha)u(c, n) = u(c, n). \quad (17.45)$$

$$\tilde{u}(c, h | n) = \alpha u(c, n) + (1 - \alpha)u(c, h). \quad (17.46)$$

From (17.43), (17.45), there is no projection bias if the future and current states are identical. But from (17.44), (17.46) projection bias exists if $\alpha \neq 0$ and the two states differ. Suppose that

$$u(c, h) = 20, u(c, n) = 10, \alpha = 0.5,$$

then we have $\tilde{u}(c, n | h) = \tilde{u}(c, h | n) = 15$. If the current state is n and the future state is h , then the change in predicted utility is 5. Reversing the states, the change in predicted utility is -5 . In each case, the direction of change is correct (stylized fact 1), but the absolute value of the change is $5 < 10$. However, in the absence of projection bias, the absolute value of the change is 10. Hence, in each case, the magnitude of the change is underappreciated (stylized fact 2).

In writing down the individual's intertemporal preferences in the presence of projection bias, there are two polar cases to consider.

1. The individual has complete foresight about the entire future temporal path of states $s_1, s_2, \dots, s_T$: In this case, the intertemporal utility at date $t = 1$ is given by

$$U(c_1, c_2, \dots, c_T | s_1) = u(c_1, s_1) + \sum_{\tau=2}^{\tau=T} \delta^{\tau-1} \tilde{u}(c_\tau, s_\tau | s_1), \quad (17.47)$$

where δ is the discount factor and $\tilde{u}$ is defined in (17.42).

2. There is uncertainty over the future states: Denote by E_1 , the expectation operator taken at date 1, over the relevant probability distribution over future states. Then, the expected intertemporal utility is given by

$$E_1 U(c_1, c_2, \dots, c_T | s_1) = u(c_1, s_1) + E_1 \sum_{\tau=2}^{\tau=T} \delta^{\tau-1} \tilde{u}(c_\tau, s_\tau | s_1). \quad (17.48)$$

Time inconsistency problems can arise when individuals have projection bias because the prediction of individuals about their future tastes will often not be realized. For instance, in (17.44), (17.46) $\tilde{u}(c, n | h) \neq u(c, n)$ and $\tilde{u}(c, h | n) \neq u(c, h)$. Since the projection bias arises from a mis-prediction, individuals would not know it (for otherwise they could easily correct it by setting $\alpha = 0$). Hence, individuals perceive preferences to be time consistent but they are not. The model does not address possible learning by individuals when predictions do not come out to be true. In other words, individuals are unaware that they might be making systematic forecasting errors. This does typically arise when humans are hardwired to engage in certain behaviors; considerable cognitive effort and practice are needed to shed such behaviors.

17.6.2 *Habit formation, life-cycle consumption, and projection bias*

Consider a consumer with projection bias who, at time $t = 1$, allocates a given initial income Y over T periods. For pedagogical simplicity, there is no uncertainty, the discount factor $\delta = 1$, and the interest rate is zero. The actual instantaneous utility of the consumer at time t is given by $u(c_t, s_t)$, where c_t is consumption and s_t is the state of the world at time t . Preferences are of the habit formation type, i.e.,

$$u(c_t, s_t) = v(c_t - s_t), v' > 0, v'' < 0. \quad (17.49)$$

s_t is a stock of habits that evolves in the following manner

$$s_{t+1} = (1 - \lambda)s_t + \lambda c_t; \lambda \in (0, 1]. \quad (17.50)$$

Current consumption adds to the habit stock, and the initial state, $s_1 > 0$, is given.

Solving (17.50) recursively, we get

$$s_{t+1} = (1 - \lambda)^t s_1 + \lambda c_t + \lambda (1 - \lambda)^1 c_{t-1} + \lambda (1 - \lambda)^2 c_{t-2} + \dots + \lambda (1 - \lambda)^{t-1} c_1. \quad (17.51)$$

This setup satisfies the following two standard features of the habit formation model.

1. Current consumption, by adding to the stock of habit, directly reduces utility in all future time periods. Using (17.49), (17.51) we get

$$\frac{\partial u(c_t, s_t)}{\partial c_{t-k}} = -\lambda (1 - \lambda)^{k-1} v'(c_t - s_t) < 0; k = 1, 2, \dots, t - 1. \quad (17.52)$$

Hence, one needs to consume ever greater amounts to get the same “kick” from a habit.

2. The marginal utility from current consumption is increasing in the current stock of habits because

$$\frac{\partial}{\partial s_t} \left(\frac{\partial u(c_t, s_t)}{\partial c_t} \right) = -v''(c_t - s_t) > 0. \quad (17.53)$$

Given (17.42), (17.47), (17.49), the consumer's optimization problem at time $t = 1$ is to choose $c_1, c_2, \dots, c_T$ in order to maximize

$$U(c_1, c_2, \dots, c_T | s_1) = v(c_1 - s_1) + \sum_{\tau=2}^{\tau=T} [\alpha v(c_\tau - s_1) + (1 - \alpha)v(c_\tau - s_\tau)], \quad (17.54)$$

subject to the equation of motion for the stock variable (17.50), which we rewrite as

$$s_{t+1} - s_t = \lambda(c_t - s_t); \text{ given } s_1 > 0, \quad (17.55)$$

and the feasibility constraint that takes account of the assumption of zero interest rate,

$$\sum_{\tau=1}^{\tau=T} c_\tau \leq Y. \quad (17.56)$$

Denote the solution under no-projection bias ($\alpha = 0$), or the unbiased solution, by $c_1^u, c_2^u, \dots, c_T^u$, and the solution under projection bias ($\alpha > 0$), or the biased solution, by $c_1^b, c_2^b, \dots, c_T^b$. The qualitative features of the solution for the general case can be found in Loewenstein et al. (2003).³

We derive below the closed-form solution for an illustrative two-period model, $T = 2$, and assuming log preferences

$$v(c_t - s_t) = \ln(\theta + c_t - s_t); \theta = \max\{s_1, s_2\};$$

this ensures that $\theta + c_t - s_t > 0$, so we have a well-defined utility function with $v' > 0, v'' < 0$.

For $T = 2$, substituting s_2 from (17.55) and c_2 from (17.56) into (17.54), the consumer chooses c_1 to maximize the following concave utility function

$$\begin{aligned} U(c_1, c_2 | s_1) &= \ln(\theta + c_1 - s_1) + \alpha \ln[\theta + Y - c_1 - s_1] \\ &\quad + (1 - \alpha) \ln[\theta + Y - (1 + \lambda)c_1 - (1 - \lambda)s_1], \end{aligned}$$

given the initial state variable s_1 . We assume an interior solution throughout. The first order condition with respect to c_1 is

$$\frac{1}{\theta + c_1 - s_1} - \frac{\alpha}{\theta + Y - c_1 - s_1} - \frac{(1 - \alpha)(1 + \lambda)}{\theta + Y - (1 + \lambda)c_1 - (1 - \lambda)s_1} = 0. \quad (17.57)$$

Consider first, the absence of projection bias, so $\alpha = 0$. Evaluating (17.57) at $\alpha = 0$, the unbiased solution, c_1^u , is given by

$$c_1^u = \frac{1}{1 + \lambda} \left(\frac{\tilde{Y}}{2} + \lambda s_1 \right), \quad (17.58)$$

where

$$\tilde{Y} = Y - \lambda\theta.$$

³ The solution to the general case cannot be obtained by the usual optimal control method. The reason is that the presence of a habit stock variable does not allow one to reduce the system to a system of first order difference equations. What one would get, for instance, by eliminating the shadow prices, at any point t , is a system of two $t - 1$ order difference equations in c, s . Hence, the qualitative features of the solution can only be derived by using the method of induction.

We can rewrite (17.58) as $c_1^u = \frac{1}{1+\lambda} \left(\frac{\tilde{Y}}{2} - s_1 \right) + s_1$, so a sufficient condition for $c_1^u > s_1$ is that $\frac{\tilde{Y}}{2} > s_1$. We next show that when an individual consumes more than her stock of habits, then she consumes an increasing profile of consumption. This outcome occurs if the initial stock of habits is sufficiently small.

Proposition 17.8 Suppose that there is no projection bias. If $\frac{\tilde{Y}}{2} > s_1$ (or $c_1^u > s_1$), then $c_1^u < c_2^u$.

Proof: (a) Substituting (17.58) in (17.56). Then, for $T = 2$, the optimal solution for c_2^u is

$$c_2^u = c_1^u + \left(\frac{2\lambda}{1+\lambda} \right) (\tilde{Y} - 2s_1) + \lambda\theta. \quad (17.59)$$

From (17.58) we get

$$c_1^u - s_1 = \frac{1}{1+\lambda} \left(\frac{\tilde{Y}}{2} - s_1 \right). \quad (17.60)$$

From (17.60), $c_1^u > s_1 \Leftrightarrow \frac{\tilde{Y}}{2} > s_1$, which implies, from (17.59), that $c_2^u > c_1^u$. ■

Proposition 17.9 (Loewenstein et al., 2003): If $c_t^u > s_t$ for some t , then $c_t^u < c_{t+1}^u < c_{t+2}^u < \dots < c_T^u$.

From Proposition 17.8, we get the standard result in habit formation models that $s_1 = 0$ is a sufficient condition for an increasing profile of optimal consumption. By frontloading consumption, in this case, the stock of habits is raised early on, reducing the marginal utility of consumption in the subsequent periods. Hence, the opposite, planning an increasing profile of consumption, is optimal.

Let us now introduce the possibility of projection bias. The next proposition states the main result.

Proposition 17.10 Suppose $T = 2$ and there is projection bias ($\alpha > 0$). If $\frac{\tilde{Y}}{2} > s_1$ (so $c_1^u > s_1$), then $c_1^u < c_1^b$.

Proof: Implicitly differentiate (17.57) with respect to α

$$\frac{\partial c_1}{\partial \alpha} = \left(-\frac{\partial^2 U}{\partial c_1^2} \right)^{-1} \left(\frac{(1+\lambda)}{\theta + Y - (1+\lambda)c_1 - (1-\lambda)s_1} - \frac{1}{\theta + Y - c_1 - s_1} \right). \quad (17.61)$$

For $\frac{\partial c_1}{\partial \alpha} > 0$, we require that $\frac{(1+\lambda)}{\theta + Y - (1+\lambda)c_1 - (1-\lambda)s_1} > \frac{1}{\theta + Y - c_1 - s_1} \Leftrightarrow Y > 2s_1 - \theta$. But we know from Proposition 17.8 that the condition $\frac{\tilde{Y}}{2} > s_1$ ensures that $c_1^u > s_1$, and $\frac{\tilde{Y}}{2} > s_1 \Leftrightarrow Y > 2s_1 + \lambda\theta$. Clearly, in this case, $Y > 2s_1 - \theta$. Hence, if $\frac{\tilde{Y}}{2} > s_1$ (so $c_1^u > s_1$), then $\frac{\partial c_1}{\partial \alpha} > 0$. Since c_1^u corresponds to the optimal solution when $\alpha = 0$ and c_1^b corresponds to the optimal solution when $\alpha > 0$ it follows that $c_1^u < c_1^b$, as claimed. ■

The analogous result when there are T time periods is given in Proposition 17.11 below.

Proposition 17.11 (Loewenstein et al., 2003): If $c_1^u > s_1$ and $\alpha > 0$, then $\sum_{\tau=1}^t c_\tau^u < \sum_{\tau=1}^t c_\tau^b$ for $t < T$.

The intuition behind Proposition 17.10 is as follows. Projection bias implies an underappreciation of the magnitude of change. Here, the consumer underappreciates the effect of habit formation as well as the negative effect of the current stock on all future instantaneous utilities. Hence, relative to the unbiased case, the consumer with projection bias consumes too much. Therefore, a person with projection bias will consume her income “too quickly” relative to the optimal unbiased consumption profile. An important implication of this idea is that consumers might not save enough. This provides an alternative explanation of the savings inadequacy problem that does not rely on arguments of present-biased preferences (see Part 3 of the book).

17.6.3 *An application to consumer durables*

Suppose that a consumer can purchase one unit of a consumer durable at time $t = 1$ at some price P that provides a stream of utility $d_1, d_2, \dots, d_T$. The consumer’s “state” in any period is the utility in that period, i.e., $s_t = d_t$, $t = 1, \dots, T$. There is no discounting, so the discount factor $\delta = 0$. Suppose that the consumer buys the good in period 1. Then her true or unbiased utility (corresponding to $\alpha = 0$), U^u , is given by

$$U^u = \sum_{\tau=1}^{\tau=T} d_{\tau} - P = T\bar{d} - P, \quad (17.62)$$

where $\bar{d} = \frac{1}{T} \sum_{\tau=1}^{\tau=T} d_{\tau}$ is the mean, across time, of instantaneous utility.

The intertemporal utility of a consumer who has projection bias, U^b , at time $t = 1$, is given by

$$U^b = \sum_{\tau=1}^{\tau=T} [\alpha d_1 + (1 - \alpha) d_{\tau}] - P = T\bar{d} + \alpha T (d_1 - \bar{d}) - P. \quad (17.63)$$

Using (17.62), (17.63) it follows that

$$U^b \geq U^u \text{ if } d_1 \geq \bar{d}. \quad (17.64)$$

From (17.64), if $d_1 > \bar{d}$, then a consumer with projection bias may buy the consumer durable even if in the absence of projection bias he does not buy (e.g., if $T\bar{d} - P < 0$ and $T\bar{d} - P + \alpha T (d_1 - \bar{d}) > 0$). Hence, a person with projection bias may be too sensitive to her valuation at the time of purchase. Insofar as the valuation may be influenced by an emotional *hot state*, it plays a disproportionate role in the presence of projection bias.

Businesses might wish to exploit the tendency of consumers to buy in a *hot state*. They may induce such a state through sales hype, attractive displays, in-store music, and one-click shopping on the internet. Often salesmen will offer a discount, conditional on buying today, but the discount is not available if the purchase is delayed. Sellers might also try to turn non-durable goods into durable goods. So, for instance, they might sell an annual or bi-annual membership to a health club rather than a daily one.

DellaVigna and Malmendier (2002) provide evidence that people overpay for health club membership, by buying on an annual basis, relative to a “pay as you use” basis. One possible explanation is that people have self-control problems; once people sign up to a health club membership,

they procrastinate and do not fully use it (see Part 3 of the book). However, the explanation based on projection bias suggests that people overestimate their use of the membership because at the time of signing, they are in a hot state. In the future, they cool down as their enthusiasm wanes, and they underuse their membership. However, due to projection bias, individuals underpredict the extent to which they will cool down.

This has interesting implications for government policy. In the US and UK, for instance, “cooling-off” laws allow consumers to cancel their purchase within a certain number of days subsequent to the purchase. One interpretation of these laws is that they are designed to counter the effect of projection bias. Such laws can also alter the incentives of salespersons to mis-sell because they too wish to reduce costly returns of their products. Thus, salespersons are more likely to highlight longer-run implications of a purchase decision to the consumer that are more consistent with the cooler rather than the hotter end of the spectrum of human emotions.

17.6.4 *Other applications of projection bias*

Habit formation is a plausible hypothesis that is based on the psychological foundations of adaptation. However, evidence of habit formation is not readily available; but see Dynan (2000) for the experimental evidence. Projection bias suggests one explanation for why it might be hard to find evidence of such behavior, even if individuals exhibit it. Projection bias might lead people to underreact to habit formation. For instance, using (17.57), if the individual has extreme projection bias, say, $\alpha = 1$, then the individual’s optimal consumption profile is $c_1 = Y/2$, $c_2 = Y/2$ whether habit formation is present or absent. Hence, projection bias might mask the presence of habit formation even if it exists.

Projection bias might also explain why many pledges of charitable support are not eventually honored. This occurs particularly when a major disaster occurs that elicits a widespread feeling of empathy. If individuals make their pledges in a hot state, they overestimate their charitable urges in the future. One’s own future-selves might not honor the earlier pledge because they make decisions in a cooler state, once the immediate shock of the disaster lessens.

Habit formation models often find it difficult to explain why people develop harmful habits such as addiction in the first place.⁴ Projection bias provides two potential explanations. First, people underestimate the (negative) effect of current consumption on future utility. Second, individuals might under-appreciate the formation of the addictive habit.

The making of decisions in hot states that characterizes individuals with projection bias might also explain why some people get married without sufficient deliberation. Or why costly proposals to get married are sometimes reversed. Or why people undertake costly actions/commitments in moments of rage or extreme generosity. The existence of cooling-off periods could be one way of mitigating the harmful consequences of such actions. For instance, there are mandatory time intervals between filing for marriage or divorce.

Such decisions are, of course, irreversible for suicides. If individuals in a currently depressed state predict, on account of projection bias, that their future states are also likely to be similar, then their predicted lifetime discounted value of life is relatively lower. Hence, some individuals might, on the spur of the moment, make a disastrous and irreversible decision to end their life. Such individuals, if they are known to the social services, are typically closely monitored for the existence of such hot states.

⁴ See, however, Bernheim and Rangel (2004), above, who explain addiction as a mistake.

17.7 Temptation preferences: a revealed preference approach

Models of dual selves and models that consider the interaction between the emotional and the cognitive system in the brain rely on the premise that human behavior is the outcome of *brain modularity*. The primitives in such a model are the relevant modules in the brain and their interaction.

A more classical approach takes preferences as the relevant primitives and uses the revealed preference approach to recover the underlying preferences. In this approach, individuals face temptations but may either make *commitments* to eliminate them, or they might not be able to eliminate the temptations. There are two possibilities—individuals may either exercise *self-control*, or they may succumb to the temptations. This section considers these issues.

Consider two time periods. In the first period, the individual chooses from a set of *menus* and has preferences over menus given by $\succsim_1$. The items in the menu can be outcomes or, more generally, probability distributions over outcomes. In the second period, conditional on the chosen menu in the first period, the individual chooses items in the menu, based on second period preferences, $\succsim_2$. The underlying framework was introduced by Kreps and Porteus (1978).

Example 17.9 Consider two periods and two possible restaurants: A vegetarian restaurant, V , that sells healthy but bland food and a fast food restaurant, F , that sells unhealthy, but tempting food. In the first period, the individual needs to choose over three possible “menus”: $\{V\}$, $\{F\}$ and $\{V, F\}$. Menus are defined more formally below. For the moment, if menu $\{V\}$ (respectively $\{F\}$) is chosen in the first period, then, in the second period, the individual can only visit restaurant V (respectively restaurant F). If menu $\{V, F\}$ is chosen, then the individual can choose any of the two restaurants V or F in the second period. The first period preferences over menus are denoted by $\succsim_1$. In the second period, the individual can visit any of the restaurants in the chosen menu (if there is a single option on the menu, then the second period choice is trivial). Second period preferences over restaurants in the chosen menu are given by $\succsim_2$.

Option F is said to be a temptation if $\{V\} \succsim_1 \{V, F\}$. In this case, in the first period, the individual would like to commit to just choose option V rather than having to choose among options V and F in the second period. Conditional on the first period preferences $\{V\} \succsim_1 \{V, F\}$, suppose that the individual cannot commit to choosing $\{V\}$. In this case, in the second period, the individual faces a choice from the menu $\{V, F\}$. If the individual chooses F , he gives in to temptation, and if he chooses V , he is said to exercise self-control.

The seminal theoretical models that explore these issues are Gul and Pesendorfer (2001, 2004, 2005, 2007) and Dekel et al. (2001). In Example 17.9, temptation arises on account of second period preferences, $\succsim_2$. First period preferences may dictate a preference for commitment. Noor (2011) introduces the possibility that individuals might also be tempted by menus in the first period. For instance, the very fact that F is a tastier, although unhealthy, option may create a preference for the menu $\{V, F\}$ over the menu $\{V\}$. The subsequent discussion relies on Gul and Pesendorfer (2001), henceforth, GP.

17.7.1 The formal model

Consider a two-period model. Suppose that $C = \{c_1, c_2, \dots, c_n\}$ are the possible levels of consumption in period 2. Let ΔC be the set of probability distributions over C ; we denote typical

elements of ΔC by lowercase alphabets such as p, q, r . Thus, a typical element p in ΔC takes the form $p = (p_1, \dots, p_n)$, such that $\sum_{i=1}^n p_i = 1$, and $p_i \geq 0$ for all $i = 1, \dots, n$; the interpretation of p_i is the probability of consumption c_i .

Let Z be the set of all non-empty compact subsets of ΔC . The set Z comprises all possible menu of choices that, in period 1, the individual can choose from. We will typically denote elements of Z , or *menus*, as M_i, M_j, M_k , and so on. Denote the preferences of the individual over elements in the set Z , or his first period preferences, by $\succsim_1$. For instance, $M_i \succsim_1 M_j$ means that menu M_i is “at least as good as” M_j . The corresponding strict preference and indifference relations are given, respectively, by $\succ_1$ and $\sim_1$.

Suppose that the menu chosen in the first period is M_i . In the second period, the individual makes an optimal choice from M_i . An element $m_i \in M_i$ induces a second period lottery of the form $(c_1, p_1; \dots, c_n, p_n)$. Second stage preferences, $\succsim_2$, are defined over ΔC .

Define the following mixture operation over elements of the set Z . For any $M_i, M_j \in Z$ and $0 < \lambda < 1$ we have

$$\lambda M_i + (1 - \lambda)M_j = \{\lambda q + (1 - \lambda)p, \text{ where } q \in M_i, p \in M_j\}.$$

The binary preference relations $\succsim_1$ and $\succsim_2$ are the primitives of the model and they satisfy the following conditions for $M_i, M_j, M_k \in Z$.

- A1: (Preference relations) $\succsim_1$ and $\succsim_2$ are complete and transitive.
- A2: (Strong continuity) The sets $\{M_i \in Z : M_i \succsim_1 M_j\}$, $\{M_i \in Z : M_j \succsim_1 M_i\}$, and the set $\{p \in \Delta C : p \succsim_2 q\}$ are closed.
- A3: (Independence) If $M_i \succ_1 M_j$, then for all $0 < \lambda < 1$,

$$\lambda M_i + (1 - \lambda)M_k \succ_1 \lambda M_j + (1 - \lambda)M_k.$$

- A4: (Set betweenness) $M_i \succsim_1 M_j \Rightarrow M_i \succsim_1 M_i \cup M_j \succsim_1 M_j$.

Axioms A1–A3 are standard in economics and are used, for instance, in the axiomatic derivation of the expected utility formula. However, Fudenberg and Levine (2006) and Fudenberg (2006) argue that the independence axiom is less plausible when economic agents have self-control problems. They argue that the evidence that self-control is a scarce resource, which gets depleted with cognitive load is not consistent with the independence axiom.

The new axiom is *set betweenness* that we now explain in more detail by considering the following cases.

1. $M_i \sim_1 M_i \cup M_j \succ_1 M_j$: The preference $M_i \sim_1 M_i \cup M_j$ indicates that the preferred choice belongs to the set M_i . In this case, adding the option M_j to M_i is irrelevant. Hence, M_j is not a temptation.
2. $M_i \succ_1 M_i \cup M_j \sim_1 M_j$: From the first preference, the individual prefers M_i to the case where both M_i and M_j are available. Such an alternative, M_j , is termed as a *temptation*. From the second preference, when faced with a choice between elements of the sets $M_i \cup M_j$ and M_j the individual chooses an element from the set M_j . Hence, ex-ante the individual prefers to exclude the set M_j altogether from the available options. But, from the preference $M_i \cup M_j \sim_1 M_j$, if the option M_j is available, then the individual succumbs to the temptation.
3. $M_i \succ_1 M_i \cup M_j \succ_1 M_j$: The preference $M_i \succ_1 M_i \cup M_j$ reveals that M_j is a temptation. However, the preference $M_i \cup M_j \succ_1 M_j$ differentiates this from the previous case. In

this case, even when the option M_i and the temptation M_j are jointly available at the time of making the choice, the individual successfully resists the temptation, possibly by using some form of costly *self-control*.

To summarize, there are three possibilities. Either there is no temptation (case 1) or there is a temptation that cannot be resisted (case 2) or there is a temptation that can be successfully resisted (case 3).

We have made sufficient assumptions to ensure that utility functions exist that represent the preferences, $\succsim_1$ and $\succsim_2$.

Definition 17.3

- (i) A utility function $U : Z \rightarrow \mathbb{R}$ represents the first period preferences $\succsim_1$ if for $M_i, M_j \in Z$, $M_i \succsim_1 M_j \Leftrightarrow U(M_i) \geq U(M_j)$.
- (ii) A utility function $u : \Delta C \rightarrow \mathbb{R}$, sometimes called lottery utility, represents the second period preferences $\succsim_2$ if for $p, q \in \Delta C$, $p \succsim_2 q \Leftrightarrow u(p) \geq u(q)$. Furthermore, u is said to be linear if

$$u(\lambda p + (1 - \lambda)q) = \lambda u(p) + (1 - \lambda)u(q). \quad (17.65)$$

There is no difference between first stage and second stage preferences when the role of temptation preferences is ignored. In this case, the individual evaluates each menu $M_i \in Z$ by computing the expected utility, as in (17.65), for each element, $m_i \in M_i$ and then picking the element with the highest expected utility. This motivates the next definition.

Definition 17.4 (Classical preferences): Suppose that an individual satisfies the conditions on the utility function in Definition 17.3(ii). The individual has classical preferences if he proceeds as follows. (i) For each menu $M_j \in Z$, let $p_j^* \in \arg \max_{p \in M_j} u(p)$. (ii) Pick the menu, $M_k \in \arg \max_{M_j \in Z} u(p_j^*)$. In this case, the pair of preferences $(\succsim_1, \succsim_2)$ are called classical preferences.

It is obvious from Definition 17.4 that an individual who has classical preferences cannot be worse off by expanding the size of the menu. The reason is that at worse, the expected utility of all new items added to the menu will have an expected utility lower than the maximal element in the old menu. But then, the decision maker will simply not chose from any of the new elements in the menu. So, for classical preferences, we have the following condition

$$M_i \succ_1 M_j \Rightarrow M_i \cup M_j \sim_1 M_i. \quad (17.66)$$

We now introduce an axiom that connects first and second period preferences.

A5: If $M_i \cup \{p\} \succ_1 M_i$, then $p \succ_2 q$ for all $q \in M_i$.

Axiom A5, sometimes known as the *sophistication axiom* (see Lipman and Pesendorfer, 2013), requires that if the individual prefers to add an option p to a menu in M_i , then that option must be chosen in period 2. Axiom A5 is not always innocuous. For instance, firms may offer new contracts to existing customers (adding to their menus) in order to make existing contracts look more attractive, even when they know that such contracts will not be chosen.

We now state the main result in the absence of temptation preferences.

Proposition 17.12 (Classical preferences; Kreps, 1979; Gul and Pesendorfer, 2001): Suppose that the following conditions hold. (i) For all $M_i, M_j \in Z$, condition (17.66) holds. (ii)

Axioms 1–5 hold. Then $(\succsim_1, \succsim_2)$ are classical preferences. Furthermore, if $(\succsim_1, \succsim_2)$ are classical preferences, then conditions (i) and (ii) hold.

Once we depart from classical preferences and introduce the role of temptation, then the condition in (17.66) need not hold any longer. Indeed, we may have $M_i \succ_1 M_i \cup M_j$ so that individuals prefer to have a smaller set of choices in their menus in order to avoid temptation. The main result of GP can be stated in the following theorem.

Proposition 17.13 (Self-control preferences; Gul and Pesendorfer, 2001): *The preference relation $\succsim_1$ satisfies Axioms A1–A4, if and only if, there exists a utility function U satisfying Definition 17.3(i), and utility functions u and v satisfying Definition 17.3(ii) such that*

$$U(M) = \max_{p \in M} [u(p) + v(p)] - \max_{p \in M} v(p), \quad M \in Z. \quad (17.67)$$

We may call such preferences self-control preferences.

If preferences can be represented as in (17.67), we say that they have a (u, v) representation. Given below is a proof of Proposition 17.13, using the planner–doer framework in Bénabou and Pycia (2002). While the planner–doer framework is not in the tradition of the revealed preference framework, the proof shows nicely the potential relation between the two frameworks.

One of the problems at the end of the chapter asks you to show that the following proposition is true.

Proposition 17.14 *Classical preferences (Definition 17.4) are a special case of self-control preferences (see Proposition 17.13) if either (i) v is an affine transformation of u , i.e., $v = \alpha u + \beta$ for some $\alpha \geq 0$ and $\beta \in \mathbb{R}$, or (ii) u is a constant function. Furthermore, when v is a non-affine transformation of u , i.e., $v = \alpha u + \beta$ but $\alpha < 0$ and $\beta \in \mathbb{R}$, then the individual has a sole desire for commitment.*

Three main features underlie the GP framework.

B1: Suppose that the individual chooses the menu $M \in Z$ in period 1. The individual's preferences in the second period depend on tuples of the form (M, p) , where $p \in M$. In the second period, the individual's optimization problem is

$$\max_{p \in M} (u(p) + v(p)). \quad (17.68)$$

B2: Conditional on the chosen menu $M \in Z$ in period 1, suppose that the individual chooses some element $p^* \in M$ in the second period; this is the solution to (17.68). Then the first period utility of the individual is given by

$$U = u(p^*) + v(p^*) - \max_{p \in M} v(p). \quad (17.69)$$

From (17.68), the last term $\max_{p \in M} v(p)$ in (17.69) does not affect the actual choice made in the second period. It does, however, affect the individual's level of welfare. Temptation lowers the individual's utility. The second period preferences directly induce first period preferences over menus given in (17.67). In other words, in the first period, for each menu, $M \in Z$, the individual computes (17.69), and assigns a level of utility to it.

B3: In period 1, $M_i \succsim_1 M_j$ if and only if $U(M_i) \geq U(M_j)$.

Suppose that the individual chooses the menu $M \in Z$ in period 1. Denote by $p^* \in M$, the solution to the problem stated in (17.68). Suppose that p^* is unique and suppose that the individual could commit to a singleton menu $\{p^*\}$ in the first period. Using (17.69)

$$U(p^*) = u(p^*) + v(p^*) - v(p^*) = u(p^*). \quad (17.70)$$

For this reason, GP refer to u as the *commitment ordering over outcomes*. It represents the utility from singleton menus.

Now suppose that the individual were to choose a larger (non-singleton) set M of alternatives in period 1 that contains p^* . Suppose also that the individual is able to resist any potential temptations so that the chosen alternative is still p^* in the second period. Then, using (17.68), (17.69), (17.70), welfare loss to the individual is given by

$$U(p^*) - U(M) = u(p^*) - \left(u(p^*) + v(p^*) - \max_{p \in M} v(p) \right) = \max_{p \in M} v(p) - v(p^*). \quad (17.71)$$

Hence, the term $\max_{p \in M} v(p) - v(p^*)$ has the interpretation of *cost of self-control*. The more tempting the alternatives in the larger set M , the greater is the cost of self-control. For this reason GP, refer to $v(p)$ as the individual's *temptation ordering*.

Example 17.10 Consider two possible menus, $M_1 = \{p\}$ and $M_2 = \{p, q\}$. Suppose that

$$u(p) > u(q) \text{ and } v(q) > v(p). \quad (17.72)$$

We now show that the individual responds to temptation by choosing the smaller menu, M_1 , if commitment is possible. If commitment is not possible, and menu M_2 is chosen, then the individual must choose, in period 2, whether to give in to temptation or to exercise self-control. Using (17.70), we have $U(M_1) = u(p)$, while using (17.67), (17.72),

$$U(M_2) = \max \{ u(p) + v(p), u(q) + v(q) \} - v(q).$$

Consider now the following two cases.

I. Let $\max \{ u(p) + v(p), u(q) + v(q) \} = u(p) + v(p)$. In this case,

$$U(M_2) = u(p) - (v(q) - v(p)) < u(p) = U(M_1). \quad (17.73)$$

II. Let $\max \{ u(p) + v(p), u(q) + v(q) \} = u(q) + v(q)$. In this case,

$$U(M_2) = u(q) < u(p) = U(M_1). \quad (17.74)$$

Using (17.73), (17.74) we get $\{p\} \succ_1 \{p, q\}$, hence, q is a temptation. In (17.73), the individual can exercise self-control in period 2 and does not succumb to temptation. However, there is a cost of self-control, given by the term $v(q) - v(p)$. In (17.73), the individual succumbs to temptation. Indeed when preferences, $\succ_1$, have a (u, v) representation it can be shown that q tempts p in the sense $\{p\} \succ_1 \{p, q\}$ if and only if (17.72) holds.

Suppose that, in addition, a third menu $M_3 = \{q\}$ is available. In this case,

$$U(M_3) = u(q) < u(p) = U(M_1). \quad (17.75)$$

Of the two cases, I and II, considered above, let us focus only on case I:

Using (17.73) we have

$$U(M_2) \geq U(M_3) \Leftrightarrow u(p) - u(q) \geq v(q) - v(p).$$

The interesting case is the one where $u(p) - u(q) > v(q) - v(p)$, so that $U(M_2) > U(M_3)$. Hence, the overall picture in this case is

$$\{p\} \succ_1 \{p, q\} \succ_1 \{q\}. \quad (17.76)$$

Thus, q is a temptation and the individual successfully exercises self-control if presented with the menu M_2 . From (17.76), we get the main empirical prediction of this class of models. Namely, that an individual prefers to commit even when the individual will not engage in choice reversals. However, Lipman and Pesendorfer (2013) write: “We are unaware of any experimental or empirical study that seeks to document self-control.” Clearly this is an area that is in urgent need for empirical testing.

We now consider the invariance of GP preferences to affine transformations of commitment utility, u , and temptation utility, v .

Proposition 17.15 (Gul and Pesendorfer, 2001) Suppose that preferences, $\succ_1$, have a (u, v) representation (see Proposition 17.13). Suppose also that u, v are non-constant and v is not an affine transformation of u (see Proposition 17.14). Then $(\hat{u}, \hat{v})$ also represent the preferences $\succ_1$ if and only if there exist $\alpha > 0$ and $\beta_u, \beta_v \in \mathbb{R}$ such that $\hat{u} = \alpha u + \beta_u$ and $\hat{v} = \alpha v + \beta_v$.

A special case of temptation preferences arises in the context of time inconsistency (Strotz, 1955). These preferences, known as Strotz preferences, ensure that the long-run plans of the individual are time consistent. In a two-period model, the preferences prescribe the following lexicographic ordering. Begin with period 2, where some menu $M \in Z$ has already been chosen. The individual then maximizes temptation utility, v , over all elements in the menu M ; suppose that the maximal element is $p \in M$. Rolling back to the first period, the individual then assigns to the menu M , the number $u(p)$, where u is commitment utility. Finally, the individual chooses the menu with the maximal commitment utility. This is stated in the next definition.

Definition 17.5 (Strotz, 1955): Suppose that a preference pair $(\succsim_1, \succsim_2)$ can be represented by the following utility function:

1. For any first stage choice of $M \in Z$, and $p, q \in M$, $p \succsim_2 q$ if and only if the following lexicographic ordering holds

$$v(p) > v(q), \text{ or } v(p) = v(q) \text{ and } u(p) > u(q). \quad (17.77)$$

2. Looking ahead at the second period choice from any menu $M \in Z$, as given in (17.77), first period preferences $\succsim_1$, satisfy

$$U(M) := \max_{p \in M} u(p) \text{ such that } v(p) \geq v(q) \text{ for all } q \in M.$$

The preference pair $(\succsim_1, \succsim_2)$ so defined is said to be a Strotz pair or that $\succsim_1$ can be represented by a Strotz utility function.

Proposition 17.13 also holds for Strotz preferences. Thus, the binary relation $\succsim_1$ satisfies Axioms 1–4 if and only if it is a Strotz preference. Furthermore, a modified form of Proposition 17.15 also holds for Strotz preferences.⁵

⁵ The only difference is that we need separate values of α , say, $\alpha_u, \alpha_v > 0$ for, respectively, the utility functions $\hat{u}$ and $\hat{v}$; see Lipman and Pesendorfer (2013).

Example 17.11 (Lipman and Pesendorfer, 2013) Consider the following example of time inconsistent choices that is explained using quasi-hyperbolic discounting, or (β, δ) preferences, in Strotz (1955), Phelps and Pollak (1968), and Laibson (1997).⁶ Suppose that there are two time periods and $C = \{(c_1, c_2) \in [0, \bar{c}]^2\}$ where $\bar{c}$ is an upper bound on consumption in each period. Consider the following Strotz preferences (Definition 17.5):

$$\begin{cases} u(c_1, c_2) = w(c_1) + \delta w(c_2) \\ v(c_1, c_2) = w(c_1) + \beta \delta w(c_2) \end{cases}, \quad 0 < \beta < 1,$$

where u is commitment utility that applies to ex-ante choices in period 1, and v is temptation utility that applies to choices in period 2. Hence, in period 2, the individual will choose the consumption pair $(0, l)$ over $(s, 0)$ if $\beta \delta w(l) > w(s)$. In period 1, the individual must choose the optimal menu using commitment utility, u . He chooses the menu $M_1 = \{(0, l)\}$ over the menu $M_2 = \{(s, 0)\}$ if $\delta w(l) > w(s)$. Choice reversals occur if

$$\delta w(l) > w(s) > \beta \delta w(l).$$

Here commitment utility chooses $(0, l)$ over $(s, 0)$, and temptation utility chooses $(s, 0)$ over $(0, l)$, if presented with the menu $M_3 = \{(s, 0), (0, l)\}$. Faced with this possibility, in period 1 the individual might exercise self-control if it is not too costly, by choosing only the menu M_1 .

We refer the reader to the excellent survey by Lipman and Pesendorfer (2013) to pursue other developments in this literature. These include the idea that temptations might take the form of deliberate distortion in beliefs; see Epstein (2006), Epstein and Kopylov (2007), and Epstein et al. (2008). For instance, individuals might have a temptation to believe that a flood in the neighboring county will not cause them any flood risk, so that they can avoid buying insurance. Relative to the Bayesian benchmark, this model can lead to over reaction and under reaction to new information. For extensions to multiple periods, see Gul and Pesendorfer (2004) and Krussel et al. (2010).

17.7.2 Interpreting temptation preferences in a planner–doer framework

It is possible to derive GP preferences in the planner–doer framework in the tradition of Thaler and Shefrin (1981). This can help to provide a useful reinterpretation of the GP model. Bénabou and Pycia (2002) pursue this approach that we describe below.

Suppose there are two time periods and there is a long-lived planner (cognitive system) and a short-lived myopic doer (emotional system) in each period. The doer only cares about temptation utility, v , while the planner cares about the sum of commitment and temptation utility, i.e., $u + v$. We assume that u, v are strictly concave. As in the GP model, suppose that the individual chooses from some opportunity set, ΔC , which is a set of lotteries, in the first period. Conditional on a choice of M in the first period, there are two possibilities for the second period choice of an element in M , given by

$$\begin{cases} x \in \arg \max_{x' \in M} \{u(x') + v(x')\} & \text{if choice is made by planner.} \\ y \in \arg \max_{y' \in M} v(y') & \text{if choice is made by doer.} \end{cases} \quad (17.78)$$

⁶ This case is discussed at length in Part 3 of the book.

As in the Loewenstein and O'Donoghue (2004, 2007) model (see Section 18.2.2 below), we assume that the cognitive and the emotional systems simultaneously incur respective costs $r_c > 0$ and $r_e > 0$ to probabilistically influence the final outcome. The authors write (p. 423): "One can also think of the two subelves as lobbying the brain's motor control areas in the same way as interest groups lobby the government." The respective probabilities, p_c, p_e , that either of the cognitive and the emotional systems is decisive in making the final choice, are directly proportional to the resources expended, in the following manner.

$$p_c = \frac{r_c}{r_e + r_c}; p_e = \frac{r_e}{r_c + r_e}, \text{ and } p_c + p_e = 1. \quad (17.79)$$

We suppose that the costs r_c, r_e are drawn, respectively, from some compact sets $S_c \subseteq R_+$ and $S_e \subseteq R_+$. We are interested in a static Nash equilibrium in the actions of the emotional and cognitive systems, (r_c^*, r_e^*) . In light of (17.78), (17.79), the respective objective functions of the emotional and the cognitive system are given by

$$U^e = p_c(r_c, r_e) v(x) + p_e(r_c, r_e) v(y) - r_e. \quad (17.80)$$

$$U^c = p_c(r_c, r_e) (u(x) + v(x)) + p_e(r_c, r_e) (u(y) + v(y)) - r_c. \quad (17.81)$$

Solving the two first order conditions $\frac{\partial U^e}{\partial r_e} = 0$ and $\frac{\partial U^c}{\partial r_c} = 0$, simultaneously, for an interior solution, we get the unique optimal solution

$$r_e^* = \frac{(r_e + r_c)^2}{(u(x) + v(x)) - (u(y) + v(y))}; r_c^* = \frac{(r_e + r_c)^2}{v(y) - v(x)}. \quad (17.82)$$

Substituting (17.82), in (17.79), the unique respective probabilities are

$$p_e = \frac{v(y) - v(x)}{u(x) - u(y)}; p_c = \frac{u(x) + v(x) - u(y) - v(y)}{u(x) - u(y)}. \quad (17.83)$$

Having determined period 2 choices, let us now revert back to period 1. Suppose that in period 1, the individual evaluates date 2 lotteries using expected utility, and individual outcomes using her *commitment preferences* u . Then, ex-ante, the choice set M gives a level of expected utility

$$EU(M) = p_c u(x) + p_e u(y). \quad (17.84)$$

Substituting (17.83), in (17.84) we get

$$EU(M) = u(x) + v(x) - v(y). \quad (17.85)$$

Using (17.78), we can rewrite (17.85) as

$$EU(M) = \max_{x' \in M} \{u(x') + v(x')\} - \max_{y' \in M} v(y'). \quad (17.86)$$

Equations (17.67) and (17.86) are identical, as claimed. Thus, the planner–doer model in which emotions or cognition are probabilistically decisive in the second period, generates the same first period preferences as in GP.

17.8 Temptation and conflicts between commitment and flexibility

When individuals have self-control problems, say, arising through temptation, the standard prescription, in a range of models, is to commit to eliminate options that lead to such temptations. Amador et al. (2006) point out an important trade-off in this context. Eliminating a subset of the options has the benefit of reducing/eliminating temptations, but at the cost of reduced flexibility, especially when new information is likely to arrive in the future. For instance, in the context of intertemporal choice, a reduction in temptations might improve the savings rate of an individual, however, if the future marginal utility turns out to be too low, then the improvement in savings might not have been as worthwhile.

Consider a simple two-period example. In the first period, the individual can choose to buy one of two prepaid skiing holiday in the Alps: a nonrefundable holiday and a refundable holiday. The nonrefundable holiday is relatively cheaper. The individual can commit to eliminating temptations in the first period that lead him to buy the nonrefundable option. However, in the second period, due to an unfortunate accident, the individual is unable to enjoy the fruits of his first period efforts. Ex-post, he would have been better off buying the more expensive, but refundable option. If the individual had foreseen the possibility of such an event, his decision would have been the outcome of a *preference for commitment*, as well as a *preference for flexibility*.

We explore these considerations in the model of Amador et al. (2006) below, using a *multiple-selves* framework. This class of models is considered in more detail in Part 3 of the book. Here we simply note that the individual has multiple-selves, one for each time period. Each of the multiple-selves has its own objective function and none of the selves can directly control the other, although indirect control is possible.

Consider a three-period model of a single, representative, individual. Time periods are subscripted by $t = 0, 1, 2$. The individual has initial endowment y at time $t = 0$. There is no consumption in period 0 ($t = 0$) and consumption in period 1 ($t = 1$) is given by $c_1 = c$. The individual saves an amount k at time $t = 1$, to be carried into the second period ($t = 2$). There is no other source of income, and the interest rate on savings is normalized to zero, so $c_2 \equiv k$. Thus, the budget set of the individual is given by

$$B = \{(c, k) \in \mathbb{R}_+^2 : c + k \leq y\}. \quad (17.87)$$

The individual has multiple-selves and we shall refer to the self in period t as self- t . Self-2 has no important economic decisions to make, so we ignore it for the moment. Self-0 is the *principal*, while self-1 is the *agent*. The descriptions of the problems for self-0 and self-1 are given below.

1. In period 1, the preferences of self-1 are defined over first period consumption, c , and second period consumption, k . These preferences are given by

$$\theta u(c) + \beta v(k), \quad (17.88)$$

- where $\theta > 0$, $0 < \beta \leq 1$ are taste parameters, and u, v are increasing, concave and continuously differentiable functions. The parameter θ is private information to self-1 and takes on two possible values, θ_L, θ_H , with respective probabilities $p, 1-p$, and $0 < \theta_L < \theta_H$.
2. Self-0 does not know the value of θ but knows its distribution. The preferences of self-0 are given by

$$E[\theta u(c) + v(k)], \quad (17.89)$$

where E denotes the expectation operator with respect to θ . Notice that self-1 has a bias toward first period consumption ($\because 0 < \beta \leq 1$) but self-0 has no such bias. The *strength of the bias towards current consumption* is given by the term $1 - \beta$, so the greater is β , the lower is the bias towards current consumption.

17.8.1 First best outcome

Suppose that the principal (self-0) has full information on θ . The first best solution maximizes the utility of the principal, given in (17.89), subject to the budget constraint, given in (17.87). Thus, under the first best, there is no bias towards current consumption. Denoting the solution by $(c^*(\theta), k^*(\theta))$, $\theta = \theta_L, \theta_H$, we have

$$c^*(\theta) \in \arg \max_{c \in [0, y]} [\theta u(c) + v(y - c)].$$

The first order condition is given by

$$\theta u'(c^*(\theta)) = v'(y - c^*(\theta)). \quad (17.90)$$

Substituting $c^*(\theta)$ from (17.90) into (17.87) we get $k^*(\theta)$. Since u, v are strictly concave, so the first best is unique. Implicitly differentiating (17.90)

$$\frac{dc^*(\theta)}{d\theta} = \frac{-u'}{\theta u'' + v''} > 0. \quad (17.91)$$

Using (17.87), (17.91), we get the following monotonicity condition.

Lemma 17.1 *At the first best allocation $c^*(\theta_H) > c^*(\theta_L)$ and $k^*(\theta_H) < k^*(\theta_L)$.*

Thus, under full information, consumption is higher when the marginal utility of consumption at $t = 1$ is higher. We shall sometimes denote $c^*(\theta_i)$ and $k^*(\theta_i)$ by, respectively, c_i^* and k_i^* , $i = H, L$.

17.8.2 The optimal commitment solution under asymmetric information

Now suppose that self-0 does not know θ . Self-1 cannot control (even by exercising cost control) the temptation towards current consumption arising from $0 < \beta \leq 1$. Self-0 now optimally chooses an appropriate budget set $B = \bar{B}$ in the full knowledge that self-1 is decisive in making the consumption-savings choice. The main trade-off in the model is to tailor consumption to the

taste shock θ that is unobserved at $t = 0$ (flexibility) and restrict consumption opportunities for self-1 due to present-biased preferences (commitment).

Hence, the problem of self-0 is to choose $\bar{B}$ in order to maximize (17.89), subject to the constraint that the choice of self-1, $\bar{c}(\theta), \bar{k}(\theta)$, will be made according to

$$(\bar{c}(\theta), \bar{k}(\theta)) \in \arg \max_{c, k \in \bar{B}} \theta u(c) + \beta v(k).$$

This problem is equivalent to the following problem in which self-0 directly chooses the allocations $(c_i, k_i) = (c(\theta_i), k(\theta_i))$, $i = L, H$ in order to maximize her objective

$$Z = (1 - p) [\theta_H u(c_H) + v(k_H)] + p [\theta_L u(c_L) + v(k_L)], \quad (17.92)$$

subject to the following constraints.

$$IC_H : \theta_H u(c_H) + \beta v(k_H) \geq \theta_H u(c_L) + \beta v(k_L). \quad (17.93)$$

$$IC_L : \theta_L u(c_L) + \beta v(k_L) \geq \theta_L u(c_H) + \beta v(k_H). \quad (17.94)$$

$$c_H + k_H \leq y; \quad c_L + k_L \leq y. \quad (17.95)$$

Effectively, we have that $\bar{B} = \{(c_H, k_H), (c_L, k_L) : (17.95) \text{ holds}\}$, so one allocation is chosen for each type. (17.92) is just a restatement of (17.89) to take account of the uncertainty of self-0 about the values of θ , while (17.93), (17.94) are, respectively, the incentive compatibility conditions for types θ_H and θ_L ; we denote these, respectively, by IC_H and IC_L . The incentive compatibility constraint ensures that each type prefers its intended allocation. There are no participation constraints because it is not clear what an outside option might be in a model of multiple selves. Finally, condition (17.95) requires that the type-contingent budget constraint must be respected.

We first show that if the *strength of bias towards current consumption* is low enough (or β is high enough), then there is no problem in implementing the first best allocation; this result does not hold for a continuum of types.

Proposition 17.16 *There exists some $\bar{\beta} \in (\frac{\theta_L}{\theta_H}, 1)$ such that for all $\beta \in [\bar{\beta}, 1]$, the first best allocation $(c_L^*, k_L^*), (c_H^*, k_H^*)$ can be implemented under asymmetric information.*

Proof: Suppose that we evaluate IC_L at the first best allocation (c_i^*, k_i^*) when $\beta = 1$. By definition, IC_L is satisfied, so

$$\theta_L u(c_L^*) + v(k_L^*) > \theta_L u(c_H^*) + v(k_H^*) \Leftrightarrow v(k_L^*) - v(k_H^*) > \theta_L [u(c_H^*) - u(c_L^*)]. \quad (17.96)$$

The strict inequality in (17.96) arises because the first best is unique. From (17.96), it follows that there exists some $\bar{\beta} < 1$ such that

$$\bar{\beta} [v(k_L^*) - v(k_H^*)] = \theta_L [u(c_H^*) - u(c_L^*)]. \quad (17.97)$$

$$\Rightarrow \bar{\beta} = \frac{\theta_L [u(c_H^*) - u(c_L^*)]}{[v(k_L^*) - v(k_H^*)]}. \quad (17.98)$$

$$\Rightarrow \bar{\beta} \geq \theta_L \frac{u'(c_H^*)}{v'(k_H^*)}. \quad (17.99)$$

$$\Rightarrow \bar{\beta} \geq \frac{\theta_L}{\theta_H}. \quad (17.100)$$

Expression (17.99) follows from the property that for an increasing and concave function, w , $w'(c_H^*) \leq \frac{w(c_H^*) - w(c_L^*)}{c_H^* - c_L^*}$ and $k_L^* - k_H^* = c_H^* - c_L^*$, while (17.100) follows from (17.99) by using the first order condition under full information, (17.90). From (17.97), IC_L evaluated at the first best allocation holds for all $\beta \geq \bar{\beta}$. Analogously, evaluating IC_H at the first best allocation, a simple calculation shows that it holds if

$$\beta \leq \frac{\theta_H [u(c_H^*) - u(c_L^*)]}{[v(k_L^*) - v(k_H^*)]}.$$

Using (17.98) this implies that

$$\beta \leq \frac{\theta_H}{\theta_L} \bar{\beta}.$$

Using (17.100), $\frac{\theta_H}{\theta_L} \bar{\beta} > 1$, so IC_H , evaluated at the first best allocation, holds for all $\beta \leq 1$.

Thus, for all $\beta \in [\bar{\beta}, 1]$, IC_L , IC_H hold at the first best allocation, which is therefore, implementable. ■

Denote the asymmetric equilibrium solution by $(\bar{c}_H, \bar{k}_H)$, $(\bar{c}_L, \bar{k}_L)$. We now show that for high enough temptation $(1 - \beta)$, it is optimal to bunch the types, while for intermediate levels of temptation, it is optimal to separate the types. Bunching shares a common feature with *minimum savings rules* in other models, namely, that types above some threshold have the same consumption and saving bundle.

Proposition 17.17 (Amador et al., 2006)

- (a) If $\beta \geq \frac{\theta_L}{\theta_H}$, then a separating equilibrium exists such that $\bar{c}_H > \bar{c}_L$ and $\bar{k}_H < \bar{k}_L$. Both inequalities in (17.95) bind at the optimal solution.
- (b) If $\beta \leq \frac{\theta_L}{\theta_H}$, then bunching is optimal, i.e., $\bar{c}_H = \bar{c}_L$ and $\bar{k}_H = \bar{k}_L$. Both inequalities in (17.95) bind at the optimal solution.

In Part 3 we considered evidence that individuals do not save enough towards their retirement. Suppose that the government imposed a minimum savings requirement on all individuals, independent of their types. Is there a justification for such a *minimum savings rule* in a model of multiple-selves where selves have asymmetric information about the subsequent selves? The answer, it turns out from Proposition 17.17(b) is in the affirmative. A second contribution of the analysis in this section is to show that the removal of all tempting options, is suboptimal. Rather, individual allocations, tailored to the flexible needs of different types (see Proposition 17.17(a)) are optimal. Only when β is low enough as in Proposition 17.17(b) (self-control problems of self-1 are high enough), does self-0 remove the flexibility associated with a separating equilibrium and forces each type to save the same amount (commitment).

17.8.3 *Some empirical evidence on self-control*

There is surprisingly little formal evidence on the direct measurement of self-control, although one observes potential implications of self-control problems such as inadequate savings for retirement. There is now a fair bit of evidence on hyperbolic discounting that leads to self-control problems; see Part 3 of the book for details that we omit here.

Ameriks et al. (2007) is a relatively unusual study that tries to directly measure self-control problems. The authors assume that individuals correctly predict their future self-control problems, while anecdotal evidence suggests that individuals may be imperfectly aware of these problems. Survey data is used to pose hypothetical choices, so there is no guarantee that their procedure is incentive compatible; this would be more of a concern for experimental economists, although the view taken in this book is that all forms of evidence, including survey data, is admissible.

The study proceeds as follows. Individuals are told that they have won 10 certificates and each certificate entitles them to eat one free meal at a good restaurant. The certificates must be used entirely within the first two years, otherwise they are not valid. One measure of the contribution of self-control problems is the self-reported expected-ideal (EI) gap. This is the gap between the stated *expected* number of gift certificates that people use and the *ideal* number of gift certificates they would like to use in year 1 as compared to year 2. For 60% of the sample, the ideal split of the certificates over the two years is 50–50. Of the remaining sample, 15% wished to use all their certificates in the first year.

The EI gap is found to be quite small, suggesting low self-control problems. For 95% of the sample, the EI gap belongs to the set $\{-2, -1, 0, 1, 2\}$. Approximately two-thirds of the subjects choose the modal value of the EI gap, which is 0. In a regression analysis, individuals with higher self-reported value of the degree of conscientiousness exhibit smaller absolute values of the EI gap. Older individuals exhibit a smaller absolute value of the EI gap, suggesting that temptations fall with age. This may be helpful in understanding why we typically do not observe consumption splurges from lump-sum liquid retirement incomes.

In order to further explore self-control problems, subjects in the sample were given a choice of precommitting to the number of certificates that they could use in the first year. This gives rise to another measure, the revealed preference (RP) gap. This is the difference between the expected number of certificates that subjects hope to consume in the first year and the number they would like to commit to. The RP gap turns out to be quite low and is indicative of low self-control problems. Only 10% of the subjects have a desire to impose strictly binding constraints on themselves. Perhaps, as in the work of Amador et al. (2006), they have a preference for flexibility.

17.9 Happiness economics

The dominant practice in economics is to infer the utility function of individuals from their actual choices and to use the utility function to predict the choices that people make. We may refer to such utility as *decision utility* or *wantability*. Bentham (1789) had in mind a different concept, namely, *experienced utility*, which is not normally considered in modern economics. Experienced utility is the hedonic experience associated with an outcome. As such, one may obtain it by integrating the instantaneous experienced utilities associated with an outcome.

17.9.1 *Why should we be interested in subjective well-being?*

Kahneman and Thaler (2006, p. 222) write: “In the older interpretation of utility, the question of whether choices maximize utility has a simple meaning: do people choose the options that they will most enjoy? In modern decision theory, which ignores the distinction, the question is quite different: are preferences consistent with each other and with the axioms of rational choice?” Insofar as the stream of instantaneous utilities has accrued in the past, the individual has to contend with issues of imperfect memory; in this case, experienced utility is sometimes known as *remembered utility*. If instantaneous utilities accrue in the future (say, a purchase of a consumer durable), the individual might be subjected to projection bias (see Section 17.6 above). In this case, experienced utility is sometimes known as *predicted utility*. Hence, an important issue is whether experienced utility can be successfully measured.

Kahneman et al. (1997) review the evidence on remembered utility, drawing on Varey and Kahneman (1992), Fredrickson and Kahneman (1993), Kahneman et al. (1993), Redelmeier and Kahneman (1996). The typical procedure in these studies is to measure the discomfort of the subjects, say, during a colonoscopy, every 60 seconds (instantaneous utilities) and then ask them to report the disutility of the entire procedure at the end (remembered utility). The remembered utility can then be compared to the reports of instantaneous utilities. For a preference representation that takes account of these features, see Kahneman et al. (1997). The two main findings are as follows.

1. *Peak-end evaluation*. Peak-end utility is measured as a combination of the (i) average of the remembered peaks of past instantaneous utilities, and (ii) the instant utility towards the end of the experience. Peak-end evaluation has the following two implications. (a) *Duration neglect*: The duration of the experience has little effect if the average of the remembered peaks does not change much. (b) *Violations of temporal monotonicity*: Since peak-end evaluation weights the latest episode of utility, if there is a particularly low (respectively, high) recent instantaneous utility experience, overall remembered utility can be reduced (respectively, increased).
2. *Decisions by remembered utility*: When comparing two streams of past utilities and evaluating them by peak-end evaluation, the decision maker chooses the one with the highest remembered utility.

Subjective well-being relies on *expressed preferences* rather than on *revealed choice*. Revealed preference cannot be relied upon to judge the utility implications for individuals in cases where they have little or no effect on the outcome. Examples include environmental degradation, income inequality, fairness of the tax system, social capital, quality of governance, inflation, and unemployment. Indeed, in these cases, self-reported measures of *life satisfaction*, *well-being*, or *happiness* (the literature often uses these terms interchangeably), may provide an insight into the utility effects on individuals.

Utility is ordinal in the revealed preference approach. If a utility function, u , represents preferences, so does the function $\phi(u)$, where ϕ is any monotonically increasing transformation of u . Hence, based on actual choices made by individuals, we cannot know which utility function in the class of all monotonically increasing transformations of u we have actually measured. Yet, we routinely hear individuals making statements of the form: Peter is happier than John. The ability to make interpersonal comparisons of utility suggests that individuals may have some underlying cardinal measure of preferences.

Many of the measures of well-being are non-pecuniary. Economic policy that focuses purely on pecuniary measures of well-being will, therefore, not optimize overall well-being. *Subjective well-being* encompasses both *experienced utility* and *procedural utility* (Frey and Stutzer, 2002). Procedural utility refers to the actual procedure that leads to an outcome; see, for instance, Part 2 for a discussion of procedural fairness.

Can subjective well-being be measured? Traditionally the economics profession has been suspicious of self-reported measures of well-being that are based on hypothetical questions and the absence of incentives. Furthermore, the memories of subjects could be imperfect, they may be subject to projection bias, to framing, and to emotional and contextual effects. However, the implications of these potential errors depend on the intended usage of the data. Senik (2014) offers the following interesting quote attributed to Alan Blinder: “If molecules could talk, would physicists refuse to listen?”

The data are typically intended to provide an ordinal measure of well-being, and identify the determinants of well-being and happiness. For instance, we might be interested to see if reported subjective well-being is higher or lower when the quality of governance increases. The numerical increase in the reported subjective well-being is of lesser importance for this question. There is typically a high degree of consistency in the data, both in time series and cross-sectional data. Reassuringly, there is a high correlation between various measures of happiness. These considerations lead many to believe that individuals are perfectly capable of answering questions about subjective well-being in a consistent manner; see Frey and Stutzer (2002, Section 2.3) for the supporting evidence and the details.

Benjamin et al. (2012) evaluate the claim that *subjective well-being* (SWB) is a good proxy for utility in the sense that individuals make choices that would maximize their subjective well-being. Using three different samples, they give subjects a series of hypothetical choices in a variety of scenarios. Consider one of the scenarios, Scenario 1, in which individuals are asked to consider the trade-off between sleep and income.

“Say you have to decide between two new jobs. The jobs are exactly the same in almost every way but have different work hours and pay different amounts.

Option 1: A job paying \$80,000 per year. The hours for this job are reasonable, and you would be able to get about 7.5 hours of sleep on the average work night.

Option 2: A job paying \$140,000 per year. However, this job requires you to go to work at unusual hours, and you would only be able to sleep around 6 hours on the average work night.

Between these two options, taking all things together, which do you think would give you a happier life as a whole?”

At this point, subjects indicate a preference for one of the options and also indicate the intensity of the choice, based on a three point scale. Having answered this subjective well-being question, subjects are asked the following *choice question*.

“If you were limited to these two options, which do you think you would choose?”

For the choice question as well, subjects make one of the choices and indicate the intensity of the preference on a three point scale.

A total of 13 different scenarios were used across the subject pool. Subjects are given choices for jobs or housing options that trade-off financial rewards versus more sleep (Scenario 1), a shorter commute (Scenario 12), being around friends (Scenario 13), making more money relative to others (Scenario 3), and so on. In other scenarios, subjective well-being is not the only consideration. For instance, in Scenario 4, subjects choose between two career paths. One involves an easier life with fewer sacrifices, while another promises posthumous impact and fame. Scenario 2 involved an ethical choice: A more convenient option versus one that is the “right thing to do.”

The main results are as follows. Across all samples, the *SWB ranking* of the two options and the *actual choices* match for 83% of all respondents. For one sample, the Denver sample, only 13% of the rankings do not match, and for another, the Cornell sample, only 24% of the rankings do not match. Thus, subjective well-being is a good predictor of actual choices. However, for both samples, a test of proportions rejects the null hypothesis that the proportion of subjects making choice 1 is the same in the subjective well-being question and the choice question. When one of the options involves more money, respondents are more likely to choose the option with more money in the choice question, relative to predicting that this option will yield greater subjective well-being.

In order to explain the difference between the two sets of questions, the authors introduce several new explanatory variables for the Cornell sample. These include the following variables, each measured on a seven point scale: Your family's happiness, social life, control over life, level of spirituality, social status, and sense of purpose. When actual choices are regressed on subjective well-being and 11 other variables, it turns out that subjective well-being predicts choices better than all the other variables combined. Further, on average, the increase in explanatory power that is achieved by adding the 11 extra variables is modest, although in some scenarios the increase is substantial.

These results establish the importance of measures of social well-being as well as offer caveats about its use. It is no longer tenable to dismiss this line of research. The evidence supports plausible links of self-reported measures of well-being with meaningful economic variables. These include, for instance, the ability of these measures to predict job quits (Clark, 2001), probability of suicides (Helliwell, 2007), productivity (Oswald et al., 2015), and probability of a future divorce among couples (Guyen et al., 2012).

A dominant tradition in the literature, as we shall see below, equates subjective well-being with self-reported measures of happiness, health, and life satisfaction; this is the approach that we shall take in this section. Indeed, in this approach, these self-reported measures of well-being are taken to directly reflect utility. But what actually constitutes subjective well-being? Benjamin et al. (2014) explore this issue. In addition to happiness, their list includes goals, achievements, freedom, morality, and relationships. They find that happiness, health, and life satisfaction do indeed play a major role in well-being, but so do many other variables such as the quality of relationships, financial and physical security, morality, and freedom of choice.

We have considered the importance of character virtues, typically suppressed in neoclassical economics, in Chapter 7 of the book. The empirical results in Benjamin et al. confirm the importance of character virtues for well-being. Indeed, many of the variables that they find important for well-being correspond to the use in Sen (1985, 1992) of *functionings* and *capabilities*; the former refers to material standards of living and the latter to opportunities to achieve the relevant functionings, and to individual freedoms.⁷

There is a recognition in the literature that self-reported measures of well-being may not always give an accurate picture of utility, due to some of the reasons considered above. Yet, there is merit in considering these measures on two counts. First, as Benjamin et al. (2014, p. 2703) write: "Nonetheless, we believe it is more attractive to rely on what people's own stated preferences suggest about what they themselves care about than to paternalistically rely on the opinions and introspections of 'experts' (such as researchers and policymakers) regarding which aspects to track and how to weight them." Second, there might be a normative use of self-reported

⁷ For the social welfare foundations of economics in the presence of these measures of well-being, see Fleurbaey (2009) and Fleurbaey and Blanchet (2013).

measures of well-being. These measures may embody deliberative responses to a greater extent (as compared to emotional responses) that are more reflective of the actual welfare of the individuals.

Carter and McBride (2013) provide evidence that the shape of experienced utility is similar to the S-shaped utility function under prospect theory. Furthermore, they also report some evidence for loss aversion. The similarity between decision utility and experienced utility at a fundamental level, despite individual-level heterogeneity, is clearly an important development that needs to be replicated and refined.

17.9.2 *The relation between life-satisfaction/happiness and GDP*

The relation between life-satisfaction/happiness and GDP lies at the heart of the subject of subjective well-being. Many surveys prefer the word *life satisfaction* to *happiness* as it may be considered to invoke lesser emotional feelings. Recent research has thrown the conventional wisdom in the area into a state of flux. In this section, we shall primarily be interested in the relation between happiness and income. However, there might also be a relation between happiness and wealth; for the emerging evidence, see Senik (2014).

Early work in this area is associated with the work of Easterlin (1974). Van Praag (1968, 1971) had already started analyzing issues of subjective well-being using survey questionnaire techniques, a few years earlier. The results can be illustrated using a more updated dataset for the US, shown in Figures 17.5, 17.6. The data are from the United States General Social Survey. The self-reported measure of happiness takes the form of the following question: “Taken all together, how would you say things are these days—would you say that you are (3) very happy, (2) pretty happy, or (1) not too happy?”

Figure 17.5 shows that for the cross-sectional data from 1994, average US happiness increases with per capita real household income. So the richer appear to be happier. Furthermore, the curve shows diminishing marginal utility of income if we accept that happiness reflects utility. From

Figure 17.5 Mean happiness and real household income for a cross section of Americans in 1994.

Source: Di Tella and MacCulloch (2006) with permission from the American Economic Association.

Figure 17.6 Relation between mean happiness and real per capita GDP for the US between 1975 and 1997. Source: Di Tella and MacCulloch (2006) with permission from the American Economic Association.

this, we might expect that, since per capita real GDP has an upward trend, average happiness should increase over time. However, from Figure 17.6, we see that, while GDP per capita increases over time, average happiness is flat. This has come to be termed as the *Easterlin paradox*.

When Figure 17.5 is drawn for a cross section of countries, using the *World Values Survey*, the relationship between life satisfaction and GDP is relatively flat for incomes above \$10,000. Hence, further increases in income do not lead to appreciable increases in well-being; see for instance Figure 4 in Frey and Stutzer (2002) but also Figure 17.11. The idea is that income adds to happiness until basic needs are met, but not beyond that point (Veenhoven, 1991). Deaton (2008) presents the alternative idea, namely, that only after basic needs have been met can individuals derive happiness for cultural and intellectual pursuits. This view will have a bearing for the emerging results that we review below.

For a replication of the results in Figure 17.6 to other developed countries such as Japan, France, Germany, United Kingdom, Switzerland, see Easterlin (1995), Frey and Stutzer (2000), Blanchflower and Oswald (2004), Myers (2000), and Di Tella et al. (2001).⁸ Regressions of life satisfaction on lagged incomes show that individuals adapt to changes in income over a relatively short span of a few years. Based on German micro-level data, Di Tella et al. (2010) find complete adaptation within four years.

It is perhaps useful to see the results from Japan, over the period 1958–1991, in Figure 17.7. The data is drawn from Penn World Tables and the World Database of Happiness. Self-reported happiness was measured on a four point scale; average happiness was 2.7 in 1958, and despite spectacular growth in per capita real GDP, was 2.7 in 1991 as well. These results are very similar to those in Figure 17.6 and reinforce the Easterlin paradox.

The cross-sectional findings that we report above, only establish a correlation between happiness and income but do not establish any causal direction. One may expect that higher income makes people happier. However, there could also be reverse causation in which happier people earn more, perhaps because they are more productive or are able to deal with job stress better (Kenny, 1999; Graham et al., 2004).

⁸ For a book length treatment of this evidence, see Layard (2005).

Source: Frey and Stutzer (2002) with permission from the American Economic Association.

One natural experiment to establish the direction of causality is to examine the before and after happiness of people who unexpectedly win the lottery. Gardner and Oswald (2007) use the British Household Panel Survey (BHPS) to examine this question. The survey contains a mental well-being measure based on 12 questions. For each question, the lowest well-being score is 3 and the highest is 0. Thus, the aggregate worst well-being score is 36 and best is 0. A simple sum of these scores across the 12 questions for each subject gives the General Health Questionnaire score (GHQ) for the subject. Using data over 1998–2001, the authors cull out individuals who have won differing amounts of money in the lottery. There are 4822 observations for individuals who have won a small amount (less than £999) and 137 observations on medium-sized wins (greater than £1000).

The results are shown in Figure 17.8 for the three groups titled: No win (the control group), small-sized wins (£1–£999), and medium-sized wins (£1000 and above). The mean change in GHQ scores is reported for each group and for various time intervals, assuming that the lottery win takes place in period T. The standard errors are reported in the corresponding figures on the right.

In the first row in Figure 17.8, labeled (a), there is an increase in mental stress in the year of the win, particularly for medium-sized wins. In the second row, labeled (b), there is no difference in the GHQ score changes for non-winners and winners of small amounts in the year immediately after the win. However, there is an increase in mental well-being (fall in GHQ score) for individuals who have medium-sized wins. This is even more pronounced if one considers the two-year interval on either side of the win. The standard errors allow one to reject the null hypothesis at 5% that there is no change in the GHQ score for medium-sized winners. In a nutshell, small wins

Figure 17.8 Before-win and after-win happiness of people who unexpectedly win the lottery.

do not matter but larger wins raise happiness. In this case, the causality runs from income to happiness. For related findings see also Brickman et al. (1978).

Another exogenous variation in income is explored by Frijters et al. (2004). They find that after the fall of the Berlin Wall, the resulting increase in income in East Germany had a positive causal effect on reported happiness.

What accounts for the Easterlin paradox? Drawing on the work of Veblen ([1899] 1973) and Duesenberry (1949), Easterlin (1974, 1995, 2001) gives an explanation in terms of *relative income concerns* and *shifting aspiration levels*. Put simply, people feel happier with higher incomes but if everyone's income increases, then, given sufficient time, happiness does not increase. Aspiration adaptation theories postulate that the happiness of individuals depends on the gap between the actual realization of their income and their aspiration level; the higher the gap, the greater is the happiness. Furthermore, increases in income give temporary increases in happiness as the aspiration level adjusts upwards, eventually swamping the increase in happiness; this is sometimes known as the *hedonic treadmill* (Brickman and Campbell, 1971; Diener et al. 2006).

These adaptation features are similar to models of habit formation that we have studied in this chapter. Another explanation is based on the *set point theory of happiness*. In this theory, individuals have some inherent level of happiness; temporary shocks can lead to short-term departures in happiness but happiness eventually returns to its inherent level (Easterlin, 2003). The finding that approximately 33% of the variation in life satisfaction is on account of genetic factors is consistent with this explanation (De Neve et al., 2012). Furthermore, there have been attempts to isolate a gene for happiness (De Neve, 2011).

We have considered utility functions that depend on relative incomes in Part 2; see, for instance, the model of Bolton and Ockenfels (2000). Clark and Oswald (1996) provide evidence that British workers form an income reference group with other workers who have shared labor market characteristics. Knight et al. (2009) use Chinese household data to show that the main reference group is other households in the same village. For empirical evidence that shows the dependence of well-being on the difference between actual income and income aspirations, see, for instance, Stutzer (2004) and Knight and Guanatilaka (2012). Luttmer (2005) shows that controlling for an individual's income, higher incomes of neighbors reduce self-reported happiness.

Kuhn et al. (2011) exploit the exogenous variation in income caused by the Dutch postcode lottery in which the set of winners are all the buyers of the lottery tickets in a particular postcode. Each winner wins 12,500 euros per ticket and one of the postcode winners is chosen to additionally receive a brand new BMW. The data allow for tracking the consumption patterns of the winners and their neighbors. The neighbors of winners who receive a BMW, are also more likely to buy a BMW. Angelucci et al. (2009) also find positive social spillover externalities of bimonthly conditional grants to rural communities in Mexico, designed to improve their education, health, and nutrition.

The issue of reference groups is of independent interest and is needed to also impart greater empirical content to models of other-regarding preferences in Part 2 of the book. In this regard, the work of Clark and Senik (2010) is particularly important. They use data from 18 European countries in Wave 3 of the European Social Survey in which income comparison questions were asked for the year 2006–2007; they restricted the sample to the working age population, 16–65. We now briefly describe their methods and results.

The two relevant questions asked in the Survey were the following. (1) “How important is it for you to compare your income with other people's income?” The answers could be chosen on a discrete scale of 0 (not at all important) to 6 (very important). (2) “Whose income would you be most likely to compare with your own? Please choose one of the groups on this card: Work colleagues/ Family members/ Friends/ Others/ Don't compare/ Not applicable/ Don't know.” The first question about the *intensity of comparison* was answered by 19,053 respondents; 25% choose 0 (comparisons not important). However, for the remaining 75% of the subjects, income comparisons are important. Each of the numbers 1–4 is chosen by approximately 15% of the subjects; the numbers 5 and 6 are chosen by approximately 10% and 5% of the subjects, respectively.

The responses to the second question are shown in Table 17.1. Here, 35.9% of the 18,936 respondents claim that they do not compare their incomes. In Q1, this percentage was 25, so there is a degree of time inconsistency of choices for some respondents. However, 73% of those who chose 0 in Q1, choose Don't compare in Q2, so they are consistent. Of those who compare, the vast majority compares their income with work colleagues and the next most significant group is friends.

An important finding is that there is a negative correlation between intensity of comparison (higher numbers chosen on Q1) and real per capita GDP across countries as well as within countries; see Figure 17.9. A regression analysis shows that poorer households compare their

Table 17.1 Responses to the income comparison question.

	Observations	%
Work colleagues	6874	36.3
Family members	1103	5.8
Friends	2825	14.9
Others	1344	7.1
Don't compare	6789	35.9
<i>Total</i>	18936	100.0

incomes more to others. Self-employed compare less, singles compare more, and there are no noticeable gender effects. There are differences in cross-country effects of the intensity of comparison; Eastern European countries compare more relative to Western European countries.

Regarding Q2, self-employed subjects who compare are more likely to compare with family members and friends. The self-employed, on average, also appear happier as compared to the employed, possibly due to the greater job autonomy that they have; see Frey and Benz (2008) for the evidence. The employed are more likely to compare with colleagues. Women are more likely to compare with family members and income comparisons increase among the 25+ age group. Eastern Europeans are less likely to compare to other family members; such a comparison is more

likely in Spain, Poland, Finland, and Ireland. Countries in central continental Europe compare more with colleagues.

Those who compare more are less happy. The correlation coefficient between the intensity of income comparison and subjective happiness is negative and significant. The well-being correlation with income comparisons is smaller for richer as compared to the poorer individuals. The correlation of income comparisons with well-being depends on the reference group. Individuals who compare with colleagues are significantly happier than others who compare with friends. One possibility is that comparison with colleagues signals to individuals that their future incomes might be higher, but that is not true in a comparison with friends. Finally, those who compare more are also more likely to favor greater income redistribution.

Recent years have, however, seen a re-evaluation of the evidence considered above. This re-evaluation is based on alternative sources of information, such as the Gallup World Poll in 2006, and a consideration of the results based on a fuller set of countries and time periods. The results from the Gallup World Poll have a much fuller list of poorer countries as compared to the World Values Survey. These results, as we see now, question the very existence of an Easterlin paradox.

The Gallup World Poll asks questions about *life satisfaction* on an 11 point scale, while the World Values Survey asked questions about *happiness* on a 3 point scale. It is common practice in much of the literature to treat life satisfaction and happiness as synonymous; see, Van Praag et al. (2011) for supporting arguments. However, Deaton (2008) distinguishes between the two. He argues that life satisfaction involves making an overall evaluation of one's life, while happiness reflects an effect that can be gauged from *experiential questions* such as asking the individual if they have been smiling a lot, or if they have been depressed?

Figure 17.10 Relationship between mean life satisfaction and income, measured with Gallup World Poll data. GDP per capita in 2003 is measured in purchasing power parity chained dollars at 2000 prices.

Figure 17.11 The relationship between life satisfaction and income.

Source: Deaton (2008) with permission from the American Economic Association.

Figure 17.10 shows the relation between mean life satisfaction from the Gallup World Poll and the log of per capita GDP for 2003, for three different age groups. The sizes of the circles represent the associated country sizes. The relation is approximately linear. When the absolute level of per capita GDP is used, the relationship between life satisfaction and income is increasing and concave. This is shown in Figure 17.11 in which the data from the World Values Survey (10 point scale) is shown as the shaded circles and the Gallup World Poll data (11 point scale) is shown as hollow circles.

Deaton (2008) draws the following conclusions from Figures 17.10 and 17.11.

1. From Figure 17.11, individuals in richer countries in North America, Japan, Australasia, and Western Europe have higher mean life satisfaction (7.5–8.5 on an 11 point scale) relative to those in poorer countries in sub-Saharan Africa, Haiti, and Cambodia (3.1–4.5). In general the relation between life satisfaction and income is upward sloping.
2. Earlier research based on World Values Survey identified a cutoff income of about \$10,000 (Layard, 2003) or \$20,000 (Layard, 2005) beyond which income is unrelated to happiness. This assertion was widely made; see, for instance, Diener and Seligman (2004), Di Tella et al. (2003), and Frey and Stutzer (2002). Figure 17.10 paints a contrary picture. Indeed there is an almost linear relation between life satisfaction and log of income at all income levels. If anything, the relationship is the steepest for very high income levels. This is supported by the regression results in Deaton (2008).
3. The main reasons for the difference in results between the World Values Survey and the Gallup World Poll are as follows. First, the relative coverage of poor countries in the Gallup Poll is much richer, as reflected in Figure 17.11; there are hardly any filled-in circles for very low levels of income. Second, there is a disproportionate share of Eastern European countries in the World Values Survey who had middling incomes as well as great dissatisfaction

following the events of the breakdown of the former Soviet Union. Third, the World Values Survey in relatively poor countries of that time (Ghana, Nigeria, India, China) sampled the relatively better-off individuals in the poorer countries, in order to ensure comparability with the individuals in the richer countries. Presumably these individuals had much higher levels of happiness relative to the representative individuals in these countries. But this led to a much flatter relation between income and happiness.

4. Life satisfaction is age-dependent. The life satisfaction for the 15–25 year olds is highest, while that of individuals aged 60 or above is the lowest. Life satisfaction declines with age for most countries in the world except for the highest income countries such as the US, Canada, the UK, Australia, and New Zealand, where it is U shaped; see Deaton (2008) for details.

Stevenson and Wolfers (2008, 2013) and Sacks et al. (2013) also provide evidence that supports the analysis of Deaton (2008). Figure 17.12 gives more recent data based on a sample of 155 countries from the first five waves of the Gallup World Poll over the period 2008–2012; it captures 95% of the world's population.

The simple correlation between life satisfaction and log of per capita GDP is 0.79; the regression coefficient in a simple OLS regression is 0.335 with a standard error of 0.018. The regression line is shown as the unbroken line in Figure 17.12, while the dashed line is a non-parametric line. The two lines are closely aligned. In particular, the non-parametric line does not flatten out beyond some income threshold. Choosing a threshold level, say, \$15,000, and fitting separate linear regressions for countries below and above the threshold, the authors are unable to reject the null hypothesis that the regression coefficients are identical. Indeed, the relationship between life satisfaction and income appears quite steep when life satisfaction is plotted against income for the 25 largest countries; see Figure 17.13.

These results are supported by Inglehart et al. (2008), Diener et al. (2013), and Veenhoven and Vergunst (2013). The response by Easterlin et al. (2010) and Easterlin (2013) is that the positive relation between income and happiness is a short-term one and in the long term (10 years or more) there is no relation between the two. For instance, Easterlin et al. (2010) write in their abstract: “Recent critiques of the paradox, claiming the time series relationship between happiness and income is positive, are the result either of a statistical artifact or a confusion of the short-term relationship with the long-term one.” However, this conclusion has been contested by the proponents of a positive relation between happiness and per capita GDP. Beja (2014) proposes a compromise. He uses very long time series data (1973 to 2012) for a cross section of European countries and finds that, while the relation between happiness and income is a positive one, it is weak and economically not significant enough.

In light of these disparate results, the Easterlin paradox no longer enjoys undisputed acceptance in the profession, which it did a decade ago.

17.9.3 Other important economic correlates of well-being

We consider a range of correlates of well-being in this section. These include, unemployment, inflation, income inequality, social capital, health, and democratic institutions. An alternative approach is to consider *domain satisfaction*. This refers to a more disaggregated measure of satisfaction that studies the determinants of satisfaction in individual domains such as job satisfaction, and financial satisfaction (we have considered health satisfaction above). For a further discussion of these issues and the relevant empirical evidence, we refer the reader to the survey by Van Praag and Carbonell (2011).

UNEMPLOYMENT AND INFLATION

Di Tella et al. (2001) explore the foundations of the standard social welfare function in macroeconomics that typically proposes quadratic losses in unemployment and inflation. They regress measures of happiness on inflation and unemployment, using a very large cross-country dataset

from 12 European countries and the US; as is typical in these studies, they allow for country fixed effects and time trends.⁹

Both unemployment and inflation are found to reduce happiness. A one percentage point increase in unemployment from 9% (the mean unemployment rate at the time of the empirical study) to 10% reduces life satisfaction by 0.028 when happiness is measured on a scale of 1 to 4. On the same scale, a one percentage increase in inflation from the sample mean rate of 8% to 9%, reduces happiness by 0.01. Both effects are substantial. However, unemployment is relatively more deleterious for happiness. On average, individuals are willing to trade a 1 percentage point increase in unemployment against a 1.7 percentage point increase in the inflation rate.

These results have been replicated. Using data from 16 European countries, Wolfers (2003) finds that a one percentage point increase in unemployment causes 4.7 times as much unhappiness as a one percentage point increase in the inflation rate. Reference point effects have been identified in the observed aversion of unemployment. The happiness reducing effect of unemployment is smaller if the fraction of other people in the region who are unemployed is larger, or a partner is unemployed; presumably this reduces the stigma attached with being unemployed (Clark, 2003).

Unemployment is possibly more aversive to happiness than any other single characteristic, even more aversive than divorce or separation, and relatively more aversive for the more educated (Clark and Oswald, 1994). The causality runs from unemployment to unhappiness, rather than the other way around (Winkelmann and Winkelmann, 1998). It appears that the unhappiness of the unemployed cannot be accounted for, purely by their lower income. Thus, there are psychic costs of unemployment.

Psychic costs arising through anxiety, depression, loss of self-esteem, resort to alcoholism, stigma costs, scarring costs of unemployment, and strained relationships all appear to play a role in greater unhappiness.¹⁰ Luechinger et al. (2010) test for anticipatory anxiety among the unemployed by comparing private and public sector employees in Germany. Public sector employees have greater job security. For this reason, private sector workers exhibit relatively greater anxiety towards general economic shocks. For state-level panel data, Ruhm (2000) finds that there is a positive correlation between unemployment and the number of suicides in a state.

The picture emerging from this analysis shows up the inadequacy of macroeconomic explanations, in the tradition of real business cycle models, that solely use the transmission channel of voluntary unemployment as an explanation of unemployment. If people were voluntarily unemployed, it would be difficult to account for their pronounced unhappiness and low self-reported measures of well-being. This not only illustrates the usefulness of happiness economics, but also raises uncomfortable questions about the dominant practice in macroeconomics for so long.

INCOME INEQUALITY AND HAPPINESS

While the relation between happiness and income is well documented, there is comparatively less work on the relation between inequality and happiness. Alesina et al. (2004) find that inequality reduces happiness. However, while the relation is strong and statistically significant in the case

⁹ The European data is taken from the Euro-Barometer Survey Series, the US data is taken from the United States General Social Survey, and the data on unemployment and inflation is taken from OECD statistics. The dataset used in the study contains about a quarter of a million individuals.

¹⁰ For the importance of non-pecuniary costs of unemployment, see Kassenboehmer and Haisken-DeNew (2009). For the relation of non-pecuniary costs with social work norms, see Clark (2003) and Stutzer and Lalive (2004). For limited adaptation to unemployment and its scarring role, see Clark et al. (2001), Clark (2006), and Knabe and Rätzel (2011).

of Europe, it is far weaker in magnitude for the US. The authors conjecture that upward income mobility is greater in the US relative to Europe. So individuals who are poorer, do not see inequality as unduly limiting their future prospects in the US, hence, inequality has a lesser impact on their happiness.

HEALTH SATISFACTION AND HAPPINESS

Figure 17.14 shows the relation between health satisfaction and per capita GDP. The non-parametric regression curves are upward sloping, indicating that higher income is associated with greater health satisfaction. Health satisfaction falls with age. For the richest countries, the 50–59 age group has a lower health satisfaction relative to the two older groups.

Countries from the former Soviet Union exhibit extremely low health satisfaction. Other countries in the low health satisfaction group include Haiti, Rwanda, Burundi, Uganda, Cambodia, and Benin. Deaton (2008) reports that a fall in life expectancy due to HIV/AIDS cannot fully explain the poor levels of health satisfaction in sub-Saharan Africa.

Causality need not just run from good health to happiness. Indeed happier people are likely to be healthier (Diener and Chan, 2011). Other variables may be correlated with both; hence, the relationship between health and happiness may reflect these other factors, particularly genetic factors (De Neve et al., 2012). There is also significant adaptation to health disabilities. Oswald and Powdthavee (2008) report that within three years, individuals adjust to 30% of the effect of severe disability and 50% of the effect of moderate disability.

Oswald and Wu (2011) use state-level data for the US that is based on telephone surveys of the mental health of the respondents and questions about their life satisfaction and incomes in the previous month. They find a high degree of heterogeneity among the US states. Particularly interesting is the result that the high GDP states in the sample are less happy; Louisiana is one

Figure 17.14 Non-parametric regressions of average health satisfaction against per capita GDP for seven age groups. GDP is measured in purchasing power parity chained dollars at 2000 prices.

Source: Deaton (2008) with permission from the American Economic Association.

of the happier states, while California is not happier than the other states. The authors' preferred explanation is based on Adam Smith's idea of compensating wage differential. States with lower life satisfaction have to offer a compensating income differential. However, there is no correlation between mental health and per capita state GDP.

SOCIAL CAPITAL AND HAPPINESS

Social capital refers to the effects of social networks, including the associated norms of trust and reciprocity, on production efficiency and well-being (Coleman, 1993; OECD, 2001). Helliwell and Putnam (2004, p. 1436) write: "Social capital can be embodied in bonds among family, friends and neighbors, in the workplace, at church, in civic associations, perhaps even in Internet based 'virtual communities.'" They use cross-sectional data from the World Values Survey, the European Values Study, and the Canadian Benchmark Survey comprising of 29,000 observations. A range of variables is considered at the national/community level and at the individual level, such as average trust, trust in neighbors and police, membership in associations, governance, the importance of God/religion, and marital status.

The authors report a range of findings that are consistent with the importance of social capital for well-being. Being married improves happiness and life satisfaction, particularly in comparison with those who are divorced or separated; this reflects the effect of family level social capital. Church attendance reflects community level social capital. Those who attend Church and have a strong belief in God, trust others more. Frequent interactions with friends and neighbors are associated with higher well-being. Those who report that they live in a high trust neighborhood report higher life satisfaction and happiness as well as better health.

This literature continues to expand. For the effects of social capital on long-term trends in subjective well-being, see Sarracino (2010); for the positive effects of volunteer work on well-being, see Meier and Stutzer (2008); and for the public goods nature of social capital, see Becchetti et al. (2008).

Figure 17.15 The relationship between economic freedom, democracy, and well-being and happiness.

Source: Rode, M., Knoll, B., and Pitlik, H. (2013). "Economic freedom, democracy, and life satisfaction," in James Gwartney, Robert Lawson, and Joshua Hall (eds.), *Economic Freedom of the World: 2013 Annual Report* (Fraser Institute): 215-33. www.freetheworld.com. Reprinted with kind permission of The Fraser Institute.

DEMOCRACY, FREEDOM, AND LIFE SATISFACTION

Economic freedom and democracy might also directly contribute to well-being and happiness. This is illustrated directly in Figure 17.15; the left panel shows life satisfaction in autocracies and democracies, and the right panel shows life satisfaction under different economic freedom ratings (higher rating shows higher freedom).

Economic freedom is measured by the EFW index published in *Economic Freedom of the World: 2012 Annual Report*. Life satisfaction is measured by the World Values Survey. The classification of countries into autocracies and democracies is based on Cheibub et al. (2010). In a regression analysis, Rode et al. (2013) show that the effects of economic freedom and democracy on life satisfaction are significant at 1%. One possible transmission channel is that in a democracy, politicians respect the choices of people, giving the latter a feeling of well-being (Frey and Stutzer, 2002).

Veenhoven (2000) shows that for 38 developed countries, indices of political freedom, economic freedom, and personal freedom have a statistically significant correlation with happiness. Furthermore, economic freedom enhances happiness relatively more in poorer countries and political freedom relatively more in richer countries. Direct democracy refers to the exercise of direct citizen choices through referenda. Frey and Stutzer (2000) show that Swiss cantons with higher direct democracy indices are also associated with higher self-reported happiness.

CHAPTER 18

Interactions between Emotions and Cognition

18.1 Introduction

Observed human behavior is the outcome of interactions between a *cognitive* and an *emotional* module/system in the brain. The emotional system is thought to be quick, reactive, and automatic; it is typically modeled as operating at the hot end of the spectrum of human emotions. The cognitive system is slow, deliberative, focuses on the larger goals, and operates at the cold end of the spectrum of human emotions. The human emotional system is shared in common with many other mammals, but the cognitive system is unique to humans, although some elementary functions are shared with close primate relatives such as chimps. The cognitive system, developed about 150,000 years ago, and was superimposed on top of the existing emotional system. The objectives of the two modules can be in harmony or, in the more interesting case, in conflict (Tooby and Cosmides, 1992; Wilson, 2012). In this chapter, we consider the economic implications of competition and cooperation between emotions and cognition.

Section 18.2 introduces the reader to models of *dual brain modules*, or simply dual process models. In Section 18.2.1, we introduce the main premise of these models. In Section 18.2.2, we describe a general blueprint for the interaction between the emotional and the cognitive processes (Loewenstein and O'Donoghue, 2004, 2007). The blueprint is speculative in several respects, does sometimes make heroic assumptions, and one cannot always disentangle the source of observed behavior as cognitive or emotional. However, the model is an important first pass, relies on plausible ideas, is very general, and suitable for serving as a template for the development of further ideas. It has the potential to derive simple relations and concepts in behavioral economics, endogenously, and in a simple manner, playing a role similar to that of IS-LM analysis in macroeconomic analysis. We show that the model can give important insights into behavioral models of risk, time preference, and social preferences. This model deserves to be taken more seriously.

In Section 18.3, we model the interaction between a patient long-run self and a myopic short-run self in a simple consumption–savings problem (Fudenberg and Levine, 2006). In the absence of a commitment technology, the long-run self can control the consumption splurges of the short-run self through the exercise of costly willpower. We examine the dependence of optimal consumption plans on willpower costs. In a richer model, we then consider the presence of a commitment technology. Here, we show that for small windfalls in income, an increase in unanticipated income is fully consumed, while the converse holds true for large windfalls. In the absence of any costs of control, the individual never fully splurges on consumption.

It is possible that parts of the brain could have access to private information that other brain areas might not possess (Berns et al., 1997). In other contexts, it is possible that individuals might have restricted access to their own motives and beliefs (Brocas and Carrillo, 2008). People might infer their own emotions or abilities from their actual behavior. They could also take their donation of money as evidence of their altruism, or their ability to jog in extreme heat as evidence of their willpower (Bodner and Prelec, 2003).

In Section 18.4, we consider a somewhat speculative two-period model of interaction between a principal (cognitive system) and an agent (emotional system) when the agent has asymmetric information about its preferences (Bodner and Prelec, 2003; Brocas and Carrillo, 2008). We contrast the allocation of consumption and effort under full information with the case of asymmetric information. It turns out that an endogenous rate of time preference develops, despite the fact that the cognitive system undertakes no time discounting. The model does leave open several questions that are not answered in a fully satisfactory manner. For instance, how are contracts between competing brain modules enforced? How should one treat the participation constraint of a brain module? What does renegotiation of contracts mean in this case?

When a current self interacts with her future selves, the decision to acquire information has considerable strategic importance. By acquiring information, one makes all of one's own future selves aware of that information. If there is a possibility that the future selves will use this information to the detriment of the current self, then the current self might choose to be strategically uninformed. For instance, individuals vastly overestimate the effect of smoking on lung cancer (Viscusi, 1990; Lundborg and Lindgren, 2004). However, such information is freely and easily available. Why then do individuals choose not to acquire such information? One possibility, that we consider in Part 3, is that individuals procrastinate to acquire the relevant information (O'Donoghue and Rabin, 1999).

But in this chapter we consider alternative explanations. Section 18.5 considers formal models that address these issues within the framework of multiple-selves models. We first consider, in Section 18.5.1, a simple three-period model of strategic information transmission (Carrillo and Mariotti, 2000). The current self has to decide whether to learn something of strategic importance that determines the consumption behavior of future selves. We derive the conditions under which such learning is justified, relative to being strategically uninformed.

In models of asymmetric information in economics, information asymmetry typically pertains to the types of other players. Psychological evidence, however, suggests that individuals often have doubts about who they really are. Individuals often engage in introspection and reflection in an attempt to figure out the motivation, justification, and the implications of their current and past actions. Individuals often question their ability to successfully undertake a task, and sometimes struggle to discover their true underlying preferences.

Actions taken by individuals, who have asymmetric information about some relevant characteristics of their own self, are sometimes characterized by self-deception and at other times by repentance. Another relevant feature is the presence of *imperfect willpower* in humans; for instance people might lack the willpower to reduce or to give up smoking, or keep to a deadline. Finally, people might have *imperfect recall* and *motivated cognition*, i.e., they actively seek ways of managing the awareness about the degree to which subsequent selves can recall past events. In Section 18.5.2, we formally consider these issues in a model where individuals have asymmetric information about their own abilities, motivation, or self-confidence and they attempt to strategically manage information available to their future selves (Bénabou and Tirole, 2002, 2004). Among other predictions, this model has the potential to explain the roles of strategic ignorance, selective memory transmission, and self-handicapping.

18.2 Emotions and a two-modules view of the brain

In this section, we explore the implications for human behavior when the brain is viewed as comprising of two modules: an emotional module and a cognitive module. While our focus will be on economic models of more recent vintage, there is also an older literature on these models in psychology (Schneider and Shiffrin, 1977a, 1977b).

18.2.1 *An introduction to the two-modules view*

One may imagine the brain as a group of modules, or a *confederation of mechanisms* in the language of Cohen (2005), that jointly determine human behavior. These modules could have different objectives. The desired behavioral outcomes of the competing modules may sometimes be in agreement, while at other times, these could be in conflict. The premise in these models is that observed human behavior is the outcome of competition among these modules.

A useful abstraction, that has a long history in many diverse literatures, is to consider the brain as having just two main modules. One controls emotions, while the other has a cognitive function; see Loewenstein and O'Donoghue (2004, 2007) for a lucid and informative review that we draw on here. Adam Smith used the terms *passions* versus *impartial spectator* to capture the emotions versus cognitive contrast. *Passions* describe motivational forces and other visceral states such as anger, hunger, and thirst. The *impartial spectator* refers to an ability to stand back, or be emotionally neutral in some sense, and take an impartial view of one's emotional motivations. Freud (1924) referred to a similar conflict between the *id* and the *ego*. Such dual process models are also common in modern psychology; see for instance Chaiken and Trope (1999).

In common usage, we often speak of the *feeling of being in two minds*, or the *conflict between the heart and the mind*; these phrases appear to illustrate the conflict between emotions and cognition. The conflict between emotions and cognition is likely to have an evolutionary explanation (Dawkins, 2006; Tooby and Cosmides, 1992; Massey, 2002; Wilson, 2012). When humans departed from their primate relatives in their evolutionary history, about 6 million years ago, the human brain was not redesigned from scratch. Cognitive abilities, the ability to think about broader goals, and the broader implications of one's actions, were developed by adding brain structures on top of the existing brain structures. The most notable new brain structure in this regard is the prefrontal cortex, which has developed significantly in relatively recent evolutionary history.

Emotionality clearly preceded rationality in the evolutionary sequence. Define emotions for the moment, as in Cohen (2005), as low level automatic psychological processes that are engaged by stimuli (or memories) and are associated with strong positive and negative psychic utility. For instance, witness the emotion of fear that is triggered by observing a coiled object on a dark street.

As rationality developed, it did not replace emotionality as the basis of human interaction. Rather, rational abilities were gradually added to the existing, and simultaneously developing, emotional capacities. Indeed, the neural anatomy essential for full rationality, the *prefrontal cortex*, is a recent evolutionary innovation. It only emerged in the last 150,000 years of a 6-million-year existence, representing only about 2.5% of humanity's total time on earth.

Three features of evolution, namely, that it is *efficient*, *opportunistic*, and *conservative*, are important in this regard; see for instance, Cohen (2005). Evolution is *efficient* in the sense that, conditional on the environment, it optimally meets the needs of the organism. It is *opportunistic*

in the sense that it produces solutions that are closely tailored to the environment.¹ Finally, it is *conservative* in the sense that it is reluctant to discard older solutions (e.g., existing brain structures) as new environmental situations arise, even if the older solutions are not well adapted to the new environment. Evolution develops additional solutions/structures to deal with new environments.

Metcalf and Mischel (1999) also make a distinction between a hot emotional module or process, and a cool cognitive module. The emotional response is rapid, automatic, simple, relatively inflexible, and attuned to particular stimuli. The cognitive response is just the opposite, i.e., it is reflective, deliberate, slower, and more flexible. The former is limited to a small number of goals, while the latter can generate behavior that is consistent with a large number of broader goals. Cohen (2005) describes this as the familiar trade-off between speed and specialization that is faced by engineers in the design of computers.

18.2.2 *An illustrative framework*

We now consider a general framework for the interaction between the emotional and the cognitive system, following Loewenstein and O'Donoghue (2004, 2007). We begin by noting the drawbacks of this approach. Many of the assumptions in the illustrative applications may appear arbitrary, yet they are plausible. Nor can one always cleanly separate observed behavior based on the source, cognitive or emotional, that gives rise to it. This framework cannot be used to fully justify the importance of the dual process model for explaining behavioral phenomena, nor make watertight predictions. Yet, it does take an important first step in this direction and has the potential to serve as the basis of further models that can lead to much needed theoretical developments in the area.

The emotional and cognitive processes/systems are also respectively termed as the *affective* and the *deliberative* processes/systems. The emotional system, because it is automatic and quick, initially comes into play when an individual faces some stimulus (Baumeister and Vohs, 2003). The stimulus could be external (coiled object on a dark street) or internal (drop in blood glucose levels).

The cognitive system, because it is reflective and considers broader goals, can influence the emotional system by the exercise of costly *willpower*. Willpower has three relevant features for our purpose. First, it is a limited resource and can get depleted. Second, cognitive load reduces the ability to exert willpower. Third, willpower can be depleted by stress; for instance, Shiffman and Waters (2004) find that relapse among cigarette smokers was often preceded by a stressful event.²

The second feature of willpower is suggested by the experiments of Shiv and Fedorikhin (1999) who employed two groups of subjects. The first group was subjected to a high cognitive load and was asked to memorize a 7-digit number. The second group was subjected to a low cognitive load and asked to memorize a 2-digit number. The subjects were then required to walk to another part of the building to report their memorized number. On the way, they were presented with a high calorie cake and a fruit salad. A larger fraction of subjects who were subjected to a high cognitive load (63%) chose the cake, relative to the those who were subject to a low cognitive load

¹ For a more detailed discussion of these issues, see Part 5 of the book where we distinguish between changes in the environment that occur with different speeds. Long-run changes induce changes in the structure of the DNA. But for short-run and medium-run changes, other responses, such as gene-culture coevolution, are more efficient.

² For a model of the effect of stress on reducing well-being that works through a cognitive load channel, see Walde (2015).

(42%). There was only a slight difference between the two conditions when the same objects were presented symbolically in the form of photographs.

The cognitive system operates at the cool end of the spectrum and deliberates about broader goals. Thus, as a first pass, assume that it has the same objectives as the rational agent in neo-classical economic models. So, for instance, when the cognitive system faces a risky lottery, it uses expected utility theory to evaluate the lottery, and when it faces an intertemporal stream of consumption, it uses exponential discounting to evaluate the consumption stream.

The emotional system operates at the hot end of the spectrum and focuses on immediate goals. As a first pass, assume that it behaves in a manner that is consistent with the recent evidence in behavioral economics. So it uses loss aversion when presented with gains and losses and uses hyperbolic discounting when evaluating an intertemporal stream of consumption.

The cognitive system cares about the moral and ethical dimensions of a situation, while the emotional system is driven between the two extremes of purely self-regarding and purely altruistic behavior. Which of these extremes is activated depends perhaps on a set of cues which activate such emotions. In related literature, Bernheim and Rangel (2004) also assume that the brain operates in one of two states, a cold state or a hot state. The state depends stochastically on the environmental conditions (which in turn could depend on actions taken in the past). However, their primary focus is on the cold state, which maximizes expected discounted utility, while the hot state is assumed to follow a simple rule. They take as their welfare measure, the preferences of the cold state.³

The schematic outline of the dual process model is shown in Figure 18.1. A stimulus, s , which belongs to a set S , activates the emotional and the cognitive systems. In particular, it activates an emotional/motivational state $m(s)$, and a cognitive state $c(s)$; the set of emotional and cognitive states could themselves be subsets of S . The problem is to choose the optimal behavior x from a set

Figure 18.1 Schematic representation of the dual process model.

³ In Benhabib and Bisin (2005), individuals can either invoke an automatic emotional system that is susceptible to temptation or a costly cognitive system that does not succumb to temptation. They explore an internal control mechanism that takes the form of a simple cutoff rule in a consumption-savings problem. Models of multiple selves (see Part 3 of the book) do not allow for this internal control mechanism.

$X \subseteq \mathbb{R}$, given that the two systems have different objective functions and none fully dominates the other.

In particular, the objective function of the emotional system is given by $U^e(x, m(s))$, which is maximized at $x^e \in X$. We assume that $\frac{\partial}{\partial m} \left(\frac{\partial U^e}{\partial x} \right) > 0$, i.e., an increase in the motivational state increases the marginal utility of the emotional system from increasing behavior, x . The objective function of the emotional system does not depend on the cognitive state, $c(s)$. The cognitive system has the objective function $U^c(x, m(s), c(s))$, which is maximized at $x^c \in X$. We assume that $\frac{\partial}{\partial c} \left(\frac{\partial U^c}{\partial x} \right) > 0$. Since the cognitive system cares about broader goals, it also takes account of the emotional states induced by the stimulus, $m(s)$.

For the sake of expositional ease, we will assume that U^e and U^c are strictly concave in x and continuous in all arguments, and the set X is compact, so that the maximizers x^e, x^c are unique, and continuous functions of the parameters.

Finally, observed behavior is the outcome of the interaction between the emotional and the cognitive systems. For instance, the proximity of tempting foods could create an emotional state of hunger. Faced with such a stimulus at lunchtime, the objectives of the cognitive and emotional systems are likely to be in agreement with each other. However, faced with such a tempting stimulus between lunch and dinner, the cognitive system of an individual on a diet is likely to recommend the opposite course of action to the emotional system. It is this latter situation where the desired actions of the two systems are in conflict, that is the most interesting for our purposes.

What determines the relative strength of activation of the emotional and the cognitive systems, when faced with a cue? Several factors play an important role. These include the following. (i) Physical proximity of the stimulus (Mischel et al., 2003). Food is more tempting if it is placed nearby, or if its consumption by others is observed. (ii) *Changes* versus *levels* of stimuli (Frederick and Loewenstein, 1999). The emotional system is more likely to respond to changes than to levels. (iii) Vividness of stimuli (Loewenstein et al., 2001). We are often more deterred from speeding if we directly observe an accident in graphic detail relative to reading about the annual road fatality statistics.

To economize on notation, we suppress the state, s , in the objective functions of the two systems by assuming a fixed state. We assume that the individual has sufficient time to choose actual behavior so that the eventual choice is made by the cognitive system. Using the standard terminology in economics, one may think of the cognitive system as a *benevolent principal* and the emotional system as the *agent*.

We shall primarily be interested in a static model. However, we first make a few observations on willpower in a dynamic model; index discrete time by t .⁴ Willpower costs exerted by the cognitive system are directly proportional to the extent to which the emotional system is moved from its most preferred behavior at time t , x_t^e , to some $x \neq x_t^e$ that might be in the individual's longer-term interest. Thus, the willpower, w_t , exerted by the cognitive system at time t is given by

$$w_t(x_t) = U_t^e(x_t^e, m) - U_t^e(x_t, m). \quad (18.1)$$

Let W_t be the stock of willpower at time t . The stock of willpower carried forward from time t to $t + 1$ is given by $W_{t+1} = f(w_t, W_t)$, such that $f_1 < 0$ and $f_2 > 0$. Thus, exertion of willpower effort in any period depletes the stock of willpower carried over to the next period ($f_1 < 0$).

⁴ An exercise at the end of the chapter, based on Ozdenoren et al. (2012), provides a more rigorous, but also more specialized, framework of analysis.

For instance, depletion of willpower can lead to a greater incidence of impulse buying (Vohs and Faber, 2007). Furthermore, *ceteris paribus*, a greater current stock of willpower transforms into a greater stock of willpower next period ($f_2 > 0$). These ideas are fundamental to an understanding of the role of willpower in a dynamic analysis (Baumeister and Vohs, 2003).

We shall only focus on the static case below. Omitting time subscripts, (18.1) can be written as

$$w(x) = U^e(x^e, m) - U^e(x, m). \quad (18.2)$$

The objective of the principal, or the cognitive system, is to choose $x \in X$ to maximize

$$V^c(x) = U^c(x, m, c) - \phi(W, \sigma)w(x), \quad (18.3)$$

where $\phi(W, \sigma) \geq 0$ represents per unit willpower cost, and σ is cognitive load/stress. Consistent with the evidence reviewed above, $\phi_1 < 0$ and $\phi_2 > 0$. Thus, per unit willpower costs are decreasing in the stock of willpower but increasing in the cognitive load/stress facing the individual. Substituting (18.2) in (18.3) and noting that x^e is fixed for a given stimulus (hence, omitting the term $U^e(x^e, m)$), we can write the maximization problem of the cognitive system as

$$x^* \in \arg \max_{x \in X} V^c(x) = U^c(x, m, c) + \phi(W, \sigma)U^e(x, m). \quad (18.4)$$

As $\phi(W, \sigma) \rightarrow 0$, $x^* \rightarrow x^c$ and as $\phi(W, \sigma) \rightarrow \infty$, $x^* \rightarrow x^e$. The cognitive system makes the eventual decision, so it is like a chief executive of the brain. However, the objective function in (18.4) also bears another interpretation if we recognize that for a fixed state, $U^c(x^c, m, c)$ and $U^e(x^e, m)$ are fixed numbers. Choosing x to maximize (18.4) is equivalent to minimizing the following.

$$x \in \arg \min [U^c(x^c, m, c) - U^c(x, m, c)] + \phi(W, \sigma) [U^e(x^e, m) - U^e(x, m)]. \quad (18.5)$$

The interpretation of (18.5) is that actual behavior is chosen in order to minimize the weighted sum of two costs. Namely, the cost of moving the emotional and the cognitive systems from their most preferred behaviors; the relative weight placed on the cost faced by the emotional system is $\phi(W, \sigma)$.

Our framework of analysis is based on the following three premises.

- A1:** The cognitive system behaves like the textbook economic agent that operates in a world of emotionless deliberation.
- A2:** Evidence from the behavior of animals who lack the prefrontal cortex and who share their primitive mammalian brain with us is used to infer the preferences of the emotional system.
- A3:** When the required evidence in A2 is not available, then the actual behavior of humans is used to recover the preferences of the emotional self.

We now apply this framework to three different domains: Intertemporal choice, behavior under risk, and social preferences. This gives rise to a range of applications. A partial list includes: the effectiveness of advertising even when it conveys no useful information, breakdown of bargaining when there are mutual gains to be shared, unpleasant divorces, and behavior in financial markets.

INTERTEMPORAL CHOICE

Assume that the cognitive system is driven by long-term payoffs and it uses exponential discounting. Evidence from animal studies suggests extreme myopia in pigeons. There is also evidence of myopia in monkeys (Tobin et al., 1996; Stevens et al., 2005). So the objective of the emotional system is also assumed to be myopic.

Formally, suppose that an individual faces a stream of dated consumption levels, $x_1, x_2, \dots, x_T$. In line with premise A1, the utility of the cognitive system is $U^c = \sum_{j=1}^T \delta^{j-1} x_j$, where δ is the discount factor. Using premise A2 and the evidence from animal behavior, the emotional system is myopic, so its utility is given by $U^e = \lambda x_1$, where $\lambda > 0$. Substituting these expressions in (18.4) we get

$$V^c = \sum_{j=1}^T \delta^{j-1} x_j + \phi(W, \sigma) \lambda x_1. \quad (18.6)$$

Maximizing (18.6) is equivalent to maximizing

$$\tilde{V}^c = x_1 + \beta \sum_{j=2}^T \delta^{j-1} x_j, \text{ where } \beta = \frac{1}{1 + \lambda \phi(W, \sigma)} < 1. \quad (18.7)$$

The preferences expressed in (18.7) are the (β, δ) preferences of *quasi-hyperbolic discounting* (see Part 3 of the book). Depletion of willpower (reduction in W) or an increase in the cognitive load (increase in σ) increases $\phi(W, \sigma)$. Equivalently, the testable prediction of the model is that these changes (reduction in W and increase in σ) decrease β , resulting in more myopic behavior. The Shiv and Fedorikhin (1999) results mentioned above are consistent with this prediction. Vohs and Heatherton (2000) find that willpower depletion among dieters leads them to buy more ice cream. Benjamin et al. (2013) give problems to Chilean high school students with short-term and long-term trade-offs. Cognitive load leads to a reduction in short-term patience. Another prediction of the model that can be derived from its interpretation in (18.5) is that an increase in $\phi(W, \sigma)$ puts greater weight on the relative cost of moving the emotional system away from its most preferred outcome. So factors that enhance the emotional desire such as proximity to stimuli are predicted to lead to greater myopia. The results of Mischel et al. (2003) mentioned above are supportive of this prediction.

BEHAVIOR UNDER RISK

Suppose that an individual faces the lottery

$$L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n),$$

where $x_i \in R$ is the i th outcome, $p_i \geq 0$ the associated probability, and $p_1 + \dots + p_n = 1$. Given premise A1, we assume that the cognitive system uses expected utility theory. We assume the special case of expected value maximization, so

$$U^c = \sum_{i=1}^n x_i p_i. \quad (18.8)$$

What preferences should we assign to the emotional system? These issues were considered in more detail in Section 17.2.2 (Loewenstein, 2001). In studies that measure physiological response to unexpected events, the intensity of the shock rather than the likelihood of receiving it, is

the key. Other studies show that mental images of outcomes are the key to eliciting emotional responses, and that such responses are invariant to probabilities of outcomes (Loewenstein and O'Donoghue, 2007). Evidence that individuals often ignore information on probabilities when purchasing house insurance is also given in the work of Kunreuther et al. (1978).

Ditto et al. (2006) gave 80 undergraduates the option to undertake or avoid the following risky task: Work on a boring task in the lab for an extra 30 minutes with a probability that could be high (more risky) or low (less risky). The prize was chocolate chip cookies. Participants who could see and smell the cookies while they made their decision were less sensitive to risk information. In this case, under high risk and low risk, respectively, 80% and 85% of the players opted to undertake the task. In contrast, when the cookies were merely described (but not seen or smelt), participants were much more sensitive to the level of risk; 45% played the game under high risk and 95% under low risk. Insofar as the sight and smell of the cookies engages the emotional system, this evidence lends further support to the view that information on probabilities is relatively less salient for the emotional system.

In light of this evidence, suppose that the utility function of the emotional system is $U^e = \sum_{j=1}^n x_i/n = \bar{x}$, i.e., it cares only for the unweighted average of the outcomes, ignoring probabilities. Substituting U^c , U^e in (18.4) we get

$$V^c = \sum_{j=1}^n x_i p_i + \phi(W, \sigma) \bar{x}. \quad (18.9)$$

Maximizing (18.9) is equivalent to maximizing

$$\hat{V}^c = \sum_{j=1}^n \pi_i x_i, \text{ where } \pi_i = \frac{p_i + \phi/n}{1 + n\phi}. \quad (18.10)$$

It is evident from (18.10) that

$$p_i \geq \pi_i \text{ as } p_i \geq \frac{1}{n^2} = \hat{p}. \quad (18.11)$$

Hence, when the probability of an event is low enough ($p_i < \hat{p}$), then the decision weight is higher than the probability; the converse is true for high probability events ($p_i > \hat{p}$). This is consistent with an *inverse S-shaped* π . From Part I we know that the probability weighting function is inverse S-shaped. Thus, $\hat{V}^c$ is similar to the objective function of a prospect theory maximizer, as in the original 1979 version of prospect theory (see Part I), but not with rank dependent utility or with the cumulative probability version of prospect theory in Tversky and Kahneman (1992). Noting that $\partial \pi_i / \partial \phi > 0$ and $\phi_1 < 0$, $\phi_2 > 0$ we can predict when π becomes more or less S-shaped. If an individual's willpower is depleted or there is a greater cognitive load, then the decision weights should become more S-shaped.

A pervasive experimental finding when there are both positive and negative outcomes in a lottery, L , is *loss aversion*. Loss aversion implies that losses are more salient than equivalent gains, i.e., the absolute value of disutility from losses is greater than the utility from gains that are of the same magnitude. There is evidence that capuchin monkeys also exhibit loss aversion (Chen et al., 2006; see Part I for details). Using premises A2, A3, we postulate that the emotional system exhibits loss aversion according to the following utility function.

$$U^e = \begin{cases} x_i & \text{if } x_i \geq 0 \\ \lambda x_i & \text{if } x_i < 0 \end{cases}, \quad (18.12)$$

where $\lambda > 1$ is the parameter of loss aversion. Substituting (18.8), (18.12) in (18.4) we get that maximizing V^c is equivalent to maximizing

$$\bar{V}^c = \sum_{j=1}^n v(x_j), \quad (18.13)$$

where

$$v(x_i) = \begin{cases} x_i & \text{if } x_i \geq 0 \\ \hat{\lambda}x_i & \text{if } x_i < 0 \end{cases}, \text{ and } \hat{\lambda} = \frac{p_i + \lambda\phi}{p_i + \phi} > 1.$$

Hence, a loss averse emotional system induces loss aversion in the cognitive system. Furthermore, $\hat{\lambda} < \lambda$ so the cognitive system is less loss averse relative to the emotional system. Noting that $\partial \hat{\lambda}_i / \partial \phi > 0$ and $\phi_1 < 0, \phi_2 > 0$, willpower depletion and an increase in the cognitive load lead to an increase in the loss aversion of the cognitive system, $\hat{\lambda}$. Also, factors such as proximity of the stimuli that enhance the role of the emotional system (increase in ϕ) increase $\hat{\lambda}$. Benjamin et al. (2013) provide some evidence that is consistent with the first prediction. See Loewenstein and O'Donoghue (2007) for evidence supporting the second prediction.

SOCIAL PREFERENCES

Consider two individuals, labeled 1 and 2, who have respective material payoffs of x_1 and x_2 . There is evidence that the cognitive system takes account of the payoffs of others, consistent with some notion of an equitable or ethical payoff (Loewenstein and O'Donoghue, 2007). Thus, the utility of the cognitive system for individual $i = 1, 2$, is assumed to be given by $U_i^c = x_i + w_i^c x_j, j = 1, 2$ and $j \neq i$; $w_i^c > 0$ is the weight put by the cognitive system on the payoff of the other player, x_j .

Animals as well as humans often demonstrate empathy and sympathy towards others. Loewenstein and O'Donoghue (2007) review some relevant evidence; they write (p. 41) "rats who view a distressed fellow rat suspended in air by a harness will press a bar to lower the rat back to safe ground." In another experiment, as one rat is subjected to electric shocks, another rat, who is watching, retreats to a corner, motionless. In yet another experiment, monkeys could pull one of two chains to receive food with one of the chains delivering twice the amount but also an electric shock to another monkey in sight. Two thirds of the monkeys preferred the "less food" chain; one monkey refused to pull either chain for 5 days and another refused for 12 days.⁵ In general, it appears that the emotional system can demonstrate extreme empathy or antipathy towards others. We assume that the preferences of the emotional system of individual $i = 1, 2$, are given by $U_i^e = x_i + w_i^e x_j, j = 1, 2$ and $j \neq i$, and $w_i^e \geq 0$; a positive weight captures altruism and a negative weight captures envy.

Substituting U_i^c, U_i^e in (18.4) we get

$$V^c = x_i + w_i^c x_j + \phi(W, \sigma) [x_i + w_i^e x_j]. \quad (18.14)$$

The cognitive system chooses x_i, x_j to maximize V^c in (18.14); equivalently, it maximizes

$$V^{c*} = x_i + \omega_i x_j, \text{ where } \omega_i = \frac{(w_i^c + \phi w_i^e)}{1 + \phi}.$$

⁵ For a review of these studies, see Preston and de Waal (2002).

It is clear that

$$\omega_i \geq w_i^c \Leftrightarrow w_i^e \geq w_i^c.$$

Hence, the emotional system might induce the cognitive system to assign a lower weight to the payoff of the other player when $w_i^e < w_i^c$. Indeed, if $w_i^e < 0$ and $\frac{w_i^e}{\phi} < |w_i^c|$, then the cognitive system, which is inherently altruistic ($w_i^c > 0$), becomes envious, $\omega_i < 0$, and derives utility by lowering the payoff of the other individual. If, on the other hand, $w_i^e > w_i^c$, then the emotional system amplifies the altruism of the cognitive system. Furthermore, ω_i is increasing (decreasing) in per unit costs of willpower, ϕ , if $w_i^e - w_i^c$ is positive (negative). Hence, depending on the relative empathy triggered in the emotional system, it is possible that a decrease in willpower or an increase in cognitive load/stress (which increase ϕ) can either increase or decrease a concern for the payoff of others.

A NOTE ON WELFARE COMPARISON

Neoclassical economics typically uses revealed preference arguments to make welfare comparisons. An individual's actual choices are used to make inferences about preferences. These preferences can be used to make statements about the well-being of the individual when the environment changes. Central to this exercise is the view that individuals choose options that maximize their well-being.

Behavioral economics, on the other hand, shows that individuals might not always behave in their best interest. Should a social planner stand back and respect individual preferences? In the context of the dual process models, two main candidate functions for behavioral welfare economics are U^c and V^c (see (18.3) for the relation between the two); we can rule out U^e as it is too unstable with respect to the stimulus. However, there are interesting arguments associated with each of them.

The main argument in favor of U^c is that it captures the behavior of the cognitive system from a detached perspective. But there are two important drawbacks of using U^c . First, the set of emotional states is an argument of U^c and so imparts to it a degree of instability. Second, most people would agree that, fixing outcomes, a policy that reduced the need to exercise willpower and so reduced per unit willpower costs, ϕ , would be an improvement. This is not guaranteed by U^c . While the second of these criticisms can be avoided by considering V^c as the appropriate criterion, however, the presence of emotional states as an argument in V^c does not eliminate the first criticism. Thus, advertising by firms might appeal to the emotional system of an individual, so it also has an affect on V^c , yet the advertisements might not always promote the best-long term interests of the individual. For instance, for a long time, advertisements associated cigarette smoking with a macho image, yet the advertised product was known to the cigarette companies to be harmful to the consumers.

18.3 A dual selves model with costly commitment

One possible framework to model emotions is to consider each individual as comprising of a patient long-run (LR) self and a myopic short-run (SR) self. These are models of *dual selves*. An example is the Shefrin and Thaler (1988) model that we considered in Part 3 of the book. Here, we consider another model in this tradition, due to Fudenberg and Levine (2006).

A model that is related to the dual selves model is the model of *multiple-selves* (see Part 3 of the book). Fudenberg–Levine claim that dual selves models are better grounded in psychological evidence, and are analytically simpler. Furthermore, these models typically have a unique equilibrium, while models of multiple-selves often have multiple equilibria. We use a simple consumption–savings model to illustrate the dual selves model.

18.3.1 *The model without commitment*

Consider an infinitely lived consumer who makes a consumption–savings decision in each time period $t \in T = \{1, 2, \dots, \infty\}$. In any period, the consumer has wealth y_t , which can either be consumed, c_t , or saved, s_t . There is no other source of income. There is an exogenous and time-invariant gross return of $R = 1 + r$ on each unit of savings carried over to the next period, hence, $y_{t+1} = R s_t$. Initial wealth y_1 is given exogenously. Suppose that the marginal propensity to save is α_t in period $t \in T$ so that $s_t = \alpha_t y_t$ and $c_t = (1 - \alpha_t) y_t$. The resource constraint at time $t + 1$ is given by

$$y_{t+1} = R \alpha_t y_t, t \in T. \quad (18.15)$$

The objective of the SR self is to myopically maximize current utility. Thus, the SR self chooses α_t to maximize

$$u(y_t, \alpha_t) = \log(1 - \alpha_t) y_t = \log c_t, t \in T. \quad (18.16)$$

In the absence of any control exerted by the LR self, the optimal choice of the SR self, from (18.16), is to choose $\alpha_t = 0$, i.e., consume the entire current income.

The LR self can induce the SR self to choose some non-zero marginal propensity to save, $\alpha_t \neq 0$, by expending some self-control or willpower costs, $C(y_t, \alpha_t)$. Assuming that these costs are linear and proportional to the amount saved, we get

$$C(y_t, \alpha_t) = \gamma [\log(1 - 0) y_t - \log(1 - \alpha_t) y_t] = -\gamma \log(1 - \alpha_t), t \in T. \quad (18.17)$$

In (18.17), $\gamma > 0$ is the marginal cost of inducing the SR self to save extra. Furthermore, C is increasing and convex in α_t .

The LR self uses exponential discounting to maximize the present discounted value of lifetime consumption, subject to the resource constraint in (18.15). Hence, the utility of the LR self is given by

$$U = \sum_{t=1}^{\infty} \delta^{t-1} [u(y_t, \alpha_t) - C(y_t, \alpha_t)], \quad (18.18)$$

where $0 < \delta < 1$ is the discount factor, $u(y_t, \alpha_t)$ is defined in (18.16), and $C(y_t, \alpha_t)$ is defined in (18.17). Comparing (18.16), (18.18), the instantaneous utility functions of the LR self and the SR self are identical, except for the costs of self-control. Substitute (18.16), (18.17) in (18.18) and add and subtract $\gamma \log(1 - \alpha_t) y_t$ from the instantaneous utility function to get

$$U = \sum_{t=1}^{\infty} \delta^{t-1} [(1 + \gamma) \log(1 - \alpha_t) y_t - \gamma \log y_t]. \quad (18.19)$$

The problem of the LR self is to choose the sequence of marginal propensities to save, $\{\alpha_t\}_1^\infty$, in order to maximize (18.19) subject to the constraint (18.15). Fudenberg and Levine (2006) show that the unique solution is a constant, time-invariant, savings rate, α , that lies between zero and one.⁶ When $\alpha_t = \alpha$ for all t , then (18.15) can be solved recursively to give

$$y_t = (R\alpha)^{t-1} y_1, \quad (18.20)$$

where y_1 is the initial level of wealth. Substitute (18.20) in (18.19) we get

$$U = \frac{(1 + \gamma)}{1 - \delta} [\log(1 - \alpha) + \log y_1] + \frac{\delta}{(1 - \delta)^2} \log R\alpha. \quad (18.21)$$

Since we have an interior and unique solution, using $\frac{\partial U}{\partial \alpha} = 0$, we get the optimal value of α ,

$$\alpha = \frac{\delta}{1 + \gamma(1 - \delta)}. \quad (18.22)$$

As γ , the per unit cost of inducing the SR self to save an extra unit increases, it becomes optimal to reduce α , the marginal propensity to save. Furthermore, $\frac{\partial}{\partial \delta} \left(\frac{\partial \alpha}{\partial \gamma} \right) > 0$, thus, as the degree of patience (as reflected in the magnitude of δ) increases, the marginal impact of self-control costs on the savings rate increases.

In the special case of no self-control costs, we have $\gamma = 0$; in this case, using (18.22), the optimal savings rate, denoted by α^* , is

$$\alpha^* = \delta. \quad (18.23)$$

Hence, optimal consumption in the absence of self-control costs is

$$c_t^* = (1 - \delta) y_t, \quad t \in T. \quad (18.24)$$

Substitute (18.23) in (18.21) to get

$$U = \frac{1}{1 - \delta} [\log(1 - \delta) + \log y_1] + \frac{\delta}{(1 - \delta)^2} \log R\delta. \quad (18.25)$$

In the absence of self-control costs, (18.25) expresses lifetime utility of the LR self as a function of initial wealth, the discount rate, and the rate of return on savings.

18.3.2 *Commitment via a cash-in-advance constraint*

So far we have assumed that the LR self does not have access to a commitment technology. For that reason, the LR self can only control the SR self through the costly exercise of willpower. We now allow for the possibility that such a technology is available; essentially we wish to give the

⁶ The proof is available in the supplementary section of an earlier version of the paper by Fudenberg and Levine (2006) and applies to any CRRA utility function of which log utility is a special case.

LR self the power to remove the source of temptation for the SR self. Each period is now divided into two sequential subperiods: the *bank subperiod* and the *nightclub subperiod*.

At any time t , in the first subperiod, the bank subperiod, there is no consumption temptation. The LR self chooses, in this period, to save some amount $s_t = \alpha_t y_t$. This amount is kept in the bank and available only in the next period at time $t + 1$. The rest, $x_t = (1 - \alpha_t)y_t$, is passed on to the second subperiod in time t , as cash. In the nightclub subperiod, the SR self has access to a cash amount, x_t , and it consumes an amount, c_t , such that $0 \leq c_t \leq x_t$; consumption always takes place only in the nightclub subperiod. The discount factor between two successive nightclub subperiods is δ .

Any cash leftover from the nightclub subperiod of period t , i.e., $x_t - c_t \geq 0$, is deposited into the bank and carried over to period $t + 1$, along with the savings, s_t , made in the bank subperiod of period t . There is a time-invariant gross return R on savings, hence, the individual's wealth at the beginning of period $t + 1$ is

$$y_{t+1} = R(s_t + x_t - c_t). \quad (18.26)$$

We look at two possible subcases.

I. Savings is the only source of income

The LR self can costlessly impose any savings rate in any period by controlling the amount of cash available to the SR self to spend; this is the commitment technology. From (18.23), we know that in the absence of self-control costs, $\alpha^* = \delta$. This savings rate can be readily implemented by choosing to pass on the cash

$$x_t = (1 - \delta)y_t, \quad (18.27)$$

to the SR self in the nightclub period. Since the SR self is completely myopic, it will immediately consume all the cash received.

II. Stochastic income augments savings income

At $t = 1$, the cash available for the SR self in the nightclub period is x_1 . Now suppose that in the first, and only the first, nightclub subperiod, the SR self faces additive income uncertainty of the following form: Income is $x_1 + \tilde{z}_1$, where $\tilde{z}_1$ is a random variable with density f . The interpretation is that the income of the SR self is $x_1 + z_1$ with probability $f(z_1)$ for all z_1 in the support of f . Then the budget constraint for the SR self in the first nightclub period is given by

$$c_1 \leq x_1 + z_1. \quad (18.28)$$

We need to study the individual's optimization problem for each possible realization, z_1 . Second period wealth is given by

$$y_2 = R(s_1 + x_1 + z_1 - c_1) \equiv R(y_1 + z_1 - c_1), \quad (18.29)$$

where $s_1 + x_1 \equiv y_1$ and $y_1 + z_1$ gives the actual income in period 1. Net of first period consumption, c_1 , the savings are invested at a gross rate R to give y_2 .

The random income is available only in the first nightclub subperiod, leading to a potential violation of the cash-in-advance constraint for the SR self. Hence, the first best outcome is no longer guaranteed. The SR self in the first nightclub subperiod could have extra cash, z_1 , to play

around with, hence, the LR self, in the first period, might wish to exert costly willpower effort. The cost of this effort is as given in (18.17),

$$C = \gamma [\log(x_1 + z_1) - \log c_1].$$

The first period utility of the LR self is $\log c_1 - \gamma [\log(x_1 + z_1) - \log c_1]$, which can be written as

$$(1 + \gamma) \log c_1 - \gamma \log(x_1 + z_1). \quad (18.30)$$

From the second period onwards, however, there is no need to exert costly willpower because the SR self faces no subsequent income uncertainty and, so, the cash-in-advance constraint is never violated. Hence, the lifetime utility of the LR self starting from period 2 is found by substituting $y_2 = y_1$ in (18.25) (taking account that we are summing from period 2 onwards) to give

$$\frac{\delta}{1 - \delta} [\log(1 - \delta) + \log y_2] + \frac{\delta^2}{(1 - \delta)^2} \log R\delta. \quad (18.31)$$

Putting together (18.30), (18.31), the LR self maximizes

$$(1 + \gamma) \log c_1 - \gamma \log(x_1 + z_1) + \frac{\delta}{1 - \delta} [\log(1 - \delta) + \log y_2] + \frac{\delta^2}{(1 - \delta)^2} \log R\delta, \quad (18.32)$$

subject to (18.29). We ignore the constraint (18.28) for the time being. The first order condition with respect to c_1 gives the optimal value of first period consumption

$$c_1^* = (1 - \theta) (y_1 + z_1), \text{ where } \theta = \frac{\delta}{\delta + (1 + \gamma)(1 - \delta)} < 1. \quad (18.33)$$

From (18.23), (18.24) in the absence of self-control problems, optimal consumption is $(1 - \delta) y_1$. One gets a similar result from (18.33) when willpower costs per unit $\gamma = 0$; here one gets $c_1^* = (1 - \delta) (y_1 + z_1)$.

Whether the individual gets to consume the optimal amount c_1^* , given in (18.33), depends on whether (18.28) binds. If $c_1^* \leq x_1 + z_1$, then c_1^* is implemented. If $c_1^* > x_1 + z_1$, then the first period consumption is constrained by the upper bound $x_1 + z_1$, so all pocket cash is consumed by the SR self in the first nightclub subperiod.

Suppose $c_1^* \leq x_1 + z_1$. Since x_1 is the solution to $\gamma = 0$ we know from (18.27), that $x_1 = (1 - \delta) y_1$. Substituting this in (18.28), if

$$c_1^* \leq (1 - \delta) y_1 + z_1 \quad (18.34)$$

then the optimal consumption plan is implemented. Define by z_1^* the value of z_1 such that (18.34) just binds, i.e.,

$$\left(1 - \frac{\delta}{\delta + (1 + \gamma)(1 - \delta)}\right) (y_1 + z_1^*) = (1 - \delta) y_1 + z_1^*,$$

which gives $z_1^* = \gamma (1 - \delta) y_1$.

Figure 18.2 Willpower costs and optimal consumption.

Figure 18.2 plots the two terms on the left and the right hand sides of (18.34). c_1^* is plotted for two values of $\gamma = 0$ and $\gamma > 0$. When $\gamma = z_1 = 0$, then $c_1^*|_{\gamma=0, z_1=0} = (1 - \delta)y_1$; the slope of $c_1^*|_{\gamma=0}$ is δ . An increase in γ reduces the value of θ in (18.33), hence, increasing the intercept and slope of the curve $c_1^*|_{\gamma>0}$ relative to that of $c_1^*|_{\gamma=0}$. The intersection of the curves $c_1^*|_{\gamma>0}$ and $(1 - \delta)y_1 + z_1$ in (z_1, c_1) space corresponds to $z_1 = z_1^*$.

For all $z_1 < z_1^*$, $c_1^* > (1 - \delta)y_1 + z_1$, hence, consumption is bounded above by $(1 - \delta)y_1 + z_1$ and the SR self does not deposit any cash in the bank to be carried forward to the next period. For all $z_1 > z_1^*$, $c_1^* < (1 - \delta)y_1 + z_1$, hence, the SR self deposits surplus cash into the bank for the next period. In the absence of self-control problems ($\gamma = 0$) we have $z_1^* = 0$, hence, the SR self does not spend all the increment in income, for any level of $z_1 > 0$.

Consider the case $\gamma > 0$. It follows that in the range of small windfalls, $z_1 < z_1^*$, an increase in unanticipated income is fully consumed (because $c_1^* > (1 - \delta)y_1 + z_1$). On the other hand, in the range of large windfalls, $z_1 > z_1^*$, an increase in unanticipated income is not fully consumed (because $c_1^* < (1 - \delta)y_1 + z_1$).

A final implication is that in an appropriately modified model where the windfall gains are deposited in a bank, the marginal propensity to consume out of these gains would be lower. The reason is that the LR self cares about future time periods and, hence, would desire to smooth out consumption.

Fudenberg–Levine show that by assuming a convex cost of delay in the model above, they can explain other behavioral findings. These include the Allais paradox and the positive relation between cognitive load and risk aversion. Benjamin et al. (2013) give empirical evidence to show that as cognitive load increases, people become more risk averse. Cognitive load was induced by asking the subjects to remember a seven digit number when they play lotteries in Allais-type paradoxes. This can also provide an explanation for the Allais paradox. However, this does not explain why the Allais paradox should arise in the absence of cognitive load (see Part 1 of the book).

Fudenberg–Levine also fit their model to estimated macroeconomic parameters such as the interest rate and the coefficient of relative risk aversion. However, some of the results are quite sensitive to the parameters used. It is also not clear how this model would explain a range of

other behavioral regularities that rely on reference dependence, loss aversion, and non-linear probability weighting (see Part I of the book for details).

18.4 Information asymmetries between emotions and cognition

In this section, we consider a fairly speculative framework that models the interaction between a myopic emotional system/module and a farsighted cognitive system/module in the presence of information asymmetries between the two (Brocas and Carillo, 2008).⁷ To borrow an analogy from principal-agent models, the cognitive module is the principal and the emotional module is the agent.

Suppose that there are only two time periods, $t = 1, 2$. In each period, the individual's consumption and labor are denoted, respectively, by

$$c_t \geq 0, l_t \in [0, L], \quad (18.35)$$

where L is an upper limit on available labor. The emotional system is self-regarding and myopic, so it cares only about instantaneous utility, which takes the quasi linear form

$$U_t(c_t, l_t; \theta_t) = \theta_t u(c_t) - l_t; \theta_t > 0. \quad (18.36)$$

θ_t is a parameter of preferences that enhances the marginal utility of consumption. We assume that θ_t is *iid* over time and takes two possible values, θ_L, θ_H , with associated probabilities $p, 1 - p$, and $0 < \theta_L < \theta_H$.⁸ Furthermore, $u' > 0, u'' < 0$.

In contrast to the emotional system, the cognitive system is utilitarian and farsighted, with preferences given by $U_1 + U_2$. The cognitive system is treated as the *principal* and the emotional system in period $t = 1, 2$ is the *agent* in that period.

The individual can transform one unit of labor into one unit of income, so the wage rate is 1. Saving, s , made in period 1, earns a risk-free per unit rate of return, $r > 0$. The budget constraints in the two periods are respectively

$$c_1 + s \leq l_1 \text{ and } c_2 \leq l_2 + (1 + r)s. \quad (18.37)$$

Second period consumption can be increased not just by working hard in period 2 but also by working hard and saving more in the first period. This feature will be important in the model. Since the marginal utility of consumption is always positive, the budget constraints hold with equality. Eliminating s from the two budget constraints, we get the intertemporal budget constraint

$$c_1 + \frac{c_2}{(1 + r)} = l_1 + \frac{l_2}{(1 + r)}. \quad (18.38)$$

⁷ For a brief survey of these models that also considers a wider range of issues such as a better understanding of memory and multitasking, see Brocas and Carillo (2014).

⁸ Brocas and Carillo (2008) consider a continuous distribution of θ . However, our two types case is able to illustrate the main points.

18.4.1 The full information equilibrium

Under full information, the principal (the cognitive system) knows the values of θ_1, θ_2 . This enables it to design contracts $\{c_1(\theta_1), l_1(\theta_1)\}, \{c_2(\theta_2), l_2(\theta_2)\}$, respectively, for the two agents, namely, the emotional systems at dates $t = 1$ and $t = 2$.⁹ The principal chooses c_1, l_1, c_2, l_2 in order to maximize the following objective function

$$(\theta_1 u(c_1) - l_1) + (\theta_2 u(c_2) - l_2), \quad (18.39)$$

subject to the feasibility constraints in (18.35) and the intertemporal budget constraint in (18.38). Ignoring (18.35) for the time being, the Lagrangian is

$$Z = (\theta_1 u(c_1) - l_1) + (\theta_2 u(c_2) - l_2) + \lambda \left[l_1 + \frac{l_2}{(1+r)} - c_1 - \frac{c_2}{(1+r)} \right],$$

where λ is the Lagrangian multiplier on the intertemporal budget constraint. The first order conditions for an interior solution to c_1, c_2 are

$$\frac{\partial Z}{\partial c_1} = 0 \Leftrightarrow \theta_1 u'(c_1) = \lambda. \quad (18.40)$$

$$\frac{\partial Z}{\partial c_2} = 0 \Leftrightarrow \theta_2 u'(c_2) = \frac{\lambda}{1+r}. \quad (18.41)$$

The partial derivatives of the Lagrangian with respect to l_1, l_2 are,

$$\frac{\partial Z}{\partial l_1} = -1 + \lambda, \quad (18.42)$$

$$\frac{\partial Z}{\partial l_2} = -1 + \frac{\lambda}{1+r}. \quad (18.43)$$

There is no interior solution to the labor supply in both periods. Suppose to the contrary that $l_1, l_2 \in (0, L)$. Then (18.42), (18.43) hold with equality. But this implies that $r = 0$, a contradiction. There is a boundary solution $l_1 = L$ at which $\frac{\partial Z}{\partial l_1} > 0$. The intuition is that one unit of labor in period 1 generates one unit of income (and one unit of disutility). This can be converted to $1 + r$ units of second period consumption. Since there is no discounting between the two periods, and $r > 0$, it is optimal that the full information solution to first period labor supply attains its upper bound, $l_1^F = L$ and the solution to l_2 is an interior one, so $\lambda = 1 + r$.

Substituting λ in (18.40), (18.41) gives the solution for c_1 and c_2 . Given $l_1^F = L$, l_2 can then be recovered from (18.38). Thus, the solution under full information is given by

$$\theta_1 u'(c_1^F) = 1 + r. \quad (18.44)$$

$$\theta_2 u'(c_2^F) = 1. \quad (18.45)$$

$$l_1^F = L, l_2^F = c_1^F(1+r) + c_2^F - L(1+r). \quad (18.46)$$

⁹ This is clearly a massively reduced-form and fairly strong assumption, the microfoundations of which are not entirely established.

The conditions (18.44), (18.45) equate the marginal utility of consumption in periods 1 and 2, respectively, with the opportunity cost. Each unit of consumption in period 1 leads to $1+r$ units of forgone second period consumption, while the opportunity cost of an extra unit of consumption in period 2 is one unit of forgone leisure. From (18.46), we can check if the solution to l_2 is an interior one.

18.4.2 The asymmetric information equilibrium

Now suppose that only the emotional system knows the true value of θ_t , $t = 1, 2$. Using backward induction, we first solve the period 2 problem. In period 2, the preferences of the emotional system and the cognitive system coincide because there is no future to worry about. The second period optimization problem is to choose c_2, l_2 to maximize

$$\theta_2 u(c_2) - l_2,$$

subject to the budget constraint

$$c_2 \leq l_2 + (1+r)(l_1 - c_1),$$

where we have used $s = (l_1 - c_1)$. Since $u' > 0$, the budget constraint binds. We can substitute l_2 from the binding budget constraint into the objective function to get an unconstrained optimization problem in c_2 . The optimal solution, $c_2^*(\theta_2)$, can be found from the first order condition

$$\theta_2 u'(c_2^*) = 1, \quad (18.47)$$

i.e., marginal utility from consumption equals its opportunity cost. The optimal second period labor supply, $l_2 = l_2^*$, can now be found from the budget constraint

$$l_2^*(\theta_2) = c_2^*(\theta_2) + (l_1 - c_1)(1+r). \quad (18.48)$$

In the first period, the preferences of the two systems are in conflict. Hence, the full information contracts are not incentive compatible under asymmetric information. Under full information, $\theta_1 u'(c_1^F) = 1+r$ and $l_1(\theta_L) = l_1(\theta_H) = L$. Since $0 < \theta_L < \theta_H$ it follows that $c_1^F(\theta_L) < c_1^F(\theta_H)$. Type θ_L will then benefit by misstating type to be θ_H in order to receive extra consumption without working harder. Hence, the principal (cognitive system) needs to design incentive compatible contracts.

Denote the contracts under asymmetric information by $\{c_1(\theta_L), l_1(\theta_L)\}$ and $\{c_1(\theta_H), l_1(\theta_H)\}$. While private contracts are enforceable by law or by the oversight of third parties, what prevents the cognitive system from reneging on the promised consumption, once the contractual amount of labor has been put in? There are no clear cut answers to these difficult questions. Brocas and Carillo (2008) conjecture that other areas of the brain might be involved in such enforcement and claim supporting evidence from neuroscientific studies.

We can use the revelation principle to find the first period optimal contracts $\{c_1(\theta_L), l_1(\theta_L)\}$ and $\{c_1(\theta_H), l_1(\theta_H)\}$ as the solution to the following problem.

$$\text{Max}_{\{c_1(\theta_1), l_1(\theta_1)\}} E_{\theta_1} [\theta_1 u(c_1(\theta_1)) - l_1(\theta_1)] + E_{\theta_2} [\theta_2 u(c_2^*(\theta_2)) - l_2^*(\theta_2)]. \quad (18.49)$$

Subject to (18.35), (18.47), (18.48), and the two incentive compatibility constraints for types θ_L, θ_H , respectively,

$$IC_L : \theta_L u(c_1(\theta_L)) - l_1(\theta_L) \geq \theta_L u(c_1(\theta_H)) - l_1(\theta_H). \quad (18.50)$$

$$IC_H : \theta_H u(c_1(\theta_H)) - l_1(\theta_H) \geq \theta_H u(c_1(\theta_L)) - l_1(\theta_L). \quad (18.51)$$

The objective function in (18.49) reflects uncertainty arising from the two periods. The operators E_{θ_1} and E_{θ_2} denote, respectively, expectations with respect to θ_1 and θ_2 ; each variable takes the value θ_L with probability p and θ_H with probability $1 - p$. The IC_L constraint requires that type θ_L cannot do better by mimicking type θ_H , while the IC_H constraint rules out similar mimicking by type θ_H . A notable difference from standard mechanism design problems is the absence of participation constraints, as it is not clear what they would imply in the current context.

The most important insight of the model can be obtained directly from the two incentive compatibility constraints. As in standard mechanism design models, IC_H binds.¹⁰ From the binding IC_H constraint we get

$$l_1(\theta_H) = \theta_H [u(c_1(\theta_H)) - u(c_1(\theta_L))] + l_1(\theta_L). \quad (18.52)$$

Substituting (18.52) in IC_L we get that $u(c_1(\theta_H)) \geq u(c_1(\theta_L))$, or $c_1(\theta_H) \geq c_1(\theta_L)$, so the level of consumption is monotonic in the type. From IC_L , we also get that

$$\theta_L [u(c_1(\theta_H)) - u(c_1(\theta_L))] + [l_1(\theta_L) - l_1(\theta_H)] \leq 0. \quad (18.53)$$

Since $u(c_1(\theta_H)) \geq u(c_1(\theta_L))$, a necessary condition for (18.53) to hold is that

$$l_1(\theta_L) \leq l_1(\theta_H). \quad (18.54)$$

This brings us to the crux of the solution. Type θ_L would like to claim to be type θ_H if it cared about consumption alone (because $c_1(\theta_H) \geq c_1(\theta_L)$). Anticipating this incentive, the principal cleverly designs the contracts in such a way that (18.54) holds, so if type θ_L wants to consume more, then it must also work more. Since more work entails greater disutility, if $l_1(\theta_H)$ is sufficiently high, then type θ_L no longer has an incentive to misrepresent its type. The authors interpret this finding as explaining behaviors such as: “I will spend the weekend in Palm Springs only if I finish the paper by Friday” or “If I decide to watch the soccer game today, then I must first complete the referee report today.”

Consider the general case when θ_1 and θ_2 are distributed continuously over the interval $[\underline{\theta}, \bar{\theta}]$. The density of θ_1 is $f(\theta_1)$ and the distribution function is $F(\theta_1)$. In this case we get the following result.

Proposition 18.18 (*Brocas and Carillo, 2008*): *Under asymmetric information and a continuous distribution of θ_1, θ_2 the optimal contracts are as follows.*

- (i) *At time $t = 1$: There exists a cutoff point $\theta_c < \bar{\theta}$ such that the optimal contracts for all types $\underline{\theta} \leq \theta_1 < \theta_c$, denoted by $\{c_1^*(\theta_1), l_1^*(\theta_1)\}_{\underline{\theta}}^{\theta_c}$, are given by*

¹⁰ Brocas and Carillo (2008) demonstrate this property when θ has a continuous distribution.

$$\left[\theta_1 + r \left(\theta_1 + \frac{F(\theta_1)}{f(\theta_1)} \right) \right] u'(c_1^*(\theta_1)) = 1 + r, \quad (18.55)$$

while the optimal amount of labor elicited in the first period is

$$l_1^*(\theta_1) = L - \left[\bar{\theta} u(c_1^*(\bar{\theta})) - \theta_1 u(c_1^*(\theta_1)) - \int_{\theta_1}^{\bar{\theta}} u(c_1^*(x)) dx \right] < L. \quad (18.56)$$

For all $\theta_c \leq \theta_1 \leq \bar{\theta}$ there is pooling of contracts. Each of these types is given the contract $\{c_1^*(\theta_c), L\}$, where $c_1^*(\theta_c)$ is the optimal consumption given in (18.55), and evaluated at $\theta_1 = \theta_c$.

- (ii) At time $t = 2$: The principal allows the time 2 agent to choose any consumption–labour pair that satisfies the intertemporal constraint (18.38). The agent then, voluntarily, chooses

$$u'(c_2^*(\theta_2)) = \frac{1}{\theta_2} \text{ and } l_2^*(\theta_2) = (1 + r)(c_1^*(\theta_1) - l_1^*(\theta_1)) + c_2^*(\theta_2); \theta_2 \in [\underline{\theta}, \bar{\theta}].$$

Since $\theta_1 + r \left(\theta_1 + \frac{F(\theta_1)}{f(\theta_1)} \right) > \theta_1$, it follows by comparing (18.44) with (18.55) that $c_1^*(\theta_1) > c_1^F(\theta_1)$, hence, consumption in the first period under asymmetric information is larger than that under full information. This reflects the information rents derived by the better informed agent in period 1. From (18.46), (18.56), under asymmetric information, the first period emotional system is asked for a lower amount of labor relative to that under full information. Hence, relative to full information, first period consumption is larger and first period labor supply is smaller. Thus, it is as if an endogenous rate of time preference develops under asymmetric information despite the fact that the cognitive self undertakes no time discounting.

18.5 Strategic ignorance, confidence, and self-esteem

In this section we consider models of multiple-selves in which individuals may have asymmetric information about some aspects of their own characteristics; for instance, about their willpower, ability, or motivations. Individuals might engage in introspection to discover themselves, or use their performance in a task to discover their underlying motivations or abilities. In this scenario, individuals might decide to strategically transmit or hide information to their own future selves, or even manage their degree of awareness of personal qualities. Among the set of phenomena explained by this model are the roles of strategic ignorance, selective memory transmission, and self-handicapping.

18.5.1 Strategic ignorance

Consider a three period version of the multiple-selves model in Carrillo and Mariotti (2000), where time $t = 1, 2, 3$; the self in period t is denoted by self t . Each self, in each period, is risk neutral and makes a simple binary consumption choice $x_t \in \{0, 1\}$; 0 denotes abstinence and 1 denotes consumption of a free good (introducing a cost of acquiring the good does not alter the qualitative predictions). To simplify further, we assume that self 3 chooses $x_3 = 0$. Current consumption increases instantaneous utility of self t but it reduces the utility of self $t + 1$ by $e > 1$

units (negative externality) with some probability $\theta \geq 0$; e.g., the good could be some unhealthy food/lifestyle.¹¹ θ is distributed uniformly over $[0, 1]$ with cumulative density F ; all selves are aware of the relevant distribution. In addition to the consumption decision, self 1 has to decide whether to costlessly learn the true value of θ .

The instantaneous utility of self t is given by

$$u_t = x_t - y_t, \quad (18.57)$$

where y_t is the externality caused by the consumption decision of self $t - 1$, so

$$y_t = \begin{cases} 0 & \text{if } x_{t-1} = 0 \\ \theta e & \text{if } x_{t-1} = 1 \end{cases}, \quad (18.58)$$

with the assumption that $x_3 = 0$. Preferences take the special *quasi-hyperbolic* $(\beta, 1)$ form, $0 < \beta < 1$ (see Part 3 of the book), so the utility of self t is

$$U_t = \begin{cases} u_1 + \beta(u_2 + u_3) & \text{if } t = 1 \\ u_2 + \beta u_3 & \text{if } t = 2 \\ u_3 & \text{if } t = 3 \end{cases}. \quad (18.59)$$

From (18.57), (18.58), (18.59) and the assumption that $x_3 = 0$, we can recursively solve backwards to work out the intertemporal utility of the successive selves.

$$U_3 = -\theta e x_2; \quad x_2 \in \{0, 1\}. \quad (18.60)$$

$$U_2 = (x_2 - \theta e x_1) + \beta(-\theta e x_2) = x_2(1 - \beta\theta e) - \theta e x_1; \quad x_1, x_2 \in \{0, 1\}. \quad (18.61)$$

$$U_1 = x_1 + \beta(x_2 - \theta e x_1) + \beta(-\theta e x_2) = x_1(1 - \beta\theta e) + x_2\beta(1 - \theta e); \quad x_1, x_2 \in \{0, 1\}. \quad (18.62)$$

Assume that $\frac{1}{\beta e} < 1$. We also make the tie-breaking assumption that when self t is indifferent between consuming and not consuming, he chooses to consume.

Using (18.62), the following three cases arise for self 1.

1. $0 \leq \theta \leq 1/e$: If $0 \leq \theta \leq 1/e$, then $1 - \beta\theta e > 0$ and $1 - \theta e \geq 0$. Thus, self 1 would like to consume in period 1 ($x_1 = 1$) and would also like self 2 to consume ($x_2 = 1$).
2. $\frac{1}{e} < \theta \leq \frac{1}{\beta e}$: If $\frac{1}{e} < \theta \leq \frac{1}{\beta e}$, then $1 - \beta\theta e \geq 0$ and $1 - \theta e < 0$. Thus, self 1 prefers to consume ($x_1 = 1$), and prefers self 2 to abstain from consumption ($x_2 = 0$).
3. $\frac{1}{\beta e} < \theta \leq 1$: In this case, self 1 prefers to abstain in both periods ($x_1 = x_2 = 0$).

With the present bias implied by $(\beta, 1)$ preferences, the preferences of self 2 are different from the preferences of self 1. Furthermore, self 1 cannot bind the choices of self 2.

4. From (18.61), it is apparent that self 2 will consume ($x_2 = 1$) if $1 - \beta\theta e \geq 0$, or $0 < \theta \leq \frac{1}{\beta e}$. Otherwise, if $\frac{1}{\beta e} < \theta \leq 1$, then self 2 abstains, $x_2 = 0$.

For self 1, if θ is high enough, so that x_2 causes a large enough negative externality in period 3, then self 1 prefers $x_2 = 0$ (as in case 2 above). However, self 2 is relatively biased towards x_2 on

¹¹ Carrillo and Mariotti (2008) also consider the more general case when current consumption creates a negative externality for all future selves.

account of his current bias and so always prefers $x_2 = 1$ unless $\frac{1}{\beta e} < \theta \leq 1$. We summarize these results in the following proposition.

Proposition 18.19 *Consider the split of the domain of θ into three regions.*

- (i) *If $\theta \in [0, \frac{1}{\beta e}]$, then there is no conflict between the choices of selves 1 and 2.*
- (ii) *If $\frac{1}{\beta e} < \theta \leq \frac{1}{\beta e}$, then there is strategic conflict between the two selves; self 1 prefers $x_2 = 0$, while self 2 prefers $x_2 = 1$.*
- (iii) *If $\frac{1}{\beta e} < \theta \leq 1$, then selves 1 and 2 prefer $x_2 = 0$.*

Let us now assume that self 1 can learn the true value of θ . As soon as the value of θ is learnt, self 2 is also privy to it; if the value is not learnt then self 2 can, at best, rely on the knowledge of the underlying distribution, F . We assume that memory cannot be unlearned, although we relax this assumption in Section 18.5.2 below.

Self 1 then knows that if $\theta \leq \frac{1}{\beta e}$, then there is no conflict with self 2 and the outcome is $x_1 = x_2 = 1$. On the other hand, if self 1 learns that $\frac{1}{\beta e} < \theta$, then there is no conflict either, and the outcome is $x_1 = x_2 = 0$. Suppose that self 1 decides not to learn the true value of θ . Since all selves are risk neutral and utility is linear in θ , the following result directly follows from our discussion.

Proposition 18.20 *(No learning and risk neutrality): If $E[\theta] \in [0, \frac{1}{\beta e}]$, then $x_1 = x_2 = 1$. However, if $\frac{1}{\beta e} < E[\theta]$, then $x_1 = x_2 = 0$.*

Let us now compute the utility of self 1 from the learning and the no learning options.

1. *Learning:* Denote the expected utility of self 1 from learning the true value of θ by U_1^L . Note that U_1^L is the utility under the learning option, but before the value of θ has been revealed. Then,

$$U_1^L = F\left(\frac{1}{\beta e}\right) \left[1 + \beta - 2\beta e E\left[\theta \mid \theta \leq \frac{1}{\beta e}\right] \right], \quad (18.63)$$

where $F\left(\frac{1}{\beta e}\right)$ is the cumulative probability that θ is at most equal to $\frac{1}{\beta e}$. In this case, selves 1 and 2 prefer to consume in their respective periods. The term in the square braces follows from risk neutrality, when (18.62) is evaluated at $x_1 = x_2 = 1$. With the complementary probability $1 - F\left(\frac{1}{\beta e}\right)$, none of the selves wants to consume and there is no externality caused to any self.

2. *No learning:* Denote the expected utility of self 1 if she chooses not to learn the true value of θ by U_1^N ; in this case self 2 only knows the distribution F of θ . Then, using Proposition 18.20 we get

$$U_1^N = \begin{cases} 1 + \beta - 2\beta E[\theta] e & \text{if } E[\theta] \leq \frac{1}{\beta e} \\ 0 & \text{if } E[\theta] > \frac{1}{\beta e} \end{cases}. \quad (18.64)$$

We get the following main result.

Proposition 18.21

- (a) *If $E[\theta] \leq \frac{1}{\beta e}$, then $U_1^N < U_1^L$, so the individual prefers to be strategically informed about θ .*

(b) If $E[\theta] > \frac{1}{\beta e}$, then $U_1^N > U_1^L$ if $E\left[\theta \mid \theta \leq \frac{1}{\beta e}\right] > \frac{1+\beta}{2\beta e}$.

Proof: Since θ is distributed uniformly over $[0, 1]$, it follows that

$$E[\theta] = \frac{1}{2}, E\left[\theta \mid \theta \leq \frac{1}{\beta e}\right] = \frac{1}{2\beta e}, F\left(\frac{1}{\beta e}\right) = \frac{1}{\beta e}. \quad (18.65)$$

(a) Suppose that $E[\theta] \leq \frac{1}{\beta e}$. Substituting (18.65) in (18.63), (18.64) it follows that

$$U_1^N < U_1^L \Leftrightarrow 0 < (\beta e - 1) \left(1 - \frac{1}{e}\right),$$

which is true because of the assumptions (i) $\frac{1}{\beta e} < 1$ so $\beta e > 1$, and (ii) $e > 1$.

(b) Suppose that $E[\theta] > \frac{1}{\beta e}$. In this case $U_1^N = 0$, so the condition $U_1^N > U_1^L$ reduces to $U_1^L < 0$. The stated result now follows directly from (18.63). ■

The intuition for Proposition 18.21 arises from the interval $\theta \in \left(\frac{1}{e}, \frac{1}{\beta e}\right]$ in which self 1 prefers $x_2 = 0$ but self 2 prefers $x_2 = 1$. Self 1 prefers to be strategically uninformed if this leads to self 2 abstaining from consumption. This occurs when $E[\theta] > \frac{1}{\beta e}$. However, this is only a necessary condition because ignorance chosen by self 1 also entails costs. For instance, it might be that $\theta > \frac{1}{\beta e}$, in which case selves 1 and 2 both prefer $x_2 = 0$. The condition $E\left[\theta \mid \theta \leq \frac{1}{\beta e}\right] > \frac{1+\beta}{2\beta e}$ in Proposition 18.21 ensures that conditional on $E[\theta] > \frac{1}{\beta e}$, θ is closer to $\frac{1}{\beta e}$ rather than to 0. The finding by Lundborg and Lindgren (2004) that individuals with higher perceived risks are less likely to be smokers offers some partial support for this theory.

18.5.2 Confidence, motivation, and self-esteem

Bénabou and Tirole (2002, 2003) consider situations where the subsequent selves of an individual might have some asymmetric information (*imperfect self-knowledge*) about the current self; we distinguish between *good* and *bad* types. A good type has *high levels of willpower*. Depending on the context, a good type might keep to deadlines, or see tasks through to completion once they have been initiated, or undertake a high level of productive effort. In contrast, a *bad type* has *inadequate willpower*. The current self might wish to undertake costly actions to convince subsequent selves of being a good type. However, the actions by a current self to convince subsequent selves of his type must be incentive compatible.

There are at least three main building blocks of the work by Bénabou and Tirole in this regard. The first two, *imperfect self-knowledge* and *imperfect willpower*, have been mentioned above in the other models in this chapter. The third building block is *imperfect recall and motivated cognition*. Imperfect recall implies, roughly, that an individual might manage, wilfully or otherwise, how past actions are remembered. The thrust of the argument is not that memory can simply be wilfully suppressed, but rather that the awareness of events in the past can be manipulated.

Consider for instance the following examples. (i) Our memory of past actions can often be self-serving. We tend to remember our successes more than our failures. We might, wrongly, ascribe our lack of success to external factors, or blame others for it. (ii) The intensity of past visceral states in our memories might diminish gradually with time. (iii) By taking down written records of an event, sharing them with friends and rehearsing the records, offers at least partial protection

from memory loss. But in many cases, we choose not to. (iv) We can control the vividness of the memory of an event by choosing the degree of attention we give to it. We sometimes pay insufficient attention to events that are unpleasant. At the extreme, we can sometimes get drunk to try to forget unpleasant events. Memory also decays naturally with time, especially if not consciously rehearsed; the latter is of course an endogenous decision.

We operationalize this as follows. At any instant of time, the current self chooses some action and the probability with which the subsequent selves can recall this action. It is possible that the current self chooses to engage in wilful self-deception. Subsequent selves are aware of the incentive for self-deception, hence, good news might get discounted in equilibrium, especially if it is likely to arise from too much self-deception. However, some self-deception might actually help. For instance, if the decision of the future selves to undertake an activity depends on the belief in their abilities, or in their “self-confidence,” then the current self might undertake actions that strengthen this belief.

There are at least three main reasons why individuals might wish to have a more optimistic and confident view of themselves, relative to a more realistic one. First, confidence in one’s abilities might directly enhance utility. Second, it might have a signaling value; self-belief might be a signal to others of one’s abilities. Third, it might have a motivational value for one’s future selves.

We now examine the motivational value of self-confidence in the context of the three period model of Bénabou and Tirole (2002). Consider a risk-neutral individual with an economic life-span of three periods $t = 1, 2, 3$. There are multiple-selves, so there is a distinct self of the individual in each period. Each self uses hyperbolic discounting and has $(\beta, 1)$ preferences, $0 < \beta < 1$. The decisions faced by the different selves are as follows.

1. Self 1 chooses an action that affects her flow payoff u_1 and the date 2 information structure. Denote by $\theta \in [0, 1]$, a random variable, such as self-confidence or ability, over which the beliefs of self 1 are given by the distribution function $F_1(\theta)$. Self 1 can alter the date 2 information structure by engaging in costly self-deception that lowers current payoff u_1 , but generates a more optimistic belief in abilities for subsequent selves, in particular, for self 2.
2. Self 2 can undertake some action or project that has current costs $c \in [0, 1]$ in terms of effort or resources at date 2. The project is successful with probability θ . If successful, the project yields a payoff of 1 unit that is obtained at date 3. The beliefs of self 2 are given by the distribution function $F_2(\theta)$.

Define the mean of θ with respect to the distribution function $F_i(\theta)$ by $\bar{\theta}_i = \int_0^1 \theta dF_i(\theta)$. Individuals are risk neutral and payoff functions are linear in θ , so the mean, $\bar{\theta}_i$, encompasses everything that the individual needs to know about the randomness in the model. In other words, $\bar{\theta}_i$ is a sufficient statistic for $F_i(\theta)$.

The expected payoff of self 2, $E_2[U]$, is given by

$$E_2[U] = \begin{cases} -c + \beta E_2\theta = -c + \beta \bar{\theta}_2 & \text{if activity is undertaken} \\ 0 & \text{if activity is not undertaken} \end{cases}, \beta \in (0, 1), \quad (18.66)$$

where E_2 is the expectation operator with respect to the distribution $F_2(\theta)$. (18.66) shows that the cost of the activity is borne in the current period but the reward is received in the next period. Self 2 undertakes the activity if $-c + \beta \bar{\theta}_2 > 0$, or¹²

¹² We do not consider the case when a self is indifferent between two choices but this can be readily incorporated by assuming some tie breaking rule.

$$\bar{\theta}_2 > \frac{c}{\beta} > c. \quad (18.67)$$

If self 2 knew the true value of θ , then she would undertake the action only if

$$\theta > \frac{c}{\beta} > c. \quad (18.68)$$

The expected payoff of self 1, $E_1 [U]$, depends on the choice made by self 2 and is given by

$$E_1 [U] = \begin{cases} u_1 + \beta(-c + \bar{\theta}_2) & \text{if self 2 undertakes the activity} \\ u_1 & \text{if self 2 does not undertake the activity} \end{cases}. \quad (18.69)$$

Self 1 prefers self 2 to undertake the activity if $u_1 + \beta(-c + \bar{\theta}_2) > u_1$, or

$$\bar{\theta}_2 > c. \quad (18.70)$$

If self 1 knew θ , then she would want the action to be undertaken if $\theta > c$. Comparing (18.67), (18.70) the crucial interval of disagreement between selves 1 and 2 is $c < \bar{\theta}_2 \leq \frac{c}{\beta}$. We summarize the main result from the discussion so far.

Lemma 18.2 *If θ is unknown to both selves, then the following hold. (1) If $c < \bar{\theta}_2 \leq \frac{c}{\beta}$, self 2 will not undertake the activity, but self 1 would like the activity to be undertaken. (2) If $\bar{\theta}_2 < c$, then none of the selves want the activity to be undertaken. (3) If $\bar{\theta}_2 > \frac{c}{\beta}$, then both selves would like the activity to be undertaken.*

MAINTAINING THE OPTIMAL DEGREE OF CONFIDENCE

Suppose that self 1 were to learn about the true value of θ . Should self 1 choose to transmit this information to self 2? The answer depends on the value of θ as well as on the credibility of information transmission. Suppose that information is completely credibly transmitted, hence, immediately believed by self 2. Thus, if self 1 chooses to reveal information, he cannot lie about the state, θ . We distinguish between two main cases.

Case I ($\bar{\theta}_2 > \frac{c}{\beta}$): From (18.67), self 2 will undertake the activity in the absence of any information from self 1. Using (18.69), the expected utility of self 1 from not passing on any information to self 2 is given by

$$E_1 [U] = u_1 + \beta(-c + \bar{\theta}_1), \quad (18.71)$$

where we have used the fact that in the absence of any transmitted information, $\bar{\theta}_1 = \bar{\theta}_2$.

On the other hand, if information is passed on to self 2, then, using (18.68), self 2 will only take the action when $\theta > \frac{c}{\beta}$. Hence, from an ex-ante perspective, before self 1 makes the decision to know θ , the expected utility of self 1 from the decision to pass on the information is

$$E_1 [U] = u_1 + \beta \int_{c/\beta}^1 (-c + \theta) dF_1(\theta). \quad (18.72)$$

Subtracting (18.71) from (18.72), the *information disclosure value* to self 1, denoted by D , can be written as

$$D = \beta \left[\int_0^c (c - \theta) dF_1(\theta) - \int_c^{c/\beta} (\theta - c) dF_1(\theta) \right] = \beta [G - L], \quad (18.73)$$

where

$$G = \int_0^c (c - \theta) dF_1(\theta) \text{ and } L = \int_c^{c/\beta} (\theta - c) dF_1(\theta)$$

denote, respectively, the gain and loss to self 1 from information disclosure; we explain in more detail below.

1. Suppose that self 1 learns $\theta < c$. Because $\bar{\theta}_2 > \frac{c}{\beta}$, self 2 will undertake the action in the absence of the information (overconfidence), but not if the information were to be revealed. Both selves do not wish the project to be undertaken if $\theta < c$, so self 1 reveals the information. By doing so, self 1 covers for the *risk of overconfidence* on the part of self 2. This corresponds to the term G in (18.73).
2. Suppose that self 1 learns $c < \theta < \frac{c}{\beta}$. In this case, self 1 would like the action to be undertaken, but because $\bar{\theta}_2 > \frac{c}{\beta}$, self 2 will undertake the action anyway, even in the absence of the information. Providing self 2 more information, i.e., that $c < \theta < \frac{c}{\beta}$ would prevent it from undertaking the action. Hence, there is a loss to self 1 from having an informed self 2, thus, self 1 prefers to *maintain the confidence* of self 2. This corresponds to the term L in (18.73).
3. Finally, if $\theta > \frac{c}{\beta}$, then self 1 is indifferent to revealing or not revealing the information because self 1 wishes the project to be undertaken and self 2 would undertake it anyway because $\bar{\theta}_2 > \frac{c}{\beta}$.

If the “risk of overconfidence motive” is stronger, then self 1 transmits information. If, however, the “confidence maintenance motive” is relatively stronger, then self 1 does not transmit information. Note that when $\beta = 1$, so the individual uses exponential discounting, then $D = G > 0$, so self 1 always transmits information; in this case the objectives of selves 1 and 2 are fully aligned. As β decreases and the present bias of self 2 increases, L increases and D falls. Thus, if the present bias of self 2 is higher, then the confidence maintenance motive dominates and so information is less likely to be transmitted.

Case II ($\bar{\theta}_2 < \frac{c}{\beta}$): Using (18.67), self 2 will not undertake the activity in the absence of additional information. In this case, self 2 will undertake the activity only if self 1 reveals $\theta > \frac{c}{\beta}$. Hence, the expected gain to self 1 from providing information to self 2 is given by

$$D = \beta \int_{c/\beta}^1 (\theta - c) dF_1(\theta) > 0.$$

Since $D > 0$, so information is always transmitted. In this case, the individual always looks for feedback on his ability.

DEGREES OF SELF-CONFIDENCE

Suppose that we have two individuals with different degrees of initial self-confidence. Which one is more eager to transmit information to its future selves? Consider two individuals whose initial

beliefs about the distribution of θ are given, respectively, by the distribution functions $F(\theta)$ and $G(\theta)$; the associated density functions are $f(\theta)$ and $g(\theta)$. The domain of θ is $[0, 1]$.

Definition 18.6 (*Confidence*): The individual with the distribution function $F(\theta)$ is said to be relatively more confident as compared to the individual with the distribution function $G(\theta)$ if the monotone likelihood ratio property is satisfied

$$\frac{f(\theta_L)}{g(\theta_L)} < \frac{f(\theta_H)}{g(\theta_H)} \quad \forall \theta_L < \theta_H \text{ in } [0, 1]. \quad (18.74)$$

Definition 18.6 requires that the more confident individual places a relatively higher probability on the higher value of θ . A straightforward implication of (18.74) is

$$F(\theta) < G(\theta) \quad \forall \theta \in [0, 1], \quad (18.75)$$

i.e., the distribution function of a more confident individual, first order stochastically dominates the distribution function of a less confident individual. Let $\bar{\theta}_1^F, \bar{\theta}_1^G$ denote, respectively, the expected values taken with respect to F and G . We assume that

$$\bar{\theta}_1^F > \bar{\theta}_1^G > c/\beta. \quad (18.76)$$

From (18.76), in the absence of additional information (so $\bar{\theta}_1^F = \bar{\theta}_2^F$ and $\bar{\theta}_1^G = \bar{\theta}_2^G$), self 2 will, undertake the activity, irrespective of the degree of initial confidence.

From (18.73), $D \geq 0$ if and only if

$$\int_0^c (c - \theta) dF_1(\theta) \geq \int_c^{c/\beta} (\theta - c) dF_1(\theta) \Leftrightarrow \int_0^{c/\beta} (\theta - c) dF_1(\theta) \leq 0.$$

Integrating by parts we get

$$|(\theta - c)F_1(\theta)|_0^{c/\beta} - \int_0^{c/\beta} dF_1(\theta) \leq 0,$$

or

$$\int_0^{c/\beta} \frac{F_1(\theta)}{F_1(c/\beta)} d\theta \geq \left(\frac{1 - \beta}{\beta} \right) c. \quad (18.77)$$

A similar expression applies for the individual who holds beliefs given by the distribution function G_1 . Using (18.74), we have

$$\frac{F_1(\theta)}{F_1(c/\beta)} < \frac{G_1(\theta)}{G_1(c/\beta)} \quad \forall \theta \leq c/\beta. \quad (18.78)$$

From (18.77), (18.78) it follows that (18.77) is more likely to hold for the less confident individual who has the initial distribution function G_1 . Hence, and equivalently, D is more likely to be positive for the less confident individual, i.e., she is more likely to transmit information. A more confident individual has more to lose by transmitting information.

SELF-HANDICAPPING AND SELF-ESTEEM

A puzzling aspect of behavior is that individuals sometimes take actions that are not conducive to good performance. Examples include, anxiety before an exam, withholding of effort, inadequate preparation, and setting of tasks for oneself where one is almost sure to fail. Such self-handicapping has been suggested by psychologists as a deliberate strategy to maintain self-esteem.

Suppose that $\bar{\theta}_2 > \frac{c}{\beta}$ so that in the absence of any information, self 2 will undertake the action. Suppose also that the efficient action is for self 1 to transmit information to self 2. Not transmitting any information (self-handicapping) is the alternative strategy for self 1. Suppose that the cost of such self-handicapping is zero. From (18.77), self-handicapping is the better alternative if

$$\int_0^{c/\beta} \frac{F_1(\theta)}{F_1(c/\beta)} d\theta < \left(\frac{1-\beta}{\beta} \right) c. \quad (18.79)$$

Using (18.78), it is more likely that (18.79) will hold for the more confident individual (who uses F_1 rather than G_1). Thus, more confident individuals are more likely to self-handicap; because they are more confident they have more to lose from learning the true value of their ability. This conclusion is not robust, however, to inclusion of costs of self-handicapping. More confident individuals are also less likely to receive bad signals, increasing the returns from self-handicapping; for a fuller analysis along these lines, see Bénabou and Tirole (2002).

AWARENESS MANAGEMENT

Suppose, for reasons mentioned above, one desires to have a positive self-assessment. How can this be achieved? One possibility is that we may be hardwired, on account of evolutionary reasons, to have positive self-assessment. However, many individuals suffer from a poor self-image, while others have to work for it, hence, this explanation is not entirely satisfactory. We focus instead on a simple strategic game between successive selves that stresses the roles of *motivation* and *cognition*.

Self 1 can, to an extent, affect the probability that self 2 remembers a piece of information. Hence, the *motivation* of self 1 might be to create greater memory awareness about signals that are more consistent with the long-term goals. In the absence of this greater awareness, the future selves who have “current biased preferences” may jeopardize these long-term goals. However, each self is rational and aware of the possibilities of self-deception by other selves. Thus, self 2 is *cognizant* of the incentives of self 1 to promote recall of events conducive to long-term goals.

Let $\lambda \in [0, 1]$ be the probability that an event, which occurs at time $t = 1$ can be remembered by self 2 at time $t = 2$. We look only at the case where the manipulation of memory by self 1 is costless.¹³ Evidence suggests that only a part of the total stock of information in one’s memory can be retrieved for conscious processing at the time of decision making. There are several possible mechanisms that self 1 can make use of. Rehearsed information is more readily available, as is information that one has direct behavioral experience of. Self 1 can also avoid situations that are directly reminiscent of unpleasant and forgettable events; for instance, by tearing up pictures of a cheating spouse, or in extreme cases taking recourse to drugs and alcohol. The information content of unpleasant news can also be questioned; for instance, on getting a low grade, a student could question if the marker has adequately understood her work. Hence, we are interested in the management of awareness of memories.

¹³ See Bénabou and Tirole (2002) for the case where such manipulation is costly.

Self 2 is aware of the incentives of self 1 to manipulate memory. Such skepticism on the part of self 2 is reflected in the use of Bayes' rule to update information.¹⁴ The technology of self-deception is as follows.

At $t = 1$, self 1 receives a binary signal σ about her ability, θ . With probability q the signal is uninformative, i.e., $\sigma = \phi$ and with probability $1 - q$, the signal is "bad news," i.e., $\sigma = L$. Hence, "good news" is defined as no news. Define

$$\theta_L \equiv E[\theta \mid \sigma = L] < E[\theta \mid \sigma = \phi] \equiv \theta_H. \quad (18.80)$$

Denote the signal recollected by self 1 as $\hat{\sigma} = \{\phi, L\}$. Memories cannot be manufactured, so $\sigma = \phi \Rightarrow \hat{\sigma} = \phi$ (if the signal is uninformative, then the recollected signal is also uninformative). However, if $\sigma = L$, then this signal is remembered only with an endogenous probability λ ,

$$\lambda = \Pr[\hat{\sigma} = L \mid \sigma = L]. \quad (18.81)$$

Hence, $1 - \lambda$ is the probability with which bad news is hidden from self 2.

Self 2 solves a Bayesian inference problem on observing the signal sent by self 1. She assesses the *reliability* of a *no news* message, r , by Bayes' rule:

$$r \equiv \Pr[\hat{\sigma} = \phi \mid \sigma = \phi] = \frac{q}{q + (1 - q)(1 - \lambda)}. \quad (18.82)$$

The numerator of (18.82) is the prior probability of the signal ϕ and the denominator is the total probability with which the signal ϕ arises. If $\lambda = 1$, then a no news signal is completely reliable, i.e., $r = 1$. The individual's *degree of self-confidence*, $\theta(r)$, is defined as

$$\theta(r) = r\theta_H + (1 - r)\theta_L. \quad (18.83)$$

So far, we have assumed that the cost of effort c of self 1, is deterministic. We now relax this assumption; let the cost of the project, c , be a random variable drawn from $[\underline{c}, \bar{c}]$ with distribution $H(c)$ and density $h(c) > 0$. We assume that

$$\frac{\underline{c}}{\beta} < \theta_L, \quad \theta_H < \frac{\bar{c}}{\beta}. \quad (18.84)$$

Analogous to (18.67), self 2 undertakes the activity if

$$E[\theta \mid \hat{\sigma}] > \frac{c}{\beta} \Leftrightarrow c < \beta E[\theta \mid \hat{\sigma}]. \quad (18.85)$$

Hence, the expected payoff of self 1 is

$$E_1[U] = u_1 + \beta \int_0^{\beta E[\theta \mid \hat{\sigma}]} (-c + E[\theta \mid \sigma]) dH(c). \quad (18.86)$$

¹⁴ Evidence is not consistent with individuals using Bayes' rule. However, here this is not important for the qualitative results, as we show below.

Suppose that self 2 was naive, and trusted the signal of self 1 without engaging in rational Bayesian updating. What expectation $E[\theta | \hat{\sigma}]$ would self 1 like self 2 to have? Analogous to (18.70), self 1 would like self 2 to undertake the activity when

$$E[\theta | \sigma] > c. \quad (18.87)$$

By manipulating the naive expectations of self 2 to be $E[\theta | \hat{\sigma}] = E[\theta | \sigma] / \beta$, the upper limit of integration in (18.86) becomes $E[\theta | \sigma]$. Thus, the expected payoff of self 1 is maximized (it is as if self 1 can induce self 2 to only undertake the action when it is in the former's self-interest). However, if self 2 is not naive this will not work.

Denote the expected utility of self 1 when the adverse information (signal L) is *concealed* by $U_C(\theta_L)$ and when it is *revealed* by $U_R(\theta_L)$. We are interested in the perfect Bayesian equilibria (PBE) of a signaling game between selves 1 and 2 in which they respectively choose λ and r (the optimal values are denoted by λ^*, r^*).

We begin by giving some intuition about the decisions of the two selves. If the bad news is hidden from self 2, it raises self-confidence from θ_L to $\theta(r^*)$ (recall that from (18.80), these are expected values). From (18.85), this additional self-confidence induces self 2 to work in the additional states of the world (a state corresponds to a cost, c) where

$$\beta\theta_L < c < \beta\theta(r^*). \quad (18.88)$$

However, the enhancement of self-confidence in this manner has a cost and a benefit. Analogous to (18.73), the net gain/loss from concealing information about the bad state is given by

$$U_C(\theta_L) - U_R(\theta_L) = \beta \left[\int_{\beta\theta_L}^{\theta_L} (\theta_L - c) dH(c) - \int_{\theta_L}^{\beta\theta(r^*)} (c - \theta_L) dH(c) \right]. \quad (18.89)$$

The first term in (18.89) is the *gain from confidence building* because over the range $\beta\theta_L < c < \theta_L$ self 1 would like self 2 to undertake effort but the latter does not wish to. The second term is the *loss from overconfidence*; over these states of the world, self 2 would like to undertake effort but self 1 does not wish self 2 to do so. The overconfidence cost is higher, the more reliability (higher r^*) self 2 places on the signal from self 1 because from (18.83), $\theta(r^*)$ is increasing in r^* .

Suppose that self 1 gets bad news, $\sigma = L$. The problem of self 1 is to choose the recall probability λ in order to maximize

$$\lambda U_R(\theta_L) + (1 - \lambda) U_C(\theta_L). \quad (18.90)$$

given the reliability, r^* , induced by his action.

Definition 18.7 A Perfect Bayesian Equilibrium is a pair of strategies (λ^*, r^*) where $\lambda^* \in [0, 1]$, $r^* \in [q, 1]$ such that:

- (a) Self 1 chooses the recall probability, λ^* , optimally to maximize (18.90), given the assessment reliability of self 2, r^* .
- (b) Self 2's choice of r^* is consistent with Bayes' rule, (18.82), given the optimal choice of self 1.

Using (18.90), the first order condition to self 1's problem is

$$U_R(\theta_L) - U_C(\theta_L) = 0. \quad (18.91)$$

Using (18.83), (18.89) in (18.91), we get

$$\beta \int_{\beta\theta_L}^{\beta(r\theta_H+(1-r)\theta_L)} (\theta_L - c) dH(c) = 0. \quad (18.92)$$

The main implications of (18.92) are given in Proposition 18.22 below.

Proposition 18.22 (Bénabou and Tirole, 2002): *There exist values of $\beta : \beta_L, \beta_H \in (0, 1)$ and $\beta_L < \beta_H$ such that the following hold.*

- (a) *For $\beta > \beta_H$, the unique equilibrium is $\lambda^* = 1$, i.e., no news is hidden from self 2.*
- (b) *For $\beta < \beta_L$ the unique equilibrium is $\lambda^* = 0$, i.e., all (bad) news is hidden from self 2.*
- (c) *For $\beta \in [\beta_L, \beta_H]$ there are three possible equilibria, $\lambda^* \in \{0, \Gamma(\beta), 1\}$ where $\Gamma(\beta)$ is a decreasing function from 1 to 0 as β rises from β_L to β_H .*

The intuition behind Proposition 18.22 is straightforward. When β is very high, overconfidence is the main concern, thus, bad news is transmitted to self 2 to dampen her overconfidence. On the other hand, when β is low, the confidence of self 2 needs to be built up, so $\lambda^* = 0$. For intermediate values of β , a range of values $\lambda^* \in (0, 1)$ is optimal, so one gets multiple equilibria; see Figure 18.3.

The multiple equilibria can be explained as follows. Suppose that self 1 is very concealing of information (low λ^*). This makes self 2 discount such information even more and so the risk that self 2 is overconfident increases. This makes self 1 even more keen to conceal information. On the other hand if self 1 truthfully reveals most information (high λ^*) self 2 considers it very reliable (using Bayes' rule). This gives an incentive for self 1 to be even more truthful.

Figure 18.3 The optimal recall probability as β varies.

Source: Roland Bénabou and Jean Tirole, "Self-confidence and personal motivation." *The Quarterly Journal of Economics* (2002) 117(3), by permission of Oxford University Press.

In the fully censored equilibrium, $\lambda^* = 0$, no information is transmitted. In this “babbling equilibrium,” the incentive for information suppression is different from Carillo and Mariotti (2000) in that self 1 does not want to suppress good news. But in trying to suppress only the bad news, she invariably ends up suppressing the good news (which, in this case, is no news). This might do more harm than good. To see this, the payoff to self 1 upon receiving good news is

$$U_R(\theta_H) = \beta \int_0^{\beta\theta(r^*)} (\theta_H - c) dH(c), \quad (18.93)$$

where r^* is the “reliability” inferred by self 2. Note that

$$\beta \int_0^{\beta\theta(r^*)} (\theta_H - c) dH(c) < \beta \int_0^{\beta\theta_H} (\theta_H - c) dH(c) \quad (18.94)$$

when all information is truthfully revealed to self 2. Thus, a child who is praised by her parents in most circumstances will never be sure if she really did well, even when she actually does well. Using (18.90), (18.93) the expected payoff of self 1, before receiving the ability signal is

$$W(\lambda^*, r^*) = qU_R(\theta_H) + (1 - q)[\lambda U_R(\theta_L) + (1 - \lambda)U_C(\theta_L)].$$

Thus, if the strategy is to truthfully reveal all information to self 2, the payoff of self 1 is $W(1, 1)$. It is possible that $W(\lambda^*, r^*) < W(1, 1)$.

Example 18.12 Let $q = 1/2$, $\theta_L = 0$, $\theta_H = 1$, and $\bar{c} < 1$. Suppose $\lambda^* = 0$, so by Bayes’ rule $r^* = q$. Note that

$$W(\lambda^*, r^*) - W(1, 1) = (1 - q) \int_{\beta\theta_L}^{\beta\theta(r^*)} (\theta_L - c) dH(c) - q \int_{\beta\theta(r^*)}^{\beta\theta_H} (\theta_H - c) dH(c). \quad (18.95)$$

Substituting $r^* = q = 1/2$, $\theta_L = 0$, $\theta_H = 1$ in (18.95) we get:

$$W(\lambda^*, r^*) - W(1, 1) = -\frac{1}{2} \left[\int_0^{\beta/2} c dH(c) + \int_{\beta/2}^{\beta} (1 - c) dH(c) \right]. \quad (18.96)$$

Since $\bar{c} < 1$ we get $W(\lambda^*, r^*) < W(1, 1)$, hence, the individual will not benefit from hiding information from subsequent selves.

PERSONAL EVALUATION BIASES AND BAYES’ RULE

In experimental evidence, most individuals overestimate their abilities in absolute terms and their abilities relative to others. Bénabou and Tirole (2002) cite survey evidence that shows 94% of college professors thought they were better than their average colleague. We now turn to the question of the rationality of such beliefs.

Consider a large population that, using the law of large numbers, allows us to identify q , $1 - q$ as the proportions of the population that, respectively, receives the good ($\sigma = \phi$) and the bad ($\sigma = L$) signals. Suppose that less than half the population receives the good news, i.e., $q < 1/2$.

Selves 1 belonging to the proportion q can only signal good news to Selves 2. Suppose that the proportion $1 - q$, which receives the bad news, uses an identical optimal recall probability

$\lambda^* \in (0, 1)$; a symmetry argument or a unique equilibrium outcome can be used to justify this. Denote by r^* , the corresponding reliability placed by self 2 on the signal transmitted by self 1.

A fraction $1 - \lambda^*$ of Selves 2 of individuals who had bad news in period 1 forget about the bad news. Thus, the proportion of Selves 2 who overestimate their ability to be high, but actually have low ability, is $(1 - q)(1 - \lambda^*)$. The overestimation of their ability is $\theta(r^*) - \theta_L$; using (18.83) this is given by $r^*(\theta_H - \theta_L)$. Hence, the total proportion of period 2 selves who think that they have high ability is given by

$$q + (1 - q)(1 - \lambda^*).$$

If $\lambda^* < 1$, then this proportion is greater than the initial proportion ($q < 1/2$) that thinks that its ability is high. In fact if λ^* is not too high in the sense that $\lambda^* < \frac{1}{2(1-q)}$, then a majority of the population now, rationally, thinks that it has high ability and an ability greater than the average.

We have seen elsewhere in this book that Bayes' rule is not an accurate description of the human inference process; for instance it neglects the base rate. In an earlier paper Bénabou and Tirole (1999) use a modified, less sophisticated form of the Bayes' rule as compared to (18.82); in particular, they use

$$r \equiv \Pr[\hat{\sigma} = \phi \mid \sigma = \phi] = \frac{q}{q + \pi(1 - q)(1 - \lambda)}, \quad (18.97)$$

where $\pi \in [0, 1]$ is a measure of the individual's cognitive sophistication. So, if $\pi = 0$, then $\Pr[\hat{\sigma} = \phi \mid \sigma = \phi] = 1$, i.e., self 2 naively trusts the signal transmitted by self 1. At the other extreme, if $\pi = 1$, then the decision maker is a fully rational Bayesian decision maker. Intermediate values of π allows for more limited cognitive sophistication. The unattractiveness of $\pi = 0$ has already been alluded to before; the assumption of a complete lack of introspection is clearly a strong one. Bénabou and Tirole show that the qualitative results carry through for intermediate values of π . Hence, there does not seem to be a gain from using the alternative version of Bayes' rule in (18.97) in this case.

WILLPOWER AND PERSONAL RULES

Bénabou and Tirole (2004) look at the related issue of signaling one's willpower to their future selves. Each self now lives over two subperiods; making the decision to undertake an activity in the first and the decision to quit or continue the activity in the second. In subperiod 1, Self 1 could undertake an activity that has some limited current benefits, for instance, abstinence from smoking or starting a paper. In the second subperiod, continuation of the activity becomes much more onerous. For instance, the craving created by abstinence from smoking since the morning must have worsened, or in the case of writing the paper, fatigue could have set in. In the absence of any consideration for the future, the individual would perhaps give up on the activity and not realize the full fruits of the task started in subperiod 1. However, doing so might signal to self 2 that one's willpower is low. This has potentially negative consequences for the decision that self 2 makes in undertaking the task in her first subperiod. If self 1 is aware of these long-term consequences of her decision she might continue with the activity in subperiod 2. Such models can account for personal rules such as I will quit smoking from now on.

Exercises for Part 6

1. (Laibson, 2001) Consider the model in Section 17.3. Prove Proposition 17.1, i.e., show in the context of the no-cues model that the optimal decision rule of the individual is

$$a = \begin{cases} 1 & \text{if } x > \tilde{x} \\ 0 & \text{if } x < \tilde{x} \end{cases}.$$

Also show that the threshold value $\tilde{x}$ is increasing in the outside option, $\bar{u}$, the discount factor, δ , and the compensatory process weighting factor, θ .

2. (Caplin and Leahy, 2001) Consider the *psychological expected utility model* in Section 17.5.
 - (a) (Possibility and probability) There is evidence that economic agents might be influenced by *possibility* rather than *probability*; for instance, Monat et al. (1972), Bankhart and Elliot (1974), Loewenstein et al. (2001). Suppose that there is an announcement that the Federal Reserve is concerned about inflation. Why might this alter the investment behavior of economic agents independent of the probability of an interest rate increase?
 - (b) (Time course of anxiety) The time path of anxiety tends to be U shaped; see for instance, Breznitz (1984). Fear is greatest when individuals are first informed of an aversive event. It then diminishes for some time before increasing sharply in anticipation of the event. In light of this evidence what do you expect to be the effect on price of those assets whose risks have only been recently revealed relative to those whose risks have been known for some time?
 - (c) Suppose that the Federal Reserve comes across some bad piece of news such as the possible shutdown of a major bank. Assume that economic agents suffer from anxiety. Show why it might now be optimal to hide the bad news for longer relative to the standard case without anxiety.
3. (Caplin and Leahy, 2004)¹⁵ Hopefulness, suspense, and anxiety are feelings related to uncertainty about the future. An anticipatory feeling is a feeling that anticipates the outcome of an event. These feelings are embedded here in an otherwise standard two-period consumption and saving problem. Consider an individual who is young and works in period t and is retired in period $t + 1$; labor income is the only source of income and there are no inheritances or bequests. The budget constraint when young (period t) is given by

$$c_t + s_t = w_t,$$

where w_t is the wage, c_t is consumption and s_t is savings in period t . The budget constraint when old (period t) is given by

$$c_{t+1} = (1 + r_{t+1}) s_t,$$

where the return r_{t+1} on savings is the only source of uncertainty in the model. Let $\mu \equiv E_t [1 + r_{t+1}]$, $\sigma^2 \equiv \text{var}_t [1 + r_{t+1}]$. Preferences of the individual are given by

$$U_t = E_t [\gamma [-\phi \ln a_t + \ln c_t] + (1 - \gamma) \ln c_{t+1}],$$

¹⁵ I am grateful to Klaus Wälde for suggesting this problem.

where a_t captures the utility-reducing anticipatory feeling in period t , $\gamma, \phi \in [0, 1]$ are preference parameters. Following Caplin and Leahy (2004), we model anticipatory feelings as a reduction in mean and an increase in the variance of uncertain consumption c_{t+1} . In order to allow for positive and negative values of anxiety, we write anxiety as

$$\ln a_t = \zeta \text{var}_t c_{t+1} - (1 - \zeta) E_t c_{t+1}, \quad 0 \leq \zeta \leq 1. \quad (6.E1)$$

E_t and var_t are, respectively, the expectation and variance operators, conditional on the information set at time t .

- (a) Compute the first order condition and interpret it in the two polar cases, $\mu = 0$ and $\sigma^2 = 0$.
- (b) Consider a more general version of the objective function

$$U_t = E_t [\gamma u(a_t, c_t) + (1 - \gamma) u(c_{t+1})].$$

Compute the first order condition for the optimal saving decision and provide an economic interpretation.

4. (Loewenstein et al., 2003) Extend the two-period model in Section 17.6.2 to three periods, $T = 3$. Recall that (c_1^b, c_2^b, c_3^b) is the optimal profile of consumption in time period $t = 1$ when the individual suffers from projection-bias ($\alpha > 0$). As time passes by, the individual's tastes change in a way that she did not predict. The individual has a chance to reoptimize in period 2. Denote by (c_2^{bb}, c_3^{bb}) the optimal consumption profile when the individual reoptimizes in time period $t = 2$ and suffers from projection bias. Show that if $c_1^b > s_1$, then we get the following result. The sign of v''' determines completely the sign of $c_2^{bb} - c_2^b$. In particular, if $v''' > 0$ (which holds for CARA and CRRA preferences) projection bias will repeatedly lead people to adjust their consumption plans upwards ($c_2^{bb} > c_2^b$). If $v''' < 0$, then $c_2^{bb} < c_2^b$ and if $v''' = 0$, then $c_2^{bb} = c_2^b$. Does this result provide an explanation for why individuals engage in inadequate savings?
5. (Fudenberg and Levine, 2006) Consider the four-period problem in O'Donoghue and Rabin (1999) with (β, δ) preferences, adapted to the case of a dual-self model. An agent has 4 periods to do a report. In the original problem, the pecuniary cost in successive periods of completing the report is 3, 5, 8, 13, and the benefit from doing the report is v . Assume now that the total cost of doing the report in any period is $1 + \gamma$ times the pecuniary cost, where $\gamma > 0$ is the self-control cost per unit. In any period, the decision to act is taken by the short-run self. Show the following.
 - (a) If $\gamma < 10/3$, the agent acts to write the report in the first period. If prevented from writing the report in period 1, then any of the subsequent short-run selves are willing to write the report.
 - (b) If $\gamma > 10/3$, then the agent never finds it optimal to act.
 - (c) The knife edge case, $\gamma = 10/3$, is the only case where the agent is willing to act in intermediate periods. [Hint: Solve the game backwards starting in period 4, being careful to include the self-control costs.]
6. (Lipman and Pesendorfer, 2013) Show that classical preferences (Definition 17.4) are a special case of self-control preferences (see Proposition 17.13) if either (i) v is an affine transformation of u , i.e., $v = \alpha u + \beta$ for some $\alpha \geq 0$ and $\beta \in \mathbb{R}$, or (ii) u is a constant function.

Show also that when $\alpha < 0$, $\beta \in \mathbb{R}$, and $v = \alpha u + \beta$, the individual has a sole desire for commitment.

7. (Lipman and Pesendorfer, 2013) Consider the setup of Example 17.11 for (β, δ) preferences. Benhabib et al. (2010) propose an alternative to (β, δ) preferences by introducing a fixed cost of delay. Thus, in period 1, the consumption pair $(0, l)$ is preferred over $(s, 0)$ if $\delta w(l) - f > w(s)$, where f is a fixed cost of delay associated with the later outcome, l , and $\delta > 0$ is the discount factor. What functional forms for commitment utility and temptation utility can be used to represent these preferences?
8. (Lipman and Pesendorfer, 2013) Consider the experimental results of Dana et al. (2006) for dictator games that we considered in Part 2 of the book. The dictator splits \$10 between himself and a passive recipient. Many dictators prefer to take \$9 and not play the game; in this case, the recipient is given no information about the experimenter's interaction with the dictator. How can you transform this into a problem with Gul–Pesendorfer temptation preferences?
9. (Lipman and Pesendorfer, 2013; Dekel et al., 2009) Consider the model of temptation preferences in Section 17.7.
 - (a) Let b denote broccoli, c denote chocolate, and p denote potato chips; c and p are the two snacks. Suppose that we have $C = \{b, c, p\}$. A dieting individual expresses the following first period preferences: $\{b\} \succ_1 \{b, c\} \succ_1 \{b, p\} \succ_1 \{b, c, p\}$ (the middle two preferences can be reversed without altering the conclusion). The preferences imply that the individual prefers to have no snacks to having at least one snack and finds having both snacks on the menu to be the worst option. These preferences appear to be plausible. Show that these expressed preferences are not consistent with the Gul–Pesendorfer and the Strotz preferences.
 - (b) Let h be a healthy dish; d a small dessert; and D a large dessert. Let $C = \{h, d, D\}$. A dieting individual expresses the following first period preferences: $\{h, d\} \succ_1 \{d\}$ and $\{h, d, D\} \succ_1 \{h, D\}$. The first preference says that the individual would like to have the option of keeping to his diet. The second preference says that the individual may wish to keep d as a compromise option on the menu. These preferences also appear plausible. However, show that they are not consistent with the Gul–Pesendorfer (u, v) preferences.
 - (c) How would you incorporate the plausible preferences expressed in (a) and (b) into a theory of temptation preferences? [Hint: One possibility is that preferences violate WARP. A second possibility, explored formally in Dekel and Lipman (2012), is that unlike in the Gul–Pesendorfer model, there might be uncertainty. For instance, the preference $\{b, p\} \succ_1 \{b, c, p\}$ in (a) might arise because the individual is uncertain whether he will succumb to temptation. Having two tempting snacks, c and p , increases the probability that he will succumb to temptation, so he prefers it the least.]
10. (Ozdenoren et al., 2012) Consider a cake eating problem in continuous time $[0, T]$ in which a consumer maximizes utility by choosing an optimal path of consumption. The instantaneous utility function at time t is given by a differentiable function $U(c(t))$ with $U(0) = 0$, $U_c > 0$, and $U_{cc} < 0$. We do not consider addictive behaviors so U does not depend on past consumption. The size of the cake remaining at time t is given by $R(t)$. The initial size of the cake, $R(0)$, is given. The main difference from the standard cake eating problem in economics comes from the assumption that the consumer is endowed with a given *stock of willpower* $W(0)$. It is possible to restrain consumption but at the cost of a depletion in willpower. The rate of willpower depletion is given by $f(W(t), c(t))$ with $f_W \leq 0$, and $f_c < 0, f_{cc} > 0$ for $c \in [0, \bar{c})$. The convexity in c indicates that the more the individual

restrains his consumption, the faster does willpower deplete. f is also assumed to be twice differentiable everywhere except at $\bar{c}$, continuous at $\bar{c}$, and $f_{cW} \geq 0$. Finally, $f > 0$ for $c \in [0, \bar{c})$, and $f = 0$ for $c \in [\bar{c}, \infty)$ for some $\bar{c} > 0$. Any willpower, $W(t')$, left over after the individual has finished the cake is devoted to an alternative activity that generates utility $m(W(t'))$; m is a constant function, and

$$t' = \sup \{t \in [0, T] : R(t) > 0\}.$$

Based on the description above, the optimization problem of the individual (Problem P-1) can, thus, be written as follows. The individual chooses $c(t)$ to maximize

$$V(0) = \int_0^T e^{-\rho t} U(c(t)) dt + e^{-\rho t'} m(W(t')) \quad (\text{P-1})$$

subject to

$$\begin{aligned} \dot{R}(t) &= -c(t) \\ \dot{W}(t) &= \begin{cases} -f(W(t), c(t)) & \text{if } R(t) > 0 \\ 0 & \text{otherwise} \end{cases} \\ R(T) &\geq 0; W(T) \geq 0; R(0) = \bar{R} \geq 0; W(0) = \bar{W} \geq 0. \end{aligned}$$

ρ is the subjective rate of discount, and $\bar{W}$ is the initial level of willpower.

(a) Derive the solution to Problem P-1 by forming the appropriate Hamiltonian. Show that the first order condition for consumption at time t can be written as

$$e^{-\rho t} U'(c(t)) + \lambda(t) (-f_c) = \alpha(t),$$

where $\lambda(t)$ is the Lagrangian multiplier on the $\dot{W}(t)$ constraint and $\alpha(t)$ is the Lagrangian multiplier on the $\dot{R}(t)$ constraint. Interpret the first order condition, in particular, the second term on the LHS that sets this condition apart from the standard conditions that ignore issues of willpower.

(b) Suppose that there is no discounting, i.e., $\rho = 0$. If $c(t) > 0$ for $t \leq s \in [0, T]$, show that

$$\dot{c}(t) = \lambda(t) \frac{f_W f_c - f_c W f}{U'' - \lambda(t) f_{cc}}. \quad (6.E2)$$

When $\lambda = 0$, we get the classical conclusion that so long as $c(t) > 0$, $\dot{c}(t) = 0$. However, when $\lambda > 0$, whether we have an increasing or decreasing profile of consumption depends on the sign of the numerator in (6.E2).

(c) This part demonstrates the importance of the initial level of willpower. Denote by W_H the minimum level of $W(0)$ such that $c(t) = \bar{R}/T$ is feasible for all $t \in [0, T]$. Denote the optimal consumption path by $c^*(t)$. Show the following. (i) If $\bar{W} \geq W_H$, then the cake is exhausted and $c^*(t) = \bar{R}/T$ for all $t \in [0, T]$. (b) If $\bar{W} < W_H$, then the cake and willpower are exhausted ($R(s) = 0$, $W(s) = 0$ for some $s \in [0, T]$) and when $c(t) > 0$, whether we have an increasing or decreasing profile of consumption depends on the sign of the numerator in (6.E2).

11. (Krussel et al., 2010) Consider a representative agent two-period model with time $t = 1, 2$. Consumption in period t is denoted by c_t . The commitment ordering over outcomes is given by $\tilde{u}(c_1, c_2) = u(c_1) + \delta u(c_2)$ where $\delta > 0$ is the discount factor and the temptation ordering is given by $\tilde{v}(c_1, c_2) = \gamma (v(c_1) + \beta \delta v(c_2))$ where $\beta \in (0, 1]$. Hence, while the commitment ordering takes the standard exponential discounting form, the temptation ordering takes the hyperbolic discounting form. Preferences are represented as in the Gul–Pesendorfer model, i.e.,

$$\max_{c_1, c_2} \{\tilde{u}(c_1, c_2) + \tilde{v}(c_1, c_2)\} - \max_{c_1, c_2} \tilde{v}(c_1, c_2). \quad (6.E3)$$

Each individual is endowed with one unit of labor in each period and an endowment of capital equal to $k_1 > 0$ at the beginning of period 1. The factors of production, labor and capital, are used by perfectly competitive firms to produce output. The production function of firms in period $t = 1, 2$ is given by $f(\bar{k}_t)$ where $\bar{k}_t$ is the aggregate per capita capital stock. Hence, in any period, the factor incomes to labor and capital are given respectively by $w(\bar{k}_t)$ and $r(\bar{k}_t)$. Let $R(\bar{k}_t) = 1 + r(\bar{k}_t)$ denote the gross return on capital. The budget constraint of the representative agent is given by

$$B(k_1, \bar{k}_1, \bar{k}_2) \left\{ (c_1, c_2) : c_1 = R(\bar{k}_1)k_1 + w(\bar{k}_1) - k_2, c_2 = R(\bar{k}_2)k_2 + w(\bar{k}_2) \right\}. \quad (6.E4)$$

- (a) Show that the consumer saves the least if second period preferences were simply $\tilde{v}(c_1, c_2)$, saves the most if second period preferences were $\tilde{u}(c_1, c_2)$, and saves an intermediate amount when preferences are given by $\tilde{u}(c_1, c_2) + \tilde{v}(c_1, c_2)$.
 (b) Now consider autarky in which the individual uses his own backyard technology, which we assume is given by $f(\bar{k}_t)$ and there is no recourse to private markets. Show that the same allocation is achieved as under (a). However, utility is higher under autarky. [Hint: The agent cannot trade along the market line under autarky and is limited to the opportunity set which lies under the market line. Hence, there is lower temptation under autarky].
 (c) Suppose now that the government undertakes a balanced budget fiscal policy. It levies a tax τ_y on total income and a tax τ_i on first period investment. This gives the modified budget constraint

$$\begin{aligned} B(k_1, \bar{k}_1, \bar{k}_2) &= \left\{ (c_1, c_2) : c_1 = \left[R(\bar{k}_1)k_1 + w(\bar{k}_1) \right] (1 - \tau_y) - (1 + \tau_i)k_2, c_2 \right. \\ &= \left. R(\bar{k}_2)k_2 + w(\bar{k}_2) \right\} \end{aligned}$$

and the balanced budget constraint of the government is $\tau_y \left[R(\bar{k}_1)k_1 + w(\bar{k}_1) \right] = -\tau_i \bar{k}_2$. Suppose that the government is a benevolent central planner who wishes to maximize the agent's indirect utility by optimally choosing τ_y, τ_i . Derive the optimal tax rates and show that it is optimal for the government to impose an investment subsidy (i.e. $\tau_i < 0$). [The intuition is that an investment subsidy increases the cost of first period temptation that would arise from the possibility of reducing savings.]

12. (Amador et al., 2006) Consider the following three-period economy, where the time index $t = 0, 1, 2$. Society moves in period $t = 0$ to choose an appropriate constitution, while the government moves in period $t = 1$ to choose some level of public spending. Society's

welfare is given by $\theta U(g) + W(c)$, where g is the level of government spending and c is private consumption. The government wants to maximize instead $\theta U(g) + \beta W(c)$, where $0 < \beta \leq 1$ and $1 - \beta$ is a measure of the strength of temptation towards government spending. The resource constraint is given by $B = \{(c, g) \in \mathbb{R}_+^2 : c + g \leq y\}$. A fiscal constitution is a subset $C \subset B$ that constrains the government to choose $(c, g) \in C$. The government has private information on θ . Restrict attention to pure commitment mechanisms with no transfers across types. An optimal constitution is some subset of C which maximizes the welfare of society, given the subsequent bias of the government towards g . Show that it is always optimal to limit government spending. How does the optimal solution trade off commitment versus flexibility?

PART 7

Bounded Rationality

INTRODUCTION TO PART 7

Neoclassical economics assumes fully rational, Bayesian, subjective expected utility maximizing decision makers who have limitless cognitive abilities and follow the rules of classical statistics. In Part 7 of the book, we consider the evidence, theoretical approaches, and applications of a competing view of human nature that is based on *bounded rationality*.

Chapter 19 mainly focuses on the *heuristics and biases program* of Daniel Kahneman and Amos Tversky. Heuristics are any decision rules used by individuals that are *fast* (in terms of the time required to take a decision) and *frugal* (in terms of the information requirements). Extensive empirical evidence shows that people do use simple heuristics and their behavior often systematically deviates from the classical rules of statistics. Such individuals may be said to be *boundedly rational*.

We describe a range of heuristics and the biases relative to the normative benchmarks. Many biases arise from the tendency to believe that small samples possess the statistical properties of large samples. This gives rise to the *law of small numbers*, which is the basis of the *representativeness heuristic*, the *gambler's fallacy*, and the *hot hands fallacy*.

Other heuristics do not necessarily invoke the law of small numbers. The *conjunction fallacy* arises from inadequate attention given to the set inclusion relation; the *availability heuristic* arises from drawing inferences based on readily available information; the *affect heuristic* arises from attention to the emotional dimension of a decision; the *anchoring heuristic* arises from tying one's inferences to anchors that are often irrelevant; *base rate underweighting* arises from giving inadequate attention to the base rate in Bayes' rule; *conservatism* arises from underweighting the likelihood of a sample; *hindsight bias* arises from discrepancies between predictive and postdictive guesses; *confirmation bias* arises from selective attention to events that is biased towards confirming one's initially held position; *false consensus* arises when people overestimate the extent to which others share their beliefs. Biases also arise from ignoring statistical phenomena such as *regression to the mean* and failing to distinguish between *necessary and sufficient conditions*.

The heuristics and biases program is one of the major achievements in social science. Some of the challenges to this program can be easily dismissed; these include subject errors and misperceptions or a misunderstanding on the part of Kahneman and Tversky of probability theory. Other challenges have sharpened the approach. For instance, presenting subjects with information in a frequency-format rather than a probability-format reduces some of the biases, yet the vast majority of subjects continue to exhibit these biases. Furthermore, a great deal of information given out by governments and firms is based on the probability-format. Experts are not exempt from the biases, although they are better at rationalizing their choices relative to non-experts.

We discuss two other approaches to bounded rationality. The first is Herbert Simon's approach that advocates *satisficing behavior* as a response to limited cognitive abilities and to the problem of infinite regress in search costs. In this approach, if the payoffs of individuals fall below their endogenous *aspiration levels*, they experiment with alternative strategies, otherwise they are passive. This is the sense in which they *satisfice*. The second approach, whose intellectual leader is Gerd Gigerenzer, compares the performance of fast and frugal heuristics against selected optimization techniques. Despite the perceived intellectual chasm between the heuristics and biases program and these approaches, we argue that the two approaches are complementary.

The heuristics and biases approach is not just a collection of empirical facts. A growing array of theoretical models is now able to organize the evidence on heuristics and biases. Prominent in this literature are models that formalize the law of small numbers and explain the gambler's and hot hands fallacies; reconcile base rate neglect with conservatism; model hindsight bias to explain financial volatility; explain overconfidence and confirmation bias; use aspiration adaptation to explain the results from well-known games; and explain limited attention and the existence of shrouded attributes in equilibrium.

We close the chapter by discussing the emerging topic of *limited attention*. Increasing evidence is being documented for limited attention, e.g., among the poor, taxpayers, eBay users, and used car buyers. Exciting theoretical models are also emerging to explain the empirical facts.

Chapter 20 considers *mental accounting*. Richard Thaler, who is a pioneer in this field, defines mental accounting as *the entire process of coding, categorizing, and evaluating events*. In neoclassical economics, all sources of income and expenditure are consolidated into a single financial account and money is completely fungible across different sources of income or expenditure. In actual practice, however, individuals form a *system of mental accounts* and the degree of fungibility of money across these accounts varies. For instance, individuals are reluctant to raid a children's educational account or consume out of home equity. In addition, people may have mental accounts for holidays, weekend drinks, book expenditures, and charitable contributions.

In life-cycle models, one implication of mental accounts and the lack of perfect fungibility is that individuals may have an account-specific marginal propensity to consume. Thus, the effects of defined pension plans, bonuses, dividends, and windfall gains depend on which mental account is used to debit or credit these income flows. A mental account that is in debt is said to be in *red*, otherwise it is said to be in *black*. Evidence indicates that individuals are particularly averse to mental accounts that are in the red; this is a form of *debt-aversion*. It can explain a range of phenomena, for instance, the *disposition effect*, namely, the tendency to hold on to loss making assets for too long and sell winners early.

Consumption that is paid for, say, a vacation, can be enjoyed as if it were free. On the other hand, the thought of future payments reduces the current flow of utility, such as the aversion to a ticking taxi meter. We incorporate these considerations in a theoretical model of mental accounting. The resulting insights can explain why we prefer to prepay for a vacation but are often willing to buy consumer durables on credit. Other phenomena that can be explained in this framework include the growing use of debit cards, popularity of fixed fee payments, and gift giving among couples with joint accounts.

Among other mental accounting phenomena that we consider are the following. Individuals often engage in *narrow bracketing* of problems, e.g., taxi drivers often target daily earnings, which prevents them from taking advantage of intertemporal labor-leisure trade-offs; *coherent arbitrariness* shows that initial preferences are malleable but gradually become coherent; the distinction between *transaction utility* and *acquisition utility*; real effects of *sunk costs*; dominance of *in-kind transfers* over *cash transfers*; the *diversification heuristic* and the formation of suboptimal portfolios; the *silver lining effect*; the *house money effect*; the *mental accounting of goals*; and the *behavioral economics of retirement savings* that relies on default options (opt-in or opt-out), initial contribution rates, and automatic escalation of contributions.

Chapter 21 considers a set of issues that would typically be considered in a course in *behavioral finance* and *behavioral corporate finance*. Financial markets have traditionally been held up by economists as a model of efficient markets. Thus, the demonstration of bounded rationality in financial markets is particularly important. Undergraduates in microeconomics courses are typically taken through the following set of arguments that justify an exclusive focus on fully rational

economic agents. (i) Irrationality, i.e., any departure from classical full rationality, should cancel out in the aggregate because positive errors are as likely to occur as negative errors. (ii) Irrational traders will eventually be out-competed by rational traders, so the former will exit the market. While plausible, the real test of these arguments is empirical, and they fail this test.

The *efficient markets hypothesis* (EMH) is the cornerstone of classical finance. It predicts that at any instant in time, prices of financial assets equal their fundamental values. However, the evidence decisively rejects EMH. For instance, stale information affects current prices; public information is not readily incorporated into stock prices; the flow of information in financial markets is not instantaneous; there can be huge movements in stock prices despite no discernible news; and prices of substitute securities in Siamese twin companies typically differ from the predicted ratio.

The evidence contradicting EMH has also led to a better understanding of the behavior of financial market participants. In turn, this has led to the development of an impressive body of theoretical literature that demonstrates why financial markets need not be efficient. Indeed, *noise traders*, who trade on *investor sentiment* can outperform rational arbitrageurs. *Professional arbitrage* is also subject to biases, and often operates under the constraint of *performance based arbitrage* that prevents it from equilibrating markets. *Gradual flow of information* and *investor heterogeneity* have implications for the *momentum* in asset prices as well as *trading volume*. Managerial biases such as *overconfidence* and *attribution bias* also lead to inefficient outcomes. These predictions are borne by the evidence.

The theoretical and empirical results in Chapter 21 make a powerful case for reconsidering the classical benchmarks in finance. We close with the following quote from Thaler (1999).

Behavioral finance is no longer as controversial a subject as it once was. As financial economists become accustomed to thinking about the role of human behavior in driving stock prices, people will look back at the articles published in the past 15 years and wonder what the fuss was about. I predict that in the not-too-distant future, the term “behavioral finance” will be correctly viewed as a redundant phrase. What other kind of finance is there? In their enlightenment, economists will routinely incorporate as much “behavior” into their models as they observe in the real world. After all, to do otherwise would be irrational.

CHAPTER 19

Judgment Heuristics

19.1 Introduction

The modern *heuristics and biases* research program commenced with the seminal articles by Tversky and Kahneman (1971, 1974). A central insight of this program is that individuals are not fully rational Bayesian decision makers, but their behavior is not random either. Individuals often ignore a substantial part of the available information or use it selectively to implement simple *rules of thumb* or *heuristics*. Most heuristics are *fast*, in terms of computation time required, and *frugal* in the use of information. These heuristics do not optimize in the classical sense, hence, their performance is not necessarily optimal. However, when there is uncertainty about the optimal solution, their performance can be at least as good or even better than some more complex methods (Gigerenzer et al., 1999).

To motivate their approach, Tversky and Kahneman (1974) give the following example. Individuals often judge distance by the heuristic of how clear it is; sharper objects are thought to be closer. This heuristic is fast and frugal. While this heuristic often works well, it might also sometimes give rise to misleading perceptions. For instance, when atmospheric conditions are hazy, distances might be overestimated. Conversely, when conditions are very clear, distances might be underestimated; for a revised account of this example, see Kahneman and Frederick (2005).

The heuristics and biases approach often considers problems that require some probabilistic assessments or inferences. Classical economics assumes that individuals respect the classical laws of probability and statistical inference. In contrast, the evidence indicates that in these situations, individuals employ a range of *judgment heuristics*. The heuristics and biases approach demonstrates a systematic departure of the actual behavior of individuals from the predictions of the laws of classical statistics.¹ It is notable that even statistically sophisticated researchers and experts typically rely on these judgment heuristics.² The heuristics and biases approach is quite distinct from the formal decision theory approach in Part 1 of the book. It does not necessarily rely on any explicit optimization method, although most formal applications use a mixture of optimization methods in conjunction with simple rules of thumb.

We begin with the *representativeness heuristic* in Section 19.2 (Tversky and Kahneman, 1974). When individuals use this heuristic, they compare the likeness of a sample, even if the sample is

¹ There are many excellent surveys and collected readings. Particularly relevant to economists are Camerer (1995), Gilovich et al. (2002), Kahneman et al. (1982), Kahneman (2003), and Kahneman (2011). For a commendable effort at using some of this machinery to analyze development issues, see WDR (2015).

² See for instance, Gilovich et al. (2002), Kahneman (2003), Kahneman (2011), and Tetlock (2006).

small, with known features of the population distribution. The evidence shows that relative to a Bayesian, users of the representativeness heuristic assign too high a probability that small samples share the properties of large samples (Camerer 1987, 1990, 1995). Such individuals behave as if they obeyed a *law of small numbers*, rather than the statistically correct, *law of large numbers*.

Reliance on the law of small numbers has several implications. Individuals find it difficult to produce sequences of outcomes of random variables, and their constructed sequences show up too much *negative autocorrelation*, which is also sometimes known as *alternation bias* or *negative recency* (Tversky and Kahneman, 1974; Bar-Hillel and Wagenaar, 1991; Rapoport and Budescu, 1997). A belief in negative autocorrelation, when there is none in the underlying distribution, in betting domains is known as the *gambler's fallacy*. For instance, gamblers are often reluctant to bet on the immediately previous winning numbers in a lottery, yet the conditional and unconditional mathematical probabilities of these numbers is unchanged. Evidence from betting behavior gives strong support to the gambler's fallacy (Metzger, 1984; Clotfelter and Cook, 1993; Terrell, 1994; Croson and Sundali, 2005), as does the evidence from the behavior of investors in stock markets (Odean, 1998).

The converse of the gambler's fallacy, i.e., a belief in *positive autocorrelation* in outcomes, when there is none, is known as the *hot hands fallacy*. When subjects observe too many consecutive outcomes of one kind, they come to believe that the realization of a similar outcome is more probable. For instance, basketball players who score heavily in a game are often perceived to be on a hot streak even when there is no evidence of underlying hot hands (Gilovich et al., 1985; Tversky and Gilovich, 1989a,b; Camerer, 1989). Similar beliefs are often assigned to winning football teams. Recent evidence indicates that for basketball and baseball, there might be an underlying hot hands phenomenon (Green and Zwiebel, 2013; Bocskocsky et al., 2014; Miller and Sanjurjo, 2015), yet we argue that it does not invalidate the hot hands fallacy.

In contrast to outcomes from sports, there is good support for the hot hands fallacy when the underlying stochastic process is inanimate. For instance, lotto stores that sell winning lotto tickets experience unusually high sales for up to 40 weeks following the lotto win (Guryan and Kearney, 2008). Individuals are willing to pay more for experts who are believed to possess hot hands (Powdthavee and Riyanto, 2015). Players who win in casinos are less likely to quit, believing that they are on a winning streak (Croson and Sundali, 2005). When the underlying stochastic process relies on human skills, one is more likely to observe a gambler's fallacy and when the process is inanimate, a hot hands fallacy is more likely to be observed (Ayton and Fischer, 2004).

The gambler's fallacy and the hot hands fallacy are both likely to be caused by the representativeness heuristic. An individual who initially believes the underlying process to be random (so zero autocorrelation in successive draws) predicts too much negative autocorrelation to try to make outcomes appear random (gambler's fallacy). However, when too many outcomes of the same type are observed, the individual starts to believe that the underlying process is positively autocorrelated, even when small samples do not statistically justify this conclusion (hot hands fallacy).

Finally, we give a useful formalization of the law of small numbers due to Rabin (2002). This model also explains the existence of *overconfidence* and the gambler's fallacy.

Section 19.3 considers the *conjunction fallacy*, namely, the tendency to assign higher probabilities to the intersection of two sets relative to any of the two sets alone. The most well known and critically discussed illustration of this phenomenon is the *Linda problem* (Tversky and Kahneman, 1983). After describing a set of features of a hypothetical female called Linda (e.g., concerned with social justice, participated in anti-nuclear demonstrations) subjects in experiments are asked to judge Linda's profession. A large number of subjects chose the composite description

“Linda is a bank teller and active in the feminist movement” relative to either of the two descriptions separately. Since the probability of the intersection cannot ever be larger than any of the individual sets, this is termed as the conjunction fallacy.

Hertwig and Gigerenzer (1999), two long-standing critics of the Kahneman–Tversky approach, claimed that the conjunction fallacy disappears if it is posed in terms of natural frequencies. However, in a between-subjects design, when the Linda problem was presented in a natural frequency format, the conjunction fallacy survived (Kahneman and Tversky, 1996). The conjunction fallacy was shown to be reduced in the presence of incentives and joint decisions made by groups of two and three individuals (Charness et al. 2010). However, other experimental evidence shows that the conjunction fallacy survives intact not only in the presence of monetary incentives but also when the same problem is framed in alternative ways (Bonini et al., 2004; Stolarz-Fantino et al., 2003). Another potential explanation of the conjunction fallacy is given in terms of the potential confound between the word “and” and the logical operator $\wedge$ (Camerer, 1995; Hertwig et al., 2008). However, other research shows that while the conjunction fallacy may be lessened slightly due to these reasons, it cannot be eliminated (Tentori et al., 2004; Tentori and Crupi, 2012).

Section 19.4 considers the *availability heuristic*. Individuals judge the probability of an event by the ease with which similar events are accessible or “available” to the mind (Tversky and Kahneman, 1974). Availability may depend on how salient the event is, or how vivid or lasting an impression it made, or even how easy it is to construct hypothetical scenarios. Media coverage is one important determinant of the availability of events (Lichtenstein et al., 1978; Eisenman, 1993). An influential early empirical study established a firm link between the perceived frequency of deaths by various causes and proxies for the availability of such events in memory (Lichtenstein et al., 1978). These results have been replicated and extended (Hertwig et al., 2005; Pachur et al., 2012). Indeed, there is a close relation between the availability heuristic and the *affect heuristic* that we consider later (Pachur et al., 2012).

Section 19.5 considers the *affect heuristic* and highlights the link between emotions and heuristics (Zajonc, 1980; Slovic et al., 2002; Loewenstein et al., 2001). The basic idea is that we classify and tag events and memories by their *affect*, for instance, positive affect (enjoyable holiday) or negative affect (painful skiing accident). In making judgments and decisions, we are then influenced by the pool of these positive and negative affects or the *affect-pool*. For instance, in buying a car, we might focus a great deal on the affect that the car has on us, for instance, a sleek car, a cool car, or an enviable car. The affect heuristic substitutes a hard question (what do I think about it?) by an easier question (what do I feel about it?) that allows for quicker decision making (Kahneman, 2011).

Evidence shows that our response to various hazards, such as smoking and nuclear power, depends on the affect, or *dread* in this case, that they invoke (Fischhoff et al., 1978; Finucane et al., 2000). Experts also exhibit the affect heuristic; the perceived riskiness of various hazardous substances is closely related to the affect that they have on experts (Slovic et al., 1999). Presenting the data in terms of natural frequencies to experts enhances the affect of an event (Slovic et al., 2000).

Anchoring, considered in Section 19.6, is one of the most robust and important heuristics that people use. Anchoring occurs when people are influenced in their judgments and decisions by an initial suggestion, or *anchor*, that may be irrelevant to the question asked. Anchors may be self-generated or provided by the experimenter. Anchoring has been observed in a wide variety of phenomena. Furthermore, once individuals fix an anchor in their minds, they adjust too slowly, and insufficiently, towards the target; this is particularly the case with self-generated anchors (Epley and Gilovich, 2001). However, when the anchors are provided by the experimenter, then

individuals typically engage System 1 of the brain (see Section 19.11) in gauging the accuracy of the anchor. System 1 is biased towards finding confirmatory evidence, which leads to anchoring.

Early studies on anchoring considered the relation between stimulus and sensation. However, Tversky and Kahneman (1974) revolutionized the field by focusing on numeric anchors, which is now the established method of eliciting anchoring effects. In a famous experiment, they rigged a wheel of fortune with numbers 1–100 to come up with either 10 or 65 (low and high anchors). They first asked subjects if the number of African nations in the United Nations was larger or smaller than the anchor (comparative judgment task). Then they asked subjects to guess the number of African nations in the United Nations (absolute judgment task). Although, in this case, the anchors are irrelevant to the questions, they had a significant effect on the subjects' guesses.

Experienced judges are also subject to the anchoring effect (Englich and Mussweiler, 2001). Anchors that are clearly implausible also have a significant effect on subjects' choices (Strack and Mussweiler, 1997; Mussweiler and Strack, 2000a). Field data show that estate agents are unduly influenced by the initially suggested list price for a house (Northcraft and Neale, 1987). Caps on damages awarded to litigants serve as an anchor and have an effect on the rate of pretrial settlements (Babcock and Pogarsky, 1999) as well as on the level of damages (Pogarsky and Babcock, 2001).

Anchoring is one of the most robust heuristics and has been documented in a wide range of contexts such as poetry reading sessions (Ariely et al., 2006); violation of a basic implication of efficient markets (Mussweiler and Schneller, 2003); and first offers in price negotiation (Galin-sky and Mussweiler, 2001). Anchoring has also been used to explain a range of other behavioral phenomena such as hindsight bias, non-linear probability weighting, and preference reversals.

Section 19.7 shows that the behavior of individuals is inconsistent with Bayes' rule, particularly when they face probabilistic information. In particular, individuals engage in *base rate neglect*, which is the tendency to give insufficient attention to the prevalence of a particular trait or feature in the overall population. Consider the well-known cab problem (Kahneman and Tversky, 1972; Bar-Hillel, 1980; Tversky and Kahneman, 1980). Cabs in a city are either green (85%) or blue (15%). One of the cabs was involved in an accident last night. A witness with a reliability rate of 80% came forward to identify that the cab involved in the accident was blue. What is the probability that a blue cab was involved? The correct answer, using Bayes' rule, is 41.4%, while the modal experimental response was 80%. Subjects appear to ignore the fact that only 15% of the cabs are blue (the base rate); thus, they engage in base rate neglect.

The base rate underweighting phenomenon is robust to several perturbations, although some might lessen it. For instance, base rate underweighting is found even when base rates are made more salient (Ajzen, 1977; Bar-Hillel, 1980), or when subjects are highly educated (Casscells et al., 1978), or when individuals have higher measured intelligence (Stanovich and West, 2000). A much better predictor of base rate underweighting is the important distinction between *causal* and *incidental* base rates (Ajzen, 1977). An example of a causal base rate is the instruction: "there are an equal number of Blue and Green taxis but 85% of the taxis involved in accidents are Green." In this case, base rate neglect is reduced (Kahneman, 2011). Furthermore, when information on base rates is combined with other non-causal information, then base rate neglect may also be reduced (Bar-Hillel, 1980).

As with many other heuristics, the claim is made that presenting the information in a *frequency format* rather than a *probability format* reduces base rate neglect (Brase, 2002b; Cosmides and Tooby, 1996; Gigerenzer and Hoffrage, 1995; Pinker, 1997). For most empirical studies that use the frequency format, the percentage of subjects who do not engage in base rate underweighting is about 40% (Barbey and Sloman, 2007). While this is an improvement over the probability

format, the case for the efficacy of frequency format is overstated. Even when data are given in natural frequencies, but the set inclusion relation is not made obvious, the benefits of natural frequency representation drop significantly (Giroto and Gonzalez, 2001). An even more practical consideration in the debate over natural frequencies versus the probability format, based on anecdotal evidence, is that most real-world economic information of interest is arguably presented in a probability format.

In contrast to base rate underweighting, the phenomenon of *conservatism* refers to *underweighting of the likelihood of a sample* (Camerer, 1995). In Section 19.7.3, we offer a reconciliation of base rate neglect with conservatism by distinguishing between the *strength* and the *weight* of *evidence* (Griffin and Tversky, 1992). For instance, in a reference letter, strength refers to the warmth and support for the applicant, while weight refers to the standing and credibility of the referee. Individuals typically give relatively greater prominence to strength. This is a form of overconfidence or base rate neglect. However, when the strength of the letter is low relative to the weight one might feel underconfident, which is a form of conservatism.

In Section 19.8, we consider *hindsight bias*. This occurs when individuals report, ex-post, that actual events coincided with their initial predictions of the events, i.e., *they knew it all along*. Hindsight bias occurs in a between-subjects (Fischhoff, 1975) and a within-subjects design (Fischhoff and Beyth, 1975). Hindsight bias differs from learning. Under learning, one learns to make better judgments about the future. Under hindsight bias, one misperceives one's own predictions made in the past, in a manner that gives rise to a lower predictive error. The main explanation of hindsight bias is that the human mind has only partial ability to recall what it used to believe in the past, particularly when one changes one's mind (Kahneman, 2011). Hindsight bias might also arise as a coping mechanism to make sense of an unpredictable world, or to signal one's competence to others (Rachlinski, 1998).

Hindsight bias is particularly important in legal judgments because jurors and judges need to determine the culpability of a defendant's action when they already know it has caused harm (Rachlinski, 1998). Hindsight bias has been found in very diverse contexts. A meta-study shows that experts are subjected to the hindsight bias (Guilbault et al., 2004). In Section 19.8.4, we apply hindsight bias to a problem in finance (Biais and Weber, 2009). We show that under hindsight bias, decision makers reduce estimates of volatility and engage in less corrective activity of incorrect models. Empirical evidence bears out the predictions of the model.

Section 19.9 considers *confirmation bias* in which individuals engage in selective interpretation of evidence so that it supports their initial beliefs. This is sometimes known as *biased assimilation* in psychology (Nickerson, 1998). There is extensive evidence of confirmation bias (Lord et al., 1979; Darley and Groos, 1983; Munro et al., 2002). Confirmation bias is not mitigated by greater cognitive abilities (Stanovich and West, 2007, 2008a,b). We also sketch a formal model of confirmation bias that can also explain the prevalence of overconfidence and underconfidence (Rabin and Schrag, 1999).

Section 19.10 considers a range of other judgment heuristics that include the following.³ People often do not take account of the phenomenon of *regression to the mean* (Galton, 1886; Tversky and

³ It is clearly not possible to consider all possible heuristics. For instance, we omit a discussion of the heuristics used to form macroeconomic expectations. Rational expectations still lie at the heart of modern macroeconomic theory and macroeconomic forecasting. Fuster et al. (2010) review evidence that is not consistent with rational expectations and outline an alternative that they call *natural expectations*. Beshears et al. (2013b) show that individuals often find it quite hard to recognize the dynamics of mean-reverting processes, an ability that is essential for existing macroeconomic models of forecasting. Ericson et al. (2015) propose a heuristic approach to choosing among time–outcome pairs that outperforms exponential and hyperbolic discounting. These approaches are likely to gain increasing importance in the future, possibly with profound effects on macroeconomics.

Kahneman, 1974). If outcomes are influenced by luck, then better (worse) than average outcomes in the current period should be expected to revert to more modest (better) levels in the future. For instance, on average, golfers with high (low) initial scores on day 1 of a tournament report lower (higher) scores on day 2 (Kahneman, 2011). People are often not very good at distinguishing between *necessary and sufficient conditions*, a distinction that is critical in many economic models (Wason, 1968). *Attribute substitution* occurs when one attribute of an object is substituted by another (Kahneman and Frederick, 2005). For instance, the answers to the two questions: “How happy are you with your life in general?” and “How many dates did you have last month?” depend on the order in which the questions are asked (Strack et al., 1988).

Section 19.11 focuses on one potential explanation of judgment heuristics. It is useful to think of the human brain as made up of two broad, but purely hypothetical, systems; System 1 and System 2 (Stanovich and West, 2000, 2002). System 1, or the emotional system, is fast, automatic, reactive, and requires little mental effort; it is also never turned off. System 2, or the cognitive system, is slow, deliberative, uses scarce cognitive resources, and takes account of the long-run consequences of our actions. Kahneman (2011) offers a powerful and cogent case for explaining judgment heuristics using this two systems approach.

Since System 1 is automatic, most judgment heuristics arise from its response. Even when an unusual situation is encountered and the services of System 2 are called upon, the agenda is often set by System 1, which controls the events that are recalled. System 1 calls the shots most of the time. This is revealed by the biases exhibited by trained statisticians in dealing with questions on probability (Tversky and Kahneman, 1973), and the extensive evidence from other expert judgments that is summarized in Section 19.18. System 1 is relatively more likely to be engaged when decisions have to be made quickly, statistical training is low, and cognitive ability is lower (Kahneman and Frederick, 2005; Oechssler et al., 2009).

In Section 19.12, we use the model of *thinking and persuasion* as a possible formalization of judgment heuristics (Shleifer et al., 2008). The idea is that, on account of cognitive limitations, individuals group different events into categories (Mullainathan, 2002). They then treat all events in the same category in an identical manner, so that there is across-category heterogeneity and within-category homogeneity; such thinkers may be termed as *coarse thinkers*. We consider the possibility that there is a persuader who controls the message received by a coarse thinker. It is never optimal for a persuader to send a misleading message to a classical Bayesian thinker but it might be optimal to mislead a coarse thinker. This model can address several puzzling phenomena such as advertising and different forms of persuasion by politicians, the media, firms, and experts. Empirical evidence supports the existence of persuasions from many domains (DellaVigna and Gentzkow, 2010).

In Section 19.13, we consider *mental models* that people form about the world around them and their place in it. These models can take several forms such as beliefs about causal relations, social identities, categorizing disparate information into coarse categories, and social worldviews (Denzau and North, 1994; WDR, 2015). Mental models are pervasive, help economize on cognitive costs, are transmitted from generation to generation, once formed they are typically inertial, and can both assist and deter optimal decisions, depending on their accuracy (Datta and Mullainathan, 2014). Humans are hardwired with some mental models, while in other cases, history plays an important role in their formation (Nunn, 2008; Alesina et al., 2013; Acemoglu et al., 2013). We also consider attempts to transform incorrect mental models into more useful ones (Datta and Mullainathan, 2014).

Section 19.14 discusses Herbert Simon’s seminal approach to bounded rationality (Simon, 1978). The idea is that in the presence of cognitive limitations, individuals should not be expected

to engage in the optimization exercises that neoclassical economic theory assumes to be the default (*substantive rationality*). As Simon (1978) famously noted: “But there are no direct observations that individuals or firms do actually equate marginal costs and revenues.” Thus, he recommends concentrating on *procedural rationality*, which focuses on the quality of the process of decisions. As Reinhard Selten has argued on many occasions, the problem is that economic problems are typically hard in the sense that they are *NP-Complete*, a term that is borrowed from the computer science literature.⁴ In an NP-Complete problem, the number of steps needed to solve a problem in any algorithm of the solution, grows exponentially with the size of the problem (e.g., the travelling salesman problem⁵). So, even for moderately difficult problems of this sort, the computing time required to solve the problem is very high. It then becomes a leap of faith that Homo economicus can solve these problems or act as if he/she can.

An example of a process that satisfies procedural rationality is *satisficing behavior*, where individuals have an *aspiration level* and adjust gradually in its direction through a sequence of steps (Simon, 1955, 1978, 2000; Selten, 2001). The word “satisficing” is a neologism that alludes to the fact that such decision procedures are satisfactory and they suffice. Empirical evidence is supportive of the theory (Caplin et al., 2011); subjects appear to search sequentially and stop searching when their aspiration level is achieved.

We demonstrate how the cooperative outcome can be achieved in the prisoner’s dilemma game as one’s aspirations adjust over time (Karandikar et al., 1998; Cho and Matsui, 2005; Börgers and Sarin, 2000). To understand the basic idea, suppose that in the prisoner’s dilemma game, players have an aspiration level that lies in between the payoffs from pure defection and pure cooperation. Then, whenever one or both players defect, one of the players finds that the payoff is below the aspiration level. Such a player then experiments by choosing another strategy. These experiments eventually lead to the cooperative outcome where all experimentation ceases.

Section 19.14.2 considers the approach of Gerd Gigerenzer and colleagues on fast and frugal heuristics. The focus of this work is to try to establish the following (Gigerenzer et al., 1999; Gigerenzer and Selten 2001): Heuristics are not mistakes, but a rational response to bounded rationality, and heuristics often outperform selected optimization methods. In some cases these heuristics are derived from evolutionary adaptation. For instance, individuals use the *gaze heuristic*, to catch a ball by employing a constant angle between the ball and the gaze. However, there should be no presumption that evolution has prepared us with the relevant heuristics needed to optimally invest in alternative pension plans or choose among alternative stocks.

We consider a range of fast and frugal heuristics, but mainly the *recognition heuristic*, and the *take-the-best* heuristic. Using the recognition heuristic, between two stocks, stock market participants invest in the stock that they recognize, relative to the one that they do not. There is some evidence that this method outperforms several investment strategies, such as purely random selection of stocks, expert judgment, and a selection of statistical selection techniques (Borges et al., 1999; Czerlinski et al., 1999). The recognition heuristic has also been used to determine which city has a higher population (Gigerenzer and Goldstein, 1996). However, doubts have

⁴ See, for instance, a video of the entertaining panel discussion on behavioral economics at the 2011 Lindau Nobel Laureate Meeting in Economic Sciences. The participants were George A. Akerlof, Robert J. Aumann, Eric S. Maskin, Daniel L. McFadden, Edmund S. Phelps, and Reinhard Selten.

⁵ Suppose that a salesman is provided with a list of cities and the distances between each pair of cities. The objective, starting with a home city, is to find the shortest possible route such that the salesman visits each city exactly once and returns to the home city.

also been raised about the robustness of these results, and contrary evidence found (Oppenheimer, 2003).

There are several concerns about this literature. First, it demonstrates the superiority of fast and frugal heuristics in domains where the relevant optimization benchmark is typically unclear. For instance, in predicting stock market prices, it is well known that the efficient markets hypothesis fails, so what is the relevant optimal solution to compare with the outcome arising from the heuristics? Furthermore, these heuristics are experimenter-provided. No compelling evidence is provided whether people do actually use these heuristics. Furthermore, in many complicated economic problems, it is not clear what these heuristics should be. In contrast, the Kahneman–Tversky approach addresses squarely the issue of which heuristics are used in different environments and the relevant optimization benchmark is unambiguous.

Section 19.15 considers what has come to be known as the *great rationality debate* in psychology, whose main protagonists are viewed as Kahneman–Tversky on the one hand, and Gerd Gigerenzer/colleagues on the other (Stanovich and West, 2000; Stanovich, 2012). The Kahneman–Tversky approach came under intense attack in the years following the publication of their work and gave rise to the rationality debate (Cohen, 1981; Einhorn and Hogarth, 1981; Lopes, 1991; Gigerenzer, 1991, 1993, 1994; Gigerenzer and Hoffrage, 1995).

This debate is often misplaced and highly muddled for, at least, the following three reasons.⁶

First, there is a basic misunderstanding of the positions of the protagonists. Kahneman–Tversky show that individuals fall short of the unambiguous statistical benchmarks required in the rational actor model in economics. Gigerenzer–colleagues show that in some domains, judgment heuristics perform quite satisfactorily against selected statistical benchmarks. Of course, both Kahneman–Tversky and Gigerenzer–colleagues may be right, and probably are right.

Second, it has been argued that data presented in terms of natural frequencies as compared to probabilities reduces or eliminates biases relative to the best statistical benchmark (Gigerenzer et al., 1988; Gigerenzer, 1991, 1993, 1994; Gigerenzer and Hoffrage, 1995). But this position is vastly overstated (Kahneman and Tversky, 1996). Even in the best case scenarios, 60% or more of the subjects continue to exhibit base rate neglect, across studies, in the presence of frequency information (Barbey and Sloman, 2007). Even for the conjunction fallacy that has been held up as the leading example of the facilitating role of the frequency format, a between-subjects design reveals a high degree of conjunction bias (Kahneman and Tversky, 1996). There are many heuristics such as the anchoring heuristic that are hardly influenced by the choice between frequencies and probabilities.

Third, the high degree of heterogeneity among subjects who exhibit biases contradicts conformity with a single rational response (Stanovich and West, 2000). Finally, there are a large number of other misconceptions about the Kahneman–Tversky position relating to context, framing effects, errors, subject misperceptions, and evolutionary adaptation that have already been well addressed and do not have a firm basis (Kahneman and Tversky, 1996; Stanovich and West, 2000; Kahneman, 2011). Kahneman and Tversky's (1996, p. 584) frustration is well captured in this quote: "The position described by Gigerenzer is indeed easy to refute but it bears little resemblance to ours. It is useful to remember that the refutation of a caricature can be no more than a caricature of a refutation."

⁶ We omit here the debate over which mental model (e.g., the dual systems model) best provides foundations for heuristics and biases (Stanovich and West, 2000). These issues are currently more central to psychologists than to economists.

Section 19.16 considers the rationale and implications of attributes of goods/services that might be *shrouded*. Attributes are said to be *shrouded* if they are partly hidden, but can be discovered by individuals at some cost. For instance, while opening a bank account, the minimum balance fees, fees for bounced checks, or other bank surcharges, might not have been very visible in the information provided. There are no advantages to firms from shrouding information in the classical case with fully rational consumers and competitive firms (Jovanovic, 1982; Milgrom, 1981). However, one does observe many examples of shrouded attributes. For instance, charging individuals high shipping costs (shrouded attribute) but low base prices (unshrouded attribute) on eBay increases sales and revenues (Hossain and Morgan, 2006). We follow up the empirical evidence with a formal model of shrouding of attributes (Gabaix and Laibson, 2006). In the presence of myopic consumers who pay insufficient attention to shrouded attributes, it may be optimal for firms to shroud information.

Section 19.17 considers the implications of *limited attention* that reflects limited cognitive abilities. Classical economics assumes full attention, which is robustly rejected by the evidence. The problem of limited attention is relatively more serious for the poor whose attention is diverted by basic problems of food, shelter, and clean water (Datta and Mullainathan, 2014; WDR, 2015). This diversion of attention is a form of *cognitive tax* (Shah et al., 2012; Mullainathan and Shafir, 2013). It reduces the quality of attention towards other important decisions; this is sometimes known as the problem of *limited bandwidth* (Banerjee and Mullainathan, 2008). The WDR (2015) is an excellent introduction to these issues.

In other contexts, consumers pay less attention to taxes that are not listed on price stickers but added at cash registers; displaying information about taxes on price stickers reduces sales (Chetty et al., 2009). Individuals pay limited attention to the rules of earned income tax credit (Hotz and Scholz, 2003). People pay less attention to electronic toll collections, as compared to manual toll collections, allowing operators to levy higher tolls (Finkelstein, 2009). Car sales in used markets are subjected to a left digit bias in odometer readings. Thus, car sales and car prices are sensitive to integer multiples of the 10,000 mile threshold (Lacetera et al., 2012; Englmaier et al., 2014). We discuss the recent work on the *sparse max operator* that formalizes a way of providing differential attention to various attributes of a good (Gabaix, 2014). We close with brief comments on the rational inattention models (Sims, 1998, 2003).

Section 19.18 collects a range of empirical results to show that experts exhibit biases in the same manner as non-experts (Tetlock, 2002; Ben-David et al., 2013; WDR, 2015). Hence, market experience does not eliminate non-standard behaviors.

19.2 The law of small numbers

In statistics, the *weak law of large numbers* is often expressed as follows.

Theorem 19.1 (*Weak Law of Large numbers; Hogg et al., 2005*) Let $\{X_n\}$ be a sequence of independently and identically distributed random variables, with a common mean μ and finite variance σ^2 . Denote the sample mean based on n observations by $\bar{X}(n) = \sum_{i=1}^n X_i/n$. Then $\bar{X}(n)$ “converges in probability” to the population mean, μ , i.e., $\lim_{n \rightarrow \infty} P[|\bar{X}(n) - \mu| \geq \varepsilon] = 0 \forall \varepsilon > 0$.

The weak law of large numbers can be strengthened to the *strong law of large numbers*, which guarantees almost sure convergence of the sample mean to the population mean (Chung, 1968). Notice that the law of large numbers is a limiting result and holds only for very large sample sizes.

By contrast, individuals are said to subscribe to the *law of small numbers* if they believe that for any sample size, the sample mean is identical to the population mean. Such people believe that the sample proportions mimic the population proportions for any sample size.

Consider the following experiment reported in Tversky and Kahneman (1974). A town is served by two hospitals. In the larger hospital, about 45 babies are born each day, and in the smaller hospital, about 15 babies are born each day. As you know, about 50% of all babies are boys. However, the exact percentage varies from day to day. For a period of 1 year, each hospital recorded the days on which more than 60% of the babies born were boys. Which hospital do you think recorded more such days?

In the sample 53 students said that both hospitals are equally likely to have recorded such days and an equal split of 21 students chose the larger and the smaller hospital, respectively. The correct answer is the smaller hospital. The reason is that the larger hospital has a larger sample size, so it is likely to better reflect the population proportion of 50%.

19.2.1 Representativeness heuristic

Tversky and Kahneman (1974) explain the *representativeness heuristic* as follows. “What is the probability that object A belongs to class B? What is the probability that event A originates from process B? . . . In answering such questions, people typically rely on the representativeness heuristic, in which probabilities are evaluated by the degree to which A is representative of B, that is, by the degree to which A resembles B.”

In one experiment, they give a description of a hypothetical individual named Steve (p. 1124): “Steve is very shy and withdrawn, invariably helpful, but with little interest in people, or in the world of reality. A meek and tidy soul, he has a need for order and structure, and a passion for detail.” Subjects in experiments were then asked to judge the probability of various professions that Steve might be engaged in, such as farmer, physician, librarian, salesman, and airline pilot. Subjects in experiments typically judged Steve’s profession by matching his description with their stereotype of that profession (representativeness). However, people do not take account of the fact that there are many more farmers than librarians; this is base rate neglect that is considered in greater detail, below.

Consider a more formal example of the representativeness heuristic (Camerer, 1987, 1990, 1995). Suppose that there are two urns, $i = A, B$, and one is chosen randomly by nature. Urn A has 1 red and 2 black balls. Urn B has 2 red and 1 black ball. It is common knowledge that nature chooses urn A with probability 0.6, so $P(A) = 0.6$ and $P(B) = 0.4$. A sequence of three balls is drawn *with replacement* from one of the urns. Subjects in experiments do not know which urn the balls are drawn from.

Let x denote the number of red balls that come up in the sample of three balls, $x = 0, 1, 2, 3$. Suppose that the sample, based on three draws, turns out to be $x = 1$. What is the posterior probability that the sample came from urn A? Using Bayes’ rule, this can be computed as follows.

$$P(A | x = 1) = \frac{P(x = 1 | A) P(A)}{P(x = 1 | A) P(A) + P(x = 1 | B) P(B)}. \quad (19.1)$$

In a single draw of a ball from an urn, there are two possibilities (red ball or black ball), hence, this is a Bernoulli experiment. Let p_A, p_B be the respective probabilities of drawing a red ball from urns A and B. Then, the thrice repeated Bernoulli experiment has a binomial distribution given by

$$P(x | i) = \binom{3}{x} p_i^x (1 - p_i)^{3-x}; i = A, B \text{ and } x = 0, 1, 2, 3. \quad (19.2)$$

A simple calculation shows that $P(x = 1 | A) = 4/9$ and $P(x = 1 | B) = 2/9$. Thus, from (19.1), we get the Bayesian estimate, $P(A | x = 1) = 0.75$. In contrast to the Bayesian estimate, an individual who uses the representativeness heuristic draws one of the following inferences.

- 1a. $P(A | x = 1) = 1$. In this interpretation, the (small) sample has exactly the same proportion of balls of each color as urn A. Hence, representativeness leads individuals to infer with certainty that the sample came from urn A.
- 1b. $P(B | x = 2) = 1$. As in 1, if the sample comprises of 2 red balls and 1 black ball, then representativeness guides the individual to infer with certainty that the balls came from urn B.
2. $0.75 < P(A | x = 1) < 1$. Here, the individual makes an inference that is intermediate between a Bayesian posterior and the extreme form of the representativeness heuristic in 1a.

19.2.2 Gambler's fallacy and hot-hands fallacy

Evidence for the law of small numbers comes from at least three kinds of tasks. In *production tasks*, individuals are asked to produce random sequences. In *recognition tasks*, subjects are asked to recognize if the given sequence is random. In *prediction tasks*, subjects are asked to predict the next element in a sequence.

INABILITY TO PRODUCE A SEQUENCE OF RANDOM NUMBERS

One implication of the law of small numbers is that many people are unable to generate a truly random sequence of events. Suppose that individual subjects are asked to generate a sequence of random tosses of a coin; denote heads by H , and tails by T . Most experimental studies find that subjects switch the outcomes too frequently, *as if* to preserve the population proportions (50–50), even in a small sample. So, for instance, the sequence H, H, H, H, H is very likely to be followed by T . In other words, the supposedly random sequences generated by individuals exhibit too much negative autocorrelation (Bar-Hillel and Wagenaar, 1991).⁷

GAMBLER'S FALLACY

If subjects produce *negative autocorrelation* when asked to produce a hypothetical random process, they are said to engage in the *gambler's fallacy*. In a well-known example, there is reduced betting on a winning number in subsequent lottery draws (Clotfelter and Cook, 1993); subjects using the law of small numbers mistakenly think that the winning number has a lower probability of coming up in subsequent draws, despite an unchanged objective probability.

Table 19.1 shows the results of a production task in Rapoport and Budescu (1997) reported by Rabin and Vayanos (2010). These subsequences are culled from an underlying hypothetical sequence of 150 tosses produced by subjects in experiments. The probabilities in the last column are the fraction of subjects who make a choice of H, conditional on the subsequence in the three leftmost columns. On average, the probability of H on the next flip, given that the last toss resulted in a H is $\frac{30+38+41.2+51.3}{4} = 40.1$. It follows, that conditional on the last toss resulting in a H, the average probability of T on the next toss is $100 - 40.1 = 59.9$; this is sometimes

⁷ For important empirical work that served to further establish this phenomenon, see Rapoport and Budescu (1992, 1997) and Budescu and Rapoport (1994).

Table 19.1 Assessed probability that the next flip of a coin will be heads (H), given a sequence of three flips; each flip is either heads (H) or tails (T). Based on Rapoport and Budescu (1997, Table 7, p. 613).

3rd-to-last	2nd-to-last	Very last	Prob. next will be H (%)
H	H	H	30.0
T	H	H	38.0
H	T	H	41.2
H	H	T	48.7
H	T	T	62.0
T	H	T	58.8
T	T	H	51.3
T	T	T	70.0

Source: Rabin and Vayanos (2010).

referred to as the *switching rate*. The difference between the probabilities of T and H is 19.8%, when the objective difference should be 0%. This negative autocorrelation suggests a gambler's fallacy.

There is negative autocorrelation not only with respect to the very last coin flip but also with respect to the "2nd-to-last" flip also. Changing the outcome from H to T on the "2nd-to-last" flip raises the average probability of an H on the next toss (last column in Table 19.1) from 43.9% to 56.1%, an increase of 12.2%. Similarly, changing the outcome from H to T in the "3rd-to-last" flip raises the average probability of an H in the next toss from 45.5% to 54.5%, an increase of 9%. Rabin and Vayanos (2010) propose a model that can account for the gambler's fallacy when the outcomes are not binary and are not iid.

A great deal of the evidence for the gambler's fallacy has come from the study of betting behavior. Clotfelter and Cook (1993) and Terell (1994) find that betting on the winning number falls in pick-3 and pick-4 games and takes several months to recover. Metzger (1984) found that people bet lower amounts on long-shot horses if another long-shot horse had won earlier in the day (the two horses can be different horses). Terrell and Farmer (1996) and Terrell (1998) show that bettors underbid on a previous race winning number in dog races, even if different dogs are involved in the two races.

Croson and Sundali (2005) confirmed the gambler's fallacy from real-world data obtained from casino players with real stakes. They considered betting on roulette wheels where one can either engage in *inside bets* on numbers 0–36 or on *outside bets* (e.g., on even/odd numbers, on numbers shaded red or black, on numbers 1–18, or 1–12, and so on). The method of identifying the gambler's fallacy is to observe a streak of winning numbers, then check if there is reduced betting on these numbers in subsequent bets. For instance, betting on Black following a streak of outcomes of color Red is an example of the gambler's fallacy. Streaks of length $l = 1, 2, \dots, 6$ are considered.

Figure 19.1 shows the results for streaks of lengths 1–6 for all outside bets. For instance, 531 bets were placed on one of the outside bets after observing one spin of the roulette wheel that produced an outside outcome; 255 of these bets, or 48%, of these bets satisfied the criterion of the gambler's fallacy. Following streaks of length 2, 258 outside bets were placed, of which the gambler's fallacy was observed in 51% of cases. Thus, for streaks of small length, the observed

Figure 19.1 Results for streaks of length 1–6 for all outside bets. The height of shaded bars is the percentage of outside outcomes and the height of blank bars is the percentage of outside bets. The horizontal axis measures streaks of length $l = 1, 2, \dots, 6$.

percentages are no different from random. However, statistically significant effects of gambler's fallacy are found for streaks of length 5 and 6. For instance, for $l = 6$, 85% of the bets are consistent with the gambler's fallacy.

The gambler's fallacy has also been applied to finance. For instance, consider the *disposition effect*, which is the tendency to sell winning stocks and hold on to loss making stocks for too long (Shefrin and Statman, 1985; Odean, 1998). The idea is that people think that a stock that has risen in the past is now due for a fall and vice versa, which is consistent with the gambler's fallacy. Odean (1998) found that people sold winning stock at a 50% higher rate than losing stock. This is a robust phenomenon and documented widely for Finnish investors (Grinblatt and Keloharju, 2001), for Israeli investors (Shapira and Venezia, 2001), for Chinese investors (Feng and Seasholes, 2005), for employee stock options (Heath et al., 1999), and for trading volumes following IPOs (Kaustia, 2004; Brown et al., 2006). The robustness of the disposition effect can be gauged from the fact that even when attempts are made to debias the subjects by making the purchase price very salient in experiments at the time of the selling decision, the disposition effect is reduced by only 25% (Frydman and Rangel, 2014).

Furthermore, while the disposition effect is relatively stronger for individual investors, institutional investors are also subjected to the disposition effect (Frazzini, 2006; Chen et al., 2007; Choe and Eom, 2009). However, Barber et al. (2007) paint a slightly nuanced picture for Taiwanese data; corporate investors and dealers exhibit the disposition effect but mutual funds and foreign investors do not. There is some evidence that the disposition effect can be mitigated with experience (Feng and Seasholes, 2005; Seru et al., 2010), and with the level of wealth (Dhar and Zhu, 2006); and it is more prevalent for hard to value stocks (Kumar, 2009).

While prospect theory has been used to justify the disposition effect, the predictions of the relevant theoretical models are sensitive to the auxiliary assumptions used.⁸ It is more straightforward to explain the disposition effect using the gambler's fallacy. Stocks that are doing well in the past are believed to revert to lower returns, so individuals sell them too early. Stocks that are not doing well are believed to appreciate, so investors hold on to them for too long.

HOT HANDS FALLACY

In contrast to the gambler's fallacy, there are instances where subjects may come to believe that there exists *positive autocorrelation* in an inherently random process. The inference of such positively autocorrelated streaks, known as the *hot hands fallacy*, has been documented in many contexts, such as in the game of basketball.

When basketball players are identified to be on a hot streak, observers assign a high probability that they will be successful in making the next shot too. However, the data does not always justify the assignment of a hot streak, given the small sample at hand. Indeed, several pioneering studies showed that the observed sequence of successful basketball shots was statistically a random sequence (Gilovich et al., 1985; Tversky and Gilovich, 1989a,b). In contrast, the betting behavior of individuals reflects beliefs in such streaks (Camerer, 1989).

Recent, unpublished research, has raised the possibility of actual hot streaks in basketball and baseball, thus, there might be no hot hands fallacy in these contexts (Green and Zwiebel, 2013; Bocskocsky et al., 2014; Miller and Sanjurjo, 2015). The basic idea is that in games like basketball, a player on a hot streak is likely to be more tightly marked by the opposition, and forced to take more difficult shots, hence, reducing the observed impact of hot streaks. Controlling for these factors, a weak hot hands phenomenon has been found in some studies. In Bocskocsky et al. (2014), for instance, players who have hot hands are 1.2 to 2.4 percentage points more likely to make a successful shot in basketball. As the authors note, there are several potential issues with how the level of difficulty of a shot is described, as well as the construction of non-standard measures (such as "complex heat") used to infer the extent of hot hands.

By contrast, Miller and Sanjurjo (2015) found stronger evidence of hot hand effects in the neighborhood of 7 percentage points. It should be pointed out, lest it not be obvious, that a statistical demonstration of the hot hands phenomenon does not necessarily negate the hot hands fallacy. For the negation to occur, it would be necessary to demonstrate that individuals see through the statistical occurrence of the hot hands phenomenon. For instance, a control group of subjects could be tested on a randomly generated sequence of basketball shots with streaks in them. Can the subjects spot that the underlying process is purely random? To the best of my knowledge such controls have not been carried out yet, hence, claims that the hot hands fallacy is not real are premature.

However, there is good evidence from other contexts where the *hot hands phenomenon* does not exist, yet the *hot hands fallacy* exists. In a novel field experiment, Guryan and Kearney (2008) find that sales at lotto stores that have sold a winning ticket soar in the immediate weeks following the lotto win; Figure 19.2 plots the log sales at lotto stores in the 40 previous and 40 subsequent weeks following a winning ticket sold at the store. The effect does diminish over time, yet it lasts for an impressive 40 weeks following the win. One possible confounding factor is that a lottery win in a zip code makes the act of playing a lottery salient. In order to check for this, the sales figures of all lotto stores in the winning zip code area are also examined. There is some overall

⁸ For prospect theory explanations of the disposition effect, see Barberis and Xiong (2009), Hens and Vleck (2011), Henderson (2012), and Kaustia (2010).

Figure 19.2 Retail level data for Lotto Texas wins.

Source: Guryan and Kearney (2008) with permission from the American Economic Association.

increase in sales in the same zip code, suggesting an advertisement, or spillover, effect. However, relative to all stores within the zip code, or stores within a mile of the winning store, the sales increase in the winning store is significantly higher, suggesting a store-specific effect.

A natural explanation for the increased sales at winning stores is the hot hands fallacy. In this case, the hot hands fallacy does not arise from a winning streak, but rather from a single observation. However, bettors typically observe a streak of losses and a win at one store, while there is a continuing streak of losses at all other stores. This observation suggests a possible expansion in the scope of the hot hands fallacy. A competing explanation is that people believe in non-existent variation in luck across stores.

The effect on sales in the winning store is increasing in the size of the win. A week after the win, sales increased in the Texas Lotto stores by 37.7%. The corresponding increase in sales for smaller jackpot games is 21.5% (for the Texas Two Step) and 12.4% (for the Cash Five game). Furthermore, the effect is stronger in areas that have more high school dropouts, higher rates of poverty, and a greater proportion of elderly people, suggesting that some or all of these factors may enhance cognitive biases that give rise to the observed effect.

The hot hands fallacy is also found in Croson and Sundali (2005) who study gambling on roulette wheels. Here, 80% of the subjects quit playing after losing on a spin. In contrast, only 20% quit on winning. This is consistent with the idea that winning players wish to continue playing because they believe that luck is on their side (i.e., they are *hot*, or on a *roll*). The regression results confirm this finding. In this case, for individual-level data, there is a statistically significant effect of winning in one round and the number of bets placed in the next round after controlling for individual heterogeneity.

Jørgensen et al. (2011) find the presence of the gambler's fallacy and the hot hands fallacy using panel data from the Danish State Lottery. There are two types of individuals in their data. The first type picks the same numbers every week. The second type of individuals avoids the non-winning numbers they chose last time (gambler's fallacy) and are more likely to choose numbers that are perceived to be on a winning streak (hot hands fallacy).

Powdthavee and Riyanto (2015) show that individuals are willing to pay for an expert who they believe has a hot hand in predicting inherently random sequences of numbers. This theme is

explored in chapter 20 in Kahneman (2011) under the title “The Illusion of Validity.” He argues that the returns to professional funds are typically (although not always) the result of luck rather than skill.⁹ As evidence, he cites the fact that the temporal correlations in performance for any mutual fund are quite weak, and close to zero, which is consistent with the luck story. Yet, small investors are willing to pay significant amounts for expert financial advice. Malmendier and Tate (2009) find that superstar CEOs (based on previous performance) underperform in subsequent periods. This is also consistent with the story in which high outcomes are achieved, at least partially, by luck, but one eventually experiences regression to the mean (see Section 19.10.1). Some of these issues are taken up in greater detail in Section 21.7 in Chapter 21.

WHY DO THESE FALLACIES ARISE?

Tversky and Kahneman (1974) report that in successive tosses of an unbiased coin, the sequence H, T, H, T, T, H is considered more likely than the sequence H, H, H, T, T, T ; however, both sequences have identical statistical probabilities. One plausible explanation is that the second sequence is not considered to be *representative* of the population proportions. As the authors beautifully put it (p. 1125): “Chance is commonly viewed as a self-correcting process in which a deviation in one direction induces a deviation in the opposite direction to restore the equilibrium. In fact, deviations are not ‘corrected’ as a chance process unfolds, they are merely diluted.” This also explains the role of the representativeness heuristic in the gambler’s fallacy; gamblers do not bet on the previously winning numbers because they believe that deviations will be corrected, rather than diluted over a sufficiently long period of time.

Like the gambler’s fallacy, the seemingly opposite phenomenon of positive correlation when the underlying process is the hot hands fallacy, can also be potentially explained by the representativeness heuristic. In this case, following several identical signals, the sequence of observed signals appears more and more representative of a positively autocorrelated underlying random process. An observer who is subject to the hot hands fallacy then makes predictions based on the incorrectly perceived underlying random process.

Ayton and Fischer (2004) suggest that the domains of the gambler’s fallacy and the hot hands fallacy might be different. They propose that the hot hands fallacy is more likely to arise for human performance, as is the case with basketball and tennis players, rather than for inanimate processes such as throws of a dice or coin tosses. The reason is that a streak in sports may signal unobservable variables about a player to observers, such as the level of confidence, fatigue, and the quality of training prior to the game. These unobservable variables do not apply to inanimate processes for which subjects may switch too often in small samples to preserve the population proportions, as suggested by the representativeness heuristic. This also potentially explains emerging evidence of hot hands in basketball and baseball referenced above, yet in inanimate processes such as the outcome of lotteries, there is strong evidence of the hot hands fallacy (see above).

In one set of experiments, the authors presented the subjects with various sequences of outcomes that had varying degrees of positive and negative autocorrelation. Subjects were asked to guess the source of these sequences: human skilled performance (e.g., a professional basketball player’s scoring attempts, or a professional tennis player’s first serve in) or an inanimate process (e.g., a coin toss, or a binary outcome roulette wheel). Each sequence consisted of 21 binary

⁹ Kahneman writes (2011, p. 218): “The idea that large historical events are determined by luck is profoundly shocking, although it is demonstrably true.” He gives an interesting example. Before an embryo is fertilized there is a 50–50 chance that it will be a male or a female. Thus there was a 1/8 chance that the world could have survived the three dictators, responsible for a large number of twentieth century deaths—Hitler, Stalin and Mao Zedong.”

Figure 19.3 Is the observed sequence with a given alternation rate more likely to have come from basketball or a coin toss?

Source: With kind permission from Springer Science + Business Media: *Memory and Cognition* 32: 1369–78. Ayton, P. and Fisher, I. (2004). "The hot hand fallacy and the gambler's fallacy: two faces of subjective randomness?" © 2004 Springer Science + Business Media.

outcomes. The alternation rate is the number of times a sequence changes direction divided by 10.

The results for one of the comparisons is shown in Figure 19.3. Consistent with the authors' predictions, sequences with low rates of alternation were rated by subjects to have more likely come from basketball rather than coin tosses. Conversely, sequences with high rates of alternation were rated as more likely to have come from a coin toss. These results highlight when the gambler's fallacy is more likely to arise (high alternation rates arising from an inanimate process) and when the hot hands fallacy is more likely to arise (low alternation rates and involvement of human skills).

19.2.3 A formal model of the law of small numbers

Consider one possible method of formalizing the law of small numbers in a simple model with the following features (Rabin, 2002).¹⁰

1. Move by nature: Nature chooses a parameter $\theta \in \Theta$. Individuals have a prior distribution $\pi(\theta)$ over the set Θ .
2. The *actual* data generating process: Consider a Bernoulli trial with two possible outcomes: x (success) and y (failure) that occur with respective probabilities $\theta \in [0, 1]$ and $1 - \theta$. Suppose that we independently repeat the Bernoulli trial n times, with replacement. Denote by n_x , the number of times that the outcome equals x in the n trials. It is well known that the number of successes follows a binomial distribution; the probability that there are n_x successes out of n Bernoulli trials is given by

$$p(n_x) = \binom{n}{n_x} \theta^{n_x} (1 - \theta)^{n - n_x}; \quad n_x = 0, 1, \dots, n.$$

¹⁰ For a theoretical application to finance, see Section 21.6 below.

3. Misperception about the data generating process: The true underlying process is one with replacement. An individual who knows the true model of the world is known as a *Bayesian*. However, suppose that individuals believe, incorrectly, that the data is generated by the following process, without replacement.

Let time period t be an odd number. At time t , an urn has N balls; θN balls denote outcome x and the remaining, $(1 - \theta)N$, balls denote outcome y . A ball is drawn with replacement at time t . At time $t + 1$, an even time period, the individual believes (incorrectly) that there are only $N - 1$ balls left in the urn. In period $t + 2$, which is an odd time period, the urn is replenished again to N balls.

Thus, in an odd period, the probability of outcome x is $\frac{\theta N}{N}$. Now suppose that outcome x materializes in an odd period. Then, in the following period (an even period), the individual believes (incorrectly) that the probability of the outcome x is $\frac{\theta N - 1}{N - 1}$, while the probability of outcome y is $\frac{(1 - \theta)N}{N - 1}$. To ensure that the problem is not vacuous, we assume that there are at least two balls corresponding to each outcome in every possible urn. So $\theta N \geq 2$ and $(1 - \theta)N \geq 2$.

Such an individual, who believes in an incorrect model of the world, but is otherwise skilled in all aspects of classical statistical inference, is referred to as an *N-Freddy*. If N is very large, then *N-Freddy* behaves very much like a Bayesian but for small N he can be very biased.

CERTAINTY ABOUT THE TRUE θ AND THE GAMBLER'S FALLACY

The gambler's fallacy is a direct implication of the model. Consider the probability of outcome x in an "even period" following outcome x in the previous (odd) period, i.e., the conditional probability $P(x | x)$. For a Bayesian who uses the correct model, $P(x) = P(x | x) = \theta$. In contrast, for *N-Freddy*, who uses an incorrect model, $P(x) = \frac{\theta N}{N} = \theta$ and $P(x | x) = \frac{\theta N - 1}{N - 1} < \theta$. Hence, following an outcome x , *N-Freddy* reduces the probability that the next draw will produce the signal x , which is precisely the gambler's fallacy. In contrast, the Bayesian is not subject to the gambler's fallacy.

Suppose we say that Freddy gets even "Freddier" if N falls. What are the implications for the gambler's fallacy? For an *N-Freddy*, $\frac{\partial P(x|x)}{\partial N} = \frac{1 - \theta}{(N - 1)^2} > 0$. So, as N falls, $P(x | x)$ also falls and the gambler's fallacy becomes even worse.

Whilst the Bayesian decision maker and Freddy might revise beliefs in the same direction, there are systematic differences between their predictions. To see this, suppose that there are two values of θ : $\theta_L < \theta_H$. Starting in an odd period, consider a sample of two consecutive x outcomes. For any θ , the likelihood of this sample for Freddy is $L(x, x | \theta) = \frac{\theta N}{N} \frac{\theta N - 1}{N - 1} = \frac{\theta(\theta N - 1)}{N - 1}$. Thus for two different values, θ_L, θ_H , the likelihood ratio for Freddy is

$$\phi_F = \frac{L(x, x | \theta_H)}{L(x, x | \theta_L)} = \frac{\theta_H(\theta_H N - 1)}{\theta_L(\theta_L N - 1)}. \quad (19.3)$$

On the other hand, for a Bayesian, who uses the correct model of the world, $P(x) = P(x | x) = \theta$, so the relevant likelihood ratio is

$$\phi_B = \frac{L(x, x | \theta_H)}{L(x, x | \theta_L)} = \frac{\theta_H^2}{\theta_L^2}. \quad (19.4)$$

Comparing (19.3) with (19.4) we get that $\phi_F > \phi_B$. Thus, Freddy assigns a lower likelihood to the signal coming from $\theta = \theta_L$ relative to the Bayesian. In other words, observing two successive x outcomes, Freddy assigns a much greater likelihood of the urn containing a larger number of x outcomes, relative to a classical statistician.

UNCERTAINTY ABOUT THE TRUE θ AND OVERCONFIDENCE

Now suppose that the urn has 4 balls, $N = 4$ (so we have a 4-Freddy) and Freddy is uncertain about the true value of θ . Suppose that the outcome can either be *good*, x , or *bad*, y . One may imagine that the draw of a ball from an urn corresponds to the outcome of a production/financial task that is overseen by a manager. We make two assumptions.

1. The probability of the good outcome, θ , takes three equally likely values, $\theta_L = \frac{1}{4}$, $\theta_M = \frac{2}{4}$, $\theta_H = \frac{3}{4}$. Thus, θ indexes the competence of the manager; higher values denote greater competence.
2. The urn is now replenished every four periods and the starting period is odd as before.

Thus, a 4-Freddy believes that the outcomes for a type θ_L manager are drawn from an urn containing four balls such that only one ball corresponds to the good outcome x and three balls correspond to the bad outcome y , thus, $x = 1$, $y = 3$. Similarly, for types θ_M and θ_H , $x = 2$ and $x = 3$, respectively. On the other hand, a Bayesian knows that all draws are independently drawn from a Bernoulli distribution and the urn is replenished every period.

Suppose that starting in period 1, the performance of the manager is good for two consecutive periods. The Bayesian knows that the random draws are identical and independent, so for any θ , he assigns the conditional probability $P(x, x | \theta) = \theta^2$, and, in particular,

$$P(x, x | \theta_L) = \frac{1}{16}, P(x, x | \theta_M) = \frac{1}{4}, P(x, x | \theta_H) = \frac{9}{16} > \frac{1}{2}. \quad (19.5)$$

Given assumptions 1 and 2, the 4-Freddy instead assigns the conditional probabilities (or sample likelihoods) as follows.

$$P(x, x | \theta_L) = \frac{1}{4} \times \frac{0}{3} = 0, P(x, x | \theta_M) = \frac{2}{4} \times \frac{1}{3} = \frac{1}{6}, P(x, x | \theta_H) = \frac{3}{4} \times \frac{2}{3} = \frac{1}{2}. \quad (19.6)$$

For any θ , relative to a Bayesian, the 4-Freddy assigns a lower value of $P(x, x | \theta)$. The reason is that once an x outcome is obtained, Freddy believes that the urn contains one less x outcome, reducing the probability that a subsequent outcome will be x .

We are now interested in computing $P(\theta_H | x, x)$, i.e., the posterior belief that the analyst is of the highest type, following a sequence of two good performances. Using Bayes' rule we get that

$$P(\theta_H | x, x) = \frac{P(x, x | \theta_H)P(\theta_H)}{P(x, x | \theta_L)P(\theta_L) + P(x, x | \theta_M)P(\theta_M) + P(x, x | \theta_H)P(\theta_H)}. \quad (19.7)$$

Noting that $P(\theta_L) = P(\theta_M) = P(\theta_H) = \frac{1}{3}$ (because each type is equally likely) and substituting (19.5) and (19.6) sequentially into (19.7), Freddy computes $P(\theta_H | x, x) = \frac{21}{28}$, while a Bayesian computes $P(\theta_H | x, x) = \frac{18}{28}$. Thus, based on a sample of two observations, the 4-Freddy is more confident than the Bayesian that the fund manager is of the highest type. This is a form of over-

confidence, based on observing very small samples, which plays an important role in behavioral finance.

Overconfidence is considered in greater detail in Section 21.7 in Chapter 21. Here, we offer some brief comments. Suppose that in financial markets, an observer who behaves like Freddy observes the performances of several financial analysts. Then those analysts who, purely by luck, achieve successive good outcomes, say, x, x, x , will be believed by the observer to be more likely to be extremely competent ($\theta = \theta_H$), relative to a Bayesian. Analogously those who achieve a sequence of bad outcomes, say, y, y, y , again purely by luck, are believed to be more likely to have low competence ($\theta = \theta_L$), relative to a Bayesian. Indeed, the observer may be willing to pay a premium to use the services of the analyst that they mistakenly perceive to be more competent (Powdthavee and Riyanto, 2015).

This situation is not unrepresentative, even if it is artificially constructed. Kahneman (2011, ch. 20) recounts that he was once invited to speak to a group of financial advisors who provided their services to very wealthy clients. Examining the data on 25 of those advisors over eight years, he ranked the advisors by performance in each year and then computed the correlation coefficients of the ranks in each pair of the eight years. The average of the correlations was close to zero, 0.01. Thus, it appears that it is not skill but luck that governs the relative performance of the advisors and the firm was rewarding luck not skill.

Needless to say, exposure to these results did not go down very well with the analysts. As Kahneman (2011, p. 216) puts it: “Their own experience of exercising careful judgment on complex problems was far more compelling to them than an obscure statistical fact.” Since financial analysts are typically good at explaining past financial events with the benefit of hindsight (see hindsight bias in Section 19.8 below), an understanding of the past gives them the mistaken view that they can predict the future.¹¹ For a theoretical model of overconfidence in finance that is consistent with the views of Kahneman (2011) described above, see Gervais and Odean (2001). In this model, investors who do better than others, purely by luck, view their success as vindication of their skill rather than luck. This creates overconfidence that might nevertheless be tempered by subsequent experience.

19.3 Conjunction fallacy

Another illustration of the violation of a basic principle of probability theory is the *conjunction fallacy*. Tversky and Kahneman (1983) posed the following problem to Stanford students who were well-trained in decision sciences.

“Linda is 31 years old, single, outspoken, and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.” Which of the following statements is most likely?

1. Linda is a bank teller (B).
2. Linda is active in the feminist movement (F).
3. Linda is a bank teller and is active in the feminist movement (BF).

¹¹ For more details, see Chapters 19 and 20 in Kahneman (2011) under the headings “Illusion of understanding” and “Illusion of validity.”

Since the event $BF \subseteq B$ and $BF \subseteq F$, it follows under classical statistics that $P(BF) \leq P(B)$ and $P(BF) \leq P(F)$. Any violation of these inequalities is a *conjunction fallacy*. The problem stated above has three choices: B , F , and BF . An earlier version of the problem was handed out with eight choices. Between 85–90% of the respondents rated the event BF as more likely relative to the separate events B and F . Thus, subjects exhibit the conjunction fallacy. In one version, 85% of the sample of doctoral students in the decision-science program at the Stanford graduate school of business committed the conjunction fallacy.

There is a very large literature on the conjunction fallacy. In addition to the literature reviewed below, the interested reader may consult the survey in Moro (2009) and Kahneman (2011, ch. 15). For a skeptical view, see Hertwig and Gigerenzer (1999). For a review of the literature on the causes of the conjunction fallacy, see Tentori et al. (2013).

The *Linda problem*, as it came to be known, was bitterly criticized and continues to be criticized, although, as we show below, no conclusive evidence of its rejection has been given. Indeed Tversky and Kahneman (1983) themselves addressed many potential criticisms, but their caveats were conveniently forgotten.

19.3.1 *Does a natural frequency format resolve the conjunction fallacy?*

Hertwig and Gigerenzer (1999) report that if the Linda problem is posed in terms of natural frequencies (e.g., 15 out of 100 rather than 15%), then subjects do not engage in the conjunction fallacy. However, Kahneman and Tversky (1996) find that presenting the information in natural frequencies does not eliminate the conjunction fallacy. They presented the following Linda problem to three groups of subjects (Groups 1, 2, 3) in a natural frequency format.

Linda is in her early thirties. She is single, outspoken, and very bright. As a student she majored in philosophy and was deeply concerned with issues of discrimination and social justice. Suppose there are 1000 women who fit this description. How many of them are

- (a) High school teachers? [Groups 1, 2, 3]
- (b) Bank tellers? [Groups 1, 2]
- (c) Bank tellers and active feminists? [Groups 1, 3]

In the between-subjects treatment, the median response for choice (c) was statistically larger than the median response for choice (b), confirming the conjunction fallacy. Subsequent evidence in Tentori et al. (2004) also supports the view that presenting the information in the form of natural frequencies does not eliminate the conjunction fallacy.

19.3.2 *Do monetary incentives and groupthink eliminate the conjunction fallacy?*

Charness et al. (2010) introduce incentives in the Linda problem and allow for consultation in groups of twos (pairs) and threes (trios); as a baseline, they also consider individual decisions (singles). The incentive for giving the correct answer is an extra \$2 over the show-up fee of \$2. The results are shown in Table 19.2; T&K, 1983 is Tversky and Kahneman (1983) and CLK, 2008 is the working paper that forms the basis of the reported results in Charness et al. (2010).

Tversky and Kahneman (1983) find that 85.2% of their subjects engage in the conjunction fallacy. The corresponding number in Charness et al. (2010), based on a test of proportions, is 58.1%

Table 19.2 Violations of the conjunction fallacy.

Study	Details	Incorrect answers/ total sample	Error rate (percent)
<i>Individuals</i>			
T&K, 1983	UBC undergrads, no incentives	121/142	85.2
CKL, 2008	UCSB students, singles, no incentives	50/86	58.1
CKL, 2008	UCSB students, singles, incentives	31/94	33.0
CKL, 2008	UCSB students, total singles	81/180	45.0
<i>Pairs</i>			
CKL, 2008	UCSB students, in pairs, no incentives	27/56	48.2
CKL, 2008	UCSB students, in pairs, incentives	5/38	13.2
CKL, 2008	UCSB students, total in pairs	32/94	34.0
<i>Trios</i>			
CKL, 2008	UCSB students, in trios, no incentives	10/39	25.6
CKL, 2008	UCSB students, in trios, incentives	5/48	10.4
CKL, 2008	UCSB students, total in trios	15/87	17.2

Source: Charness et al. (2010).

and it is statistically smaller. Furthermore, Table 19.2 shows that the violation of the conjunction rule falls significantly when singles are given incentives (from 58.1% to 33%).

The conjunction rule is violated even less when one moves from pairs to trios, as compared to moving from singles to pairs.¹² Thus, “three heads are better than one.” In the presence of incentives, trios violate the conjunction rule in only 10.4% of the cases. Since university students are likely to be better trained in probability theory, it will probably be worth replicating these results with a non-student population. Furthermore, the high rates of violations of the conjunction fallacy for singles leaves open the possibility that in real-world situations with singles, the conjunction fallacy may yet play an important role.

In contrast to these results, Bonini et al. (2004) show that monetary incentives do not crowd out the conjunction fallacy. They give subjects the option of allocating 7 euros among three options: (1) Option *B*. (2) Option $B \wedge F$ (where $\wedge$ is the logical operator “and”). (3) Option $B \wedge (\sim F)$, where $\sim F$ is the option “not *F*.” The third option controls for the objection that subjects may actually be interpreting (1) as (3), i.e., the option *B* as $B \wedge (\sim F)$. It is a dominant action to bet on Option *B*, so if subjects did not engage in the conjunction fallacy, we should observe all subjects to bet 7 euros on Option *B*.

Across all blocks of experiments, the average amount allocated to the first option was 1.99 euros. In contrast, the corresponding allocation to options 2 and 3, respectively, the dominated bets, was 3.15 euros and 1.86 euros. The difference between the allocations to options 1 and 2 is statistically significant at 5% significance, using a one tailed t-test. In the five blocks of experiments, the average percentage of subjects that engaged in the conjunction fallacy was 85.32, which is nearly identical to the figure of 85% reported in Tversky and Kahneman (1983). Furthermore,

¹² Similar advantages of group consultation in the reduction of stochastically dominated options is reported in Charness et al. (2007).

the experimental results in Stolarz-Fantino et al. (2003) further argue for the robustness of the conjunction fallacy to monetary incentives and framing effects.

19.3.3 *Why does the conjunction fallacy arise?*

One possible explanation of the conjunction fallacy is the use of the representativeness heuristic. The description of Linda as a feminist and a bank teller is relatively more representative of her described traits. Kahneman (2011, p. 158) writes of his initial excitement about the result: “we had pitted logic against representativeness, and representativeness had won!”

Conditional on Linda’s description, it is plausible that Linda is a member of the feminist movement. If this were substituted by a non-plausible event (e.g., Linda works for the local council), then there is no presumption that the conjunction fallacy would arise. Consider the following problem given in Kahneman (2011).

Which alternative is more probable?

Mark has hair.

Mark has blond hair.

In this problem, the given information does not make blond hair more plausible, hence, as expected, no conjunction fallacy was found.

Yet another potential explanation of the conjunction fallacy is based on interpreting the role of “and” in the Linda problem (Camerer, 1995, p. 598). The explanation centers on the validity of the interpretation of the word “and” as the logical operator $\wedge$ such that $A \wedge B$ means the intersection of the sets A and B . Hertwig et al. (2008) argue that in the statement A and B , “and” could be interpreted as (i) events A and B happening in temporal sequence as in “I went to the store and bought some whisky”, or (ii) as a causal relationship “Smile and the world smiles with you.” Hertwig et al. (2008) then go on to explore the precise sense in which their subjects in experiments interpret “and.” They find that subjects who interpret “and” as the logical operator are less likely to be engaged in the conjunction fallacy.

However, Tentori et al. (2004) show that although the conjunction fallacy is lessened by taking account of the literal differences between the conjunction “and” and the logical operator $\wedge$, it nevertheless remains an important fallacy. A fairly detailed discussion of these issues is provided in the careful study by Tentori and Crupi (2012). They concede that the word “and” may have different meanings in different sentences, but within the same sentence its meaning is often unambiguous. Since “and” is one of the most widely used words in the English language, ambiguity of its use within the same sentence would have been disastrous for communication, which has been at the heart of human evolution. They also point out that the multiple conjunctions considered in Hertwig et al. (2008) (e.g., in their experiment 3) have even lower probability than the single conjunctions in the Kahneman–Tversky results and these do not disprove the conjunction fallacy. They argue, in particular, that the theoretical foundations for the claims and the empirical inferences in Hertwig et al. (2008) are questionable. They perform two novel experiments and their results directly contradict the Hertwig et al. results.

Kahneman (2011, pp. 164–5) summarizes his recent feelings about the fallout from his research on the Linda problem: “The Linda problem attracted a great deal of attention, but it also became a magnet for critics of our approach . . . These arguments were sometimes extended to suggest that our entire enterprise was misguided: if one salient cognitive illusion could be weakened or explained away, others could be as well . . . The net effect of the Linda problem was an increase in the visibility of our work to the general public, and a small dent in the credibility of our approach among scholars in the field. This was not at all what we had expected.”

19.4 The availability heuristic

Tversky and Kahneman (1974) describe the availability heuristic as follows: “There are situations in which people assess the frequency of a class or the probability of an event by the ease with which instances or occurrences can be brought to mind. For example, one may assess the risk of heart attack among middle-aged people by recalling such occurrences among one’s acquaintances.”

As one might expect, this heuristic can lead to inferential mistakes. In one experiment, Tversky and Kahneman (1974) presented subjects with a mixed-gender list of names in which the men and women were equally represented. In treatment 1, the men in the list were famous but not the women. In treatment 2, the opposite was true. Subjects have to infer if there were more men named in the list than women. In treatment 1 subjects reported a higher number of men, while in treatment 2, they reported more women. Thus, when instances in a class are more easily retrieved, the class appears to be more numerous, even if the alternative classes are equally represented.

Salience of an event might also influence how easily, similar events are retrieved from memory. So, for instance, subjects assign higher probabilities to road accidents or house fires, after having just seen one. Tversky and Kahneman (1973) ask subjects the probability that a randomly picked three letter word from the dictionary begins (event *A*) or ends (event *B*) with the consonants *r* or *k*. Because it is easier to retrieve words beginning with the letters *r* or *k* rather than those that end with these consonants, subjects assigned greater probability to event *A*. However, the correct answer is event *B*.

If subjects cannot recall events from memory, then the ease of hypothetically constructing specific instances will determine which event is thought to be more likely. Tversky and Kahneman (1974) ask subjects in experiments to imagine, or hypothetically construct, all the possible contingencies, risks, or dangers that might arise from a risky expedition. If it is particularly easy to mentally construct these contingencies, then the expedition may be deemed too dangerous and abandoned. Conversely, if the contingencies are too hard to construct, then the opposite could be true. However, ease or difficulty of constructing these contingencies might not be perfectly related to the actual dangers involved in the expedition. Hence, in each case, individuals following such a heuristic could make potentially fatal errors.

More vivid memories may be more easily retrieved. Hence, individuals may assign higher subjective probabilities to a range of events such as airplane accidents, shark attacks, muggings, and snake bites. The media plays a potentially important role in creating vivid memories and selecting for us the subsets of events that can be retrieved. In particular, the media is often driven by considerations of the novelty, rarity, and poignancy of events. In the context of the availability heuristic, Eisenman (1993) shows that, based on media stories, individuals may believe that drug use has increased, when in fact it has decreased. Lichtenstein et al. (1978) find that people’s perception of risk is higher for events that are more extensively covered by the media. As Kahneman (2011, p. 138) puts it: “The world in our heads is not a precise replica of reality.”

The empirical study of Lichtenstein et al. (1978) has been very influential in establishing the availability heuristic.¹³ Their main contribution was to show a tight link between the frequency of death by various causes and two proxies for the availability of such events in human memory. They discovered that the first proxy, *direct experience* (e.g., death of a friend or close relative),

¹³ For a review of the empirical literature on the availability heuristic, see Betsch and Pohl (2002) and Kahneman (2011).

predicted better as compared to the second proxy, *indirect experience* (e.g., exposure to statistics via the media). This result is supported by Hertwig et al. (2005) who found that the best predictor of an individual's choice between the risks of two alternative causes of death is the knowledge of similar events in one's social network.

We consider now the empirical study by Pachur et al. (2012) that not only replicates the empirical work of Lichtenstein et al. (1978) but also draws attention to the relation between the availability heuristic and the *affect heuristic* that we consider below in Section 19.5. In the first set of experiments, Swiss university students were given three tasks. In the incentivized *choice task*, among the set of 24 cancers, subjects had to guess for each possible pair (276 pairs in total), the cancer that causes more deaths per year. In the *estimation task*, subjects had to guess the number of deaths caused by each type of cancer per year. In the *valuation task*, individuals were required to make *value of statistical life judgments* (VSL); this required them to place a monetary value, measured in Swiss francs, on one life saved from each type of cancer. For each type of cancer, individuals also reported the number of deaths that they could recall within their social network.

The results are shown in Table 19.3; *Mdn* denotes the median value. For the moment, we ignore column 5, the dread score; it is used later in our discussion of the affect heuristic. The main results are as follows.

1. In the binary *choice task*, there were 62.2% correct answers, i.e., subjects guessed correctly which of the two cancers caused greater fatalities.
2. In the *estimation task*, the correlation between the estimated and actual fatalities is 0.46 ($p = 0.2$).
3. In the *valuation task*, there is much variation in the monetary figures that subjects assign to saving a life from a particular kind of cancer. For instance, the VSL figure on breast cancer is four times higher than on rectal, bladder, or ovarian cancer. A fuller explanation of these results is given in the discussion on the affect heuristic below.
4. The correlation between the median estimated frequency of risk (column 3) and the mean number of recalled instances (column 6) was 0.62 and this is highly significant at the 1% level. The corresponding correlation reported in Lichtenstein et al. (1978) was 0.5 to 0.9.

In a second set of experiments, the authors consider the classic set of risks in Lichtenstein et al. (1978). These risks pertain to diverse causes of death such as diseases, homicides, asthma, suicides, murders, and natural hazards. The three tasks in this experiment (choice, estimation, and valuation) are identical to the first experiment. The main difference is that the last column in Table 19.3 is now split up into direct experiences (number of recalled instances in one's social network) and indirect experiences (the number of recalled instances in the media).

The results are as follows. In the binary choice task that compared the relative mortality rates from two different causes of death, subjects guessed the correct answer in 69% of the cases. The correlation between the estimated frequencies and direct experience is 0.50, which is significant at the 1% level. This suggests an important role of the availability heuristic. However, the correlation of indirect experiences with the estimated frequency is low.

Kuran and Sunstein (1999) introduce the idea of *availability cascades*. This refers to a self-fulfilling sequence of events that are typically sparked by an initial media report about an event that is not major, followed by an emotional, affective, reaction from the public. This gives rise to another heightened round of emotional, self-fulfilling events, and so on. Eventually, and typically, this leads to a policy response that is not justified on cost-benefit terms. The interested reader can consult the authors' explication of their ideas based on two case studies. The *Love Canal affair* and the *Alar scare*.

Table 19.3 Empirical evidence for the *availability* and *affect* heuristics.

	Annual mortality rate	<i>Mdti</i> frequency estimate	<i>Mdn</i> VSL	Affect (M dread score)	Availability (M number of instances in social network)
Penis cancer	10.2	40.0	10000	4.65	0.00
Testicular cancer	17.2	109.5	25000	4.55	0.03
Bone cancer	37.5	80.0	30000	4.88	0.12
Thyroid cancer	69.3	80.0	30000	4.44	0.03
Larynx cancer	94.2	50.0	20000	3.92	0.24
Cancer of the connective tissue	94.3	45.0	17500	4.40	0.00
Cancer of the gall bladder	196.5	30.0	11010	4.31	0.09
Malignant melanoma (skin cancer)	242.0	50.0	17102	3.59	0.24
Cervical cancer	295.8	95.0	20000	4.39	0.15
Renal cancer	339.2	50.0	20000	4.30	0.03
Cancer of the mouth and throat	351.0	60.0	12609	3.91	0.00
Esophageal cancer	384.5	50.0	15000	4.31	0.09
Rectal cancer	437.2	80.0	10000	4.14	0.00
Bladder cancer	450.5	30.0	10616	4.23	0.03
Ovarian cancer	453.2	100.0	20000	4.43	0.03
Cancer of the nervous system	455.0	90.0	30000	5.02	0.32
Hepatic cancer	513.0	110.0	10000	4.04	0.18
Stomach cancer	572.2	115.0	20000	4.22	0.18
Pancreatic cancer	897.8	60.0	17501	4.43	0.26
Colon cancer	1172.2	120.0	10000	4.23	0.15
Prostate cancer	1312.3	87.0	23115	4.53	0.32
Leukemia and lymphoma	1331.7	100.0	35000	4.91	0.38
Breast cancer	1347.3	200.0	40000	4.24	0.79
Lung cancer	2756.0	300.0	22500	4.00	0.50

19.5 The affect heuristic

There is a correlation between the ease of retrieval of information about an event, which is the basis of the availability heuristic, and the emotional, or *affective*, reactions to the event. In making judgments, individuals tag the *affect* or the positive and negative quality/feeling *induced* by the representation of an event, signal, or stimulus. These tags, in turn, produce an *affect pool* that individuals draw on, in making judgments and decisions (Slovic et al., 2002). The affective response is the immediate response to a stimulus, as distinct from a deliberative response. We have already encountered the affect heuristic in the book. Two leading examples come from Part 6. These are

the *risk as feelings* hypothesis (Loewenstein et al., 2001) and the work of Antonio Damasio that studied the link between affective reasoning and rational judgment.

In an early contribution, Zajonc (1980) noted that we do not just see a car, we see a *sleek car*, a *cool car*, an *ugly car*, depending on the *affect* of the car on us. Slovic et al. (2002, p. 398) write: “We sometimes delude ourselves that we proceed in a rational manner and weight all the pros and cons of the various alternatives. But this is probably seldom the actual case. Quite often ‘I decided in favor of X’ is no more than ‘I liked X’ . . . We buy the cars we ‘like,’ choose the jobs and houses we find ‘attractive,’ and then justify these choices by various reasons.” This view is radically different from the textbook consumer theory taught to students of economics.

Kahneman (2011) notes that these affective shortcuts are an instance of *substitution* in which one substitutes the answer to a hard question (What do I think about it?) by the answer to an easier question (How do I feel about it?). This provides a cognitive shortcut to engaging in a deliberative response that is time consuming, particularly in the case of complex and difficult problems that must be decided within a time constraint. For this reason, we speak of a heuristic in these situations—the *affect heuristic*.

On the one hand, the affect heuristic offers a speedy solution to complicated problems. On the other hand, it might not lead to an optimal payoff for an individual. Firms routinely use diverse strategies to tap into the affect heuristic of consumers to increase their sales (see the problems at the end of Part 7). The affective system is not very good at tracking small changes, or changes that are remote in time. This explains the difficulty in resisting one more fag (Slovic et al., 2002), which is not optimal for an individual interested in kicking the habit.

The policy recommendation by Cass Sunstein, in several publications, is to base public policy on a strict cost–benefit basis in order to ensure maximum mileage for the taxpayer’s dollar. This is in contrast to the position taken by Paul Slovic, the leading advocate of the affect heuristic (see below), who argues that there are no objective risks. Since experts typically measure objective risks (e.g., lives saved or lost) whereas the public has a subjective notion of risk, basing policy on a cost–benefit basis ignores the will of the public, which is not democratic. For a further discussion on this fascinating issue, see Kahneman (2011).

19.5.1 *Empirical evidence for the affect heuristic*

Fischhoff et al. (1978) showed that the perception of risks of various hazards depended on the *dread* that these hazards invoked. The hazards included antibiotics, X-rays, vaccines, smoking, and alcohol. Furthermore, the judgment of risks of various hazards, and the subjective benefits that individuals assign to these risks, are negatively correlated. Thus, individuals assign lower benefits to risks that they dread. However, there need not be any relation between the degree of risk and the benefits associated with an event. These results show that human judgments are based not only on what they *think* but also, perhaps mainly, on what they *feel*.

Alhakami and Slovic (1994) found that the relation between perceived risks and benefits from activities was influenced by how *affectively charged* the activity was. Finucane et al. (2000) exploited these results to show that the affect of an event, substance, object, or technology (we use the collective term “hazard”) determines both the perceived risk as well as the perceived benefit. Exploiting an implication of this insight they found that (i) the perceived benefits of a hazard can be altered by revealing the degree of risk, and (ii) the perceived risk can be altered by revealing the benefits. For instance, in the case of nuclear power, subjects assigned low (high) risks when it was revealed to them that the benefits are high (low). These results were even stronger when subjects had to make their decisions under greater time pressure.

Slovic et al. (1999) replicated these results with experts who were members of the British Toxicology Association, demonstrating that the affect heuristic is probably hardwired and difficult to undo with training. The experts were given a list of 30 chemical items and asked to make a quick intuitive rating of the items on an *affect scale* that ranged from bad to good; the chemicals included second hand smoking, dioxins in food, benzene, and aspirin. Once the experts had made the affect rating, they were asked to make a risk judgment of exposure to each chemical when the exposure level was 1/100 of the level rated to be dangerous by an appropriate regulatory agency. Clearly, at these levels, the chemicals should carry little or no risk and there should probably be little variation in the assessed risks. However, the affect ranking and the risk ranking of the chemicals was strongly negatively correlated for 95 out of the 97 experts; chemicals that had a relatively bad affect were judged to be relatively more risky.

We now revisit the data in Table 19.3 and interpret the results in column 5 that reports the dread score based on 12 risk characteristics in Slovic et al. (1980). Experts tabulate deaths by objective measures such as the number of lives lost. However, for most individuals, there are *better deaths* and *worse deaths*. For instance, death in a ghastly accident, or a painful death, elicits a more affective response as compared to learning that someone died in their sleep. Thus, the perception of individuals, unlike those of experts, about the risks associated with various cancers, or the risk of death by various causes, are often based on an affective reaction.

For the first set of experiments on the set of 24 different cancers (reported in Table 19.3), the availability heuristic performs better than the dread score in predicting binary choices among fatalities arising from different types of cancers. However, the dread score had better explanatory power in explaining the VSL judgment. The correlation between the two is 0.44 with a p-value of 0.03. In the second set of experiments (classic set of risks in Lichtenstein et al., 1978), the availability heuristic does better than the affect heuristic when it comes to predicting fatalities in binary comparisons of a classic set of risks. However, in the VSL judgment, both heuristics do equally well.

19.5.2 *The relative effectiveness of the probability and frequency formats*

Slovic et al. (2000) explored the effect of frequency representations and equivalent probability representations of information on the affect heuristic. The subject pool was experienced forensic psychologists and psychiatrists. Subjects were asked to guess the likelihood that a patient discharged from a mental hospital would commit an act of violence within six months of being discharged. In the first treatment, subjects were given the relative frequency estimate of other experts of similar patients committing the violent act; e.g., 10 out of every 100 such patients commit a violent act. In the second treatment, the view of other experts was given as a percentage (e.g., 10% of similar patients commit a violent act). The frequency estimates of the opinion of other experts (treatment 1) produced significantly higher estimates as compared to the probability estimates (treatment 2). Thus, frequency estimates appear to be more *affective*.

These results are in conformity with the empirical results of Denes-Raj and Epstein (1994). Here, subjects were given a prize for drawing a red bean from two different urns whose composition could be seen in a picture. The majority of the subjects chose the urn with the higher number of red beans (e.g., 10 out of 100) rather than the urn with the higher percentage of red beans (e.g., 2 out of 10). Images of a higher number of red beans are more affective.

19.6 Anchoring and adjustment

It is an extremely robust and reliable empirical finding that the inferences made by people are heavily dependent on an *initial suggestion* or *anchor*. The anchor could be informative or entirely uninformative. This phenomenon is known as *anchoring*. Unlike some of the other judgment heuristics, we can numerically measure the precise degree of anchoring. Early studies of the anchoring effect first appeared in psychophysics, which studies the relation between stimulus and sensation. For instance, the perceived duration of a target sound depended on a long or short sound (anchor) that subjects had previously been exposed to; for a brief review of this literature, see LeBoeuf and Shafir (2006).

The field was revolutionized by the work of Tversky and Kahneman (1974), who departed from the practice in psychophysics by focusing on numeric anchors. Their method has since become the established norm for experiments on anchoring. In the typical experiment, subjects are given a pair of questions. The first question asks them to make a *comparative judgment*. Here, subjects indicate if a target quantity, x_T , is greater or lower than some anchor, x_0 . In a second question, subjects are asked for an *absolute judgment*, their best estimate of the target value, x_T . Anchoring arises if in the second question, the estimated target value is influenced by the anchor, x_0 .

19.6.1 Empirical evidence for anchoring

In a celebrated experiment, Tversky and Kahneman (1974) rigged a wheel of fortune with the numbers 1–100 to stop at either of the two numbers: 10 or 65. Subjects had to write down the number that the wheel stopped at. They were then asked the following two comparative and absolute judgment questions.

Comparative judgment question: Is the percentage of African nations among UN members larger or smaller than the number you just wrote?

Absolute judgment question: What is your best guess of the percentage of African nations among UN members?

The answers to the second question were found to be anchored too closely on the irrelevant number that came up on the wheel. Those who observed the number 10 (respectively, 65) in the comparative judgment question, answered 25% (respectively, 45%) in the absolute judgment question. Kahneman (2011, p. 120) writes: “We were not the first to observe the effects of anchors, but our experiment was the first demonstration of its absurdity.” These results immediately spawned great interest and the results were replicated in a large number of contexts and shed light on many disparate phenomena.

The anchoring effect can be numerically measured. Kahneman (2011) reports the following experiment. Subjects were asked the following two questions in a San Francisco Exploratorium.

1. Is the height of the tallest redwood more or less than x_0 feet?
2. What is your best guess about the height of the tallest redwood?

Two different values of the anchor, x_0 , measured in feet, were given to two different groups of subjects; a high anchor value, $x_0^H = 1200$, and a low anchor value, $x_0^L = 180$. The answers to the target values in the second question were, respectively, $x_T^H = 844$ and $x_T^L = 282$. Using a method proposed by Jacowitz and Kahneman (1995), we can calculate the *anchoring index* as $\frac{x_T^H - x_T^L}{x_0^H - x_0^L} \times 100 = 55\%$.

In Mussweiler and Strack (1999), in the comparative condition, subjects were asked: “Is the mean temperature in Antarctica in winter higher or lower than $-x_0$ °C?” The initial temperature

was intended to serve as an anchor. Two anchors were used, a high anchor, -17°C , and a low anchor, -243°C . This is followed by an elicitation of the absolute judgment of subjects of the mean winter temperature in Antarctica. The answer in the absolute judgment condition was closely correlated with the anchor values of $-x_0^{\circ}\text{C}$.

Anchors need not always be provided by the experimenter. They can be self-generated. As an example, consider the experiment in Tversky and Kahneman (1974) in which two groups of subjects was asked to take 5 seconds to find the answers to two calculations: $1 \times 2 \times \dots \times 8$ and $8 \times 7 \times \dots \times 1$. Due to the time pressure, the first few numbers are likely to serve as anchors. If this reasoning is correct, then the first calculation gives a low anchor and the second gives a high anchor. The correct answer to the identical calculations is 40,320. However, the median answers to the ascending and descending sequences are, respectively, 512 and 2250, which is consistent with an anchoring explanation.

The finding of Tversky and Kahneman (1974) that implausible anchors influence the outcomes has been replicated widely. Strack and Mussweiler (1997) asked subjects in the comparative judgment question if Mahatma Gandhi was younger than 140 years (high anchor) or older than 9 years (low anchor); both anchors are implausible. However, the respective answers by the two groups of subjects in the absolute judgment question (Mahatma Gandhi's age) were 67 years and 50 years, demonstrating a strong anchoring effect. Mussweiler and Strack (2000a) report similar findings in which subjects had to guess the length of the Mississippi river in the absolute judgment task. In the comparative judgment tasks, two anchors were given. A short but plausible anchor, 2000 miles, and a long, but implausible anchor, 30,000 miles. The answers to the absolute judgment question were significantly influenced by the anchors; mean estimates in the low and the high anchor conditions were 3,768 miles and 12,144 miles.

Field evidence also supports anchoring. Northcraft and Neale (1987) showed that the estimated value of properties by estate agents was influenced by the list price, which served as an anchor. Estate agents were given a 10 page booklet with all relevant information about a property. The booklet also contained a list price, which was either \$83,900 (high anchor) or \$65,900 (low anchor). Agents exposed to the high anchor priced the property significantly higher and the *anchoring effect* was 41%. Business school students were only slightly more susceptible to anchoring; the anchoring effect in this case was 48%. The estate agents insisted that the anchor had no effect on their calculations, yet the significant anchoring effect is incompatible with their insistence.

Anchoring may be related to entitlements. In Ariely et al. (2006), two groups of students attend a poetry reading session. The first group is asked if they *would pay* \$2 to attend the session. The second group is asked if they would attend if they *were paid* \$2. The anchor given to the first group suggested that the poetry reading session would give them utility, while the anchor to the second group is suggestive of disutility. Later, both groups were asked if they would attend for free. A third of the subjects in the first group agreed to attend but only 8% in the second group agreed to attend.

In the efficient markets hypothesis (see Chapter 21 for details), the past pattern of prices of securities should not reveal any new information that enables one to predict the future price. Mussweiler and Schneller (2003) use the anchoring heuristic to provide one test of theory. Their subject pool is Business and Economics students at a German university who have had experience of the stock market, ranging from a year to approximately three years. They provide students with background information about a company and the relevant economic conditions, drawn from an actual financial firm.

They also show students either the left or the right panel of Figure 19.4 that plots the stock price of the company over the previous 12 months. The left panel has a salient high price and the right

Figure 19.4 High price is salient (left panel) and low price is salient (right panel). Starting and ending prices are the same in both cases. The average profits over the 12 months are 20% in both cases.

Source: Mussweiler, T. and K. Schneller (2003). "What goes up must come down—how charts influence decisions to buy and sell stocks," *The Journal of Behavioral Finance* 4(3): 121–30. Reprinted by permission of Taylor & Francis Ltd., <http://www.tandfonline.com>

panel has a salient low price. Otherwise the starting and the ending prices as well as the average profits corresponding to both panels are identical. Subjects were asked to state price expectations of the stock in each case and also asked if they would invest in the asset.

The anchoring heuristic suggests that subjects who observe the high salient price will have relatively higher price expectations and are more likely to invest as compared to subjects who are shown the low salient price. These predictions are confirmed. The predicted mean prices when the high and low price, respectively, is salient are 132 and 112; the difference is statistically significant.

19.6.2 Legal and regulatory implications of anchoring

Experienced individuals also exhibit the anchoring effect. The subjects in Englich and Mussweiler (2001) are experienced trial judges with an average experience of 15 years. In one experiment, they were given the case of a fictitious shoplifter who is accused of stealing from a supermarket for the 12th time. Detailed case material was compiled and it included opinions from a psycho-legal expert, and testimonies by the defendant and a witness. A pre-test with experienced legal professions showed that the case material was complete and realistic. In the pre-test, the mean sentence was 5.62 months with a standard deviation of 2.57.

Subjects in the experiment were asked to determine an appropriate sentence. In two different treatments, the case material showed that the prosecutor had asked for a sentence of, respectively, 9 months (high anchor) and 3 months (low anchor). Subjects in the high anchor treatment chose a sentence of 8 months and those in the low anchor treatment chose a sentence of 5 months. The anchoring effect was $\frac{8-5}{9-3} \times 100 = 50.0\%$. Crucially, the authors find that experience does not mitigate the anchoring effect. Legal professionals and experienced judges exhibit a similar bias.

Anchoring has interesting regulatory implications. Consider, for instance, the problem of caps on damages in litigation. Saks et al. (1997) considered two treatments. In the first treatment, damages were capped at the relatively high level of \$250,000 for trial awards for minor injuries. In the second treatment, there were no caps. They found that the average trial award was \$3895 in the uncapped treatment and \$15,718 in the capped treatment; anchoring at a high cap level significantly increased the average trial award.

Babcock and Pogarsky (1999) considered the rate of pretrial settlements with and without caps. They conducted experiments in which subjects in their role as either plaintiffs or defendants received case material on a personal injury lawsuit. They then had to negotiate a settlement with

the other party within 20 minutes. The default award made by a judge, should the bilateral negotiation fail, was capped at \$250,000 in one treatment and left uncapped in another treatment. It was found that the rate of pretrial settlement was higher in the capped treatment.

Pogarsky and Babcock (2001) found that the rate of pretrial settlement is negatively influenced if the damages cap is set very high. They considered a cap of \$1,000,000 in the capped treatment and reduced the severity of the plaintiff's injuries in the case material, relative to Babcock and Pogarsky (1999). This ensured that the cap appeared to any reasonable observer as too high. Unknown to the subjects, an actual trial court judge had opined a settlement of \$325,000, based on the case material. The non-binding settlement cap reduced the settlement rate, as the authors had expected; 79% of the plaintiff–defendant pairs settled in the uncapped treatment, while 67% settled in the capped treatment. Thus, litigants appear to look ahead and anticipate the effect on the award of damages that is caused by high caps.

19.6.3 *Robustness of anchoring*

The anchoring phenomenon is remarkably robust to a wide range of domains, contexts, and frames. These include estimates of price (Mussweiler et al., 2000; Northcraft and Neale, 1987); the probability of a nuclear war (Plous, 1989); the evaluations of lotteries and gambles (Chapman and Johnson, 1994); issues of legal judgment (Chapman and Bornstein, 1996; Englich and Mussweiler, 2001); and first offers in price negotiation (Galinsky and Mussweiler, 2001). Anchoring has been used to explain a range of other judgment heuristics. These include the hindsight bias (Fischhoff, 1975); preference reversals (Lichtenstein and Slovic, 1971); and non-linear probability weighting (Tversky and Kahneman, 1974).

Anchoring is also robust to a wide variety of conditions. These include, clearly uninformative/random anchors (Mussweiler and Strack, 2000b; Tversky and Kahneman, 1974), or anchors known to be very extreme (Chapman and Johnson, 1994; Strack and Mussweiler, 1997). Anchoring appears not to be affected by forewarning the subjects or by the provision of incentives (Tversky and Kahneman, 1974; Wright and Anderson, 1989; Wilson et al., 1996; Chapman and Johnson, 2002). We have already noted that experienced subjects also exhibit the anchoring effect. In conjunction, these findings suggest that humans appear hardwired to use the anchoring heuristic.

19.6.4 *Explanations of anchoring*

In light of the robustness and reliability of the phenomenon, it is important to ask what causes anchoring. Tversky and Kahneman (1974) conjectured an explanation in terms of *insufficient adjustment* from an anchor to a proposed target. Quattrone (1982) and Quattrone et al. (1981) propose a bounded rationality explanation for insufficient adjustment. In this proposal, the individual begins with an *anchor*, x_0 , about some target value, x_T , that is believed to belong to an interval $[a, b]$, where a, b are real numbers. Suppose that $x_0 \notin [a, b]$. The individual then engages in a series of improvements of the anchor using a *satisficing heuristic* and stops whenever he hits one of the boundaries of the interval $[a, b]$. If the guess that $x_T \in [a, b]$ is objectively correct, the individual ends up at a distance $x - a$ or $b - x$ from the actual value, x . This is referred to as insufficient adjustment. However, if $x_0 \in [a, b]$, then no adjustment is needed.

Evidence for the insufficient adjustment hypothesis is given in LeBoeuf and Shafir (2006, 2009) who were inspired by the original experiments in the psychophysics of anchoring. In LeBoeuf and Shafir (2006), subjects were required to draw a line that was 3.5 inches (or 89 mm) long; this corresponds to x_T . They were given one of two anchors; see Figure 19.5. The short anchor, x_0^s , was a line starting from the bottom of the page; subjects were told that this line was shorter than 3.5

Figure 19.5 Anchoring and insufficient adjustment.

Source: *Journal of Behavioral Decision Making* 19(4): 393–406. LeBoeuf, R. and Shafir, E., “The long and short of it: physical anchoring effects.” Copyright © 2006 John Wiley & Sons, Ltd.

inches. Subjects were asked to extend it, so that, in their assessment, it was 3.5 inches (88.9 mm) in length. Another group of subjects were shown a line starting from the top of the page and told that it was longer than 3.5 inches; this is the long anchor, x_0^l . They had to shorten the long line to 3.5 inches. Subjects exposed to x_0^s produced, on average, a line length of 61.2 mm with a standard deviation of 17 mm, and subjects exposed to x_0^l produced a line that had an average length of 74.7 mm with a standard deviation of 15.4 mm.

A second explanation for anchoring is that anchors induce System 1 in the brain to search for anchor-consistent information. In this explanation, the anchor serves a *priming function*. Consider Tversky and Kahneman’s (1974) experiments on anchoring described above in which subjects are asked for the number of African countries in the UN. Suppose that the wheel of fortune comes up with a high number, which is the higher anchor. A high anchor enables one to access information that is consistent with the number of countries in Africa being high. For instance, that Africa has a large size, or Africa has a large coastline.

It is crucial to appreciate that System 1 attempts to evaluate the given information by trying to prove that it is true (Snyder and Swan, 1978; Crocker, 1982; Trope and Bassok, 1982; Klayman and Ha, 1987). As Kahneman (2011) argues, System 1 tries its best to construct a world in which the anchor is the true number. System 2 is deliberative, yet it deliberates on the menu of memories chosen by System 1. Hence, a biased set of memories, evoked by priming, have a ripple effect on the decision made by the individual in the absolute judgment task.

When should we evoke the insufficient adjustment explanation and when should we evoke the priming explanation? Epley and Gilovich (2001) give one possible resolution of this problem. They distinguish between two kinds of anchors. Those that are self-generated and those that are provided by the experimenter. They argue that self-generated anchors are known to be wrong from the beginning, so the individual does not need to engage in retrieving anchor-consistent information to judge its correctness. Rather, the problem is to adjust the initial anchor towards the target, as explained above in the case of insufficient adjustment. However, anchors provided by the experimenter need to be evaluated for correctness by evoking anchor-consistent information.

Consider two examples of self-generated anchors from Epley and Gilovich (2001). (1) Subjects are asked to estimate the freezing point of vodka. In thinking about the answer, participants typically start at 0°C, the freezing point of water, and adjust downwards, knowing that the freezing

point of alcohol is lower than water. (2) Which year was George Washington first elected president? In this case, most Americans seem to begin with the year of the declaration of independence, 1776, and adjust upwards from it.

Epley and Gilovich find that self-generated anchors trigger adjustment, while those provided by the experimenter do not. For instance, in the second question (election year of George Washington), 64% of the subjects were found to engage in anchoring and adjustment when the anchor was self-generated. However, when the anchor was provided by the experimenter in two other questions, mean length of a whale, and mean winter temperature in Antarctica, only 12% and 14%, respectively, engaged in anchoring and adjustment. This reasoning is confirmed in the experimental results of Epley and Gilovich (2006). Furthermore, they find that adjustment entails cognitive effort. When subjects are exposed to cognitive load, say, having to remember a set of numbers, or they are drunk, then they engage in insufficient adjustment.

19.7 Base rate neglect and conservatism

The use of Bayes' rule underpins all aspects of neoclassical economics. In this section, we examine the evidence on Bayes' rule. Suppose that we have n mutually exclusive random variables $X_1, X_2, \dots, X_n$ such that the sample space $X = X_1 \cup X_2 \cup \dots \cup X_n$. Then Bayes' rule implies the following computation for any event $A \subseteq X$ such that $P(A) > 0$,

$$P(X_i | A) = \frac{P(A | X_i)P(X_i)}{P(A)} = \frac{P(A | X_i)P(X_i)}{\sum_{j=1}^n P(A | X_j)P(X_j)}. \quad (19.8)$$

In (19.8), $P(X_i)$ and $P(A)$, $i = 1, \dots, n$, are referred to as the *base rates*.

19.7.1 Base rate neglect

An important empirical finding is that base rates have very low salience in calculations of $P(X_i | A)$. Meehl and Rosen (1955) is an early study that found underweighting of base rates by clinical psychologists. Consider the following well-known *cab problem* introduced by Kahneman and Tversky (1972); modified versions of the problem are considered in Bar-Hillel (1980) and Tversky and Kahneman (1980).

There are only two cab companies in the city, Green and Blue; 85% of the cabs are Green. There was an accident last night. A witness comes forward to testify that the cab involved in the accident was Blue. In similar conditions, the reliability of the witness is 80%, i.e., the probability that the witness gets it wrong is 20%. What is the probability that the actual cab involved in the accident was Blue?

Let X_1 = Blue cab, X_2 = Green cab, and let the event, "identification by the witness that the cab is Blue" be A . Then, using (19.8),

$$P(X_1 | A) = \frac{P(A | X_1)P(X_1)}{P(A | X_1)P(X_1) + P(A | X_2)P(X_2)}. \quad (19.9)$$

Using $P(A | X_1) = 0.8$ (probability of a correct identification), $P(A | X_2) = 0.2$ (probability of an incorrect identification), $P(X_1) = 0.15$ (base rate), and $P(X_2) = 0.85$ (base rate) we get

$$P(X_1 | A) = 0.414.$$

By contrast, the median and the modal response was $P(X_1 | A) = 0.8$. Notice that 0.8 is also the probability with which the witness correctly identifies a Blue cab as the one involved in the accident. In particular, individuals appear to underweight base rates, which is not consistent with Bayes' rule. They ignore the fact that only 15% of the taxis are actually Blue. The problem of underweighting of base rates diminishes but does not disappear when greater salience is given to base rates in the design of experiments (Ajzen, 1977; Bar-Hillel, 1980).¹⁴

Consider an adaptation of the problem that Casscells et al. (1978) gave to students at Harvard Medical School. Suppose that a police Breathalyzer test discovers false drunkenness in 5% of the cases when the driver is sober. However, the Breathalyzers are always able to detect a truly drunk person with complete certainty. In the general population, a fraction 1/1000 of drivers engage in driving while drunk. Suppose that a driver is checked at random, and takes a Breathalyzer test, which shows that the driver is drunk. How high is the probability he or she really is drunk? The modal response was 95%, the mean response was 56% and a sixth of the students gave the correct answer, which is approximately 2%. Thus, even very educated and clever subjects underweight the base rate in relatively simple problems.

In some cases, underweighting of base rates does not take place. Consider, for instance, the following variant of the cab problem from Kahneman (2011). "There are only two cab companies in the city, Green and Blue, who own an equal number of cabs. 85% of the cabs involved in accidents are Green." The rest of this problem is identical to the earlier cab problem following the instruction: "There was an accident last night" . . . This, and the earlier cab problem, are mathematically equivalent. Yet, one finds that subjects give attention to the base rate in the second problem. The median response is that the cab involved in the accident was blue is 0.60. Indeed this appears as an average of the correct answer, 0.41, and the reliability of the witness, 0.80.

What accounts for the relative salience of base rates in this case? The answer depends on the distinction made by Ajzen (1977) between *causal* and *incidental* base rates. A causal base rate conveys information on some causal factors relevant to the problem, while incidental base rates do not. For instance, in the original cab problem, the base rates are incidental. However, in the modified cab problem, the base rates are causal because they suggest to the decision maker that drivers of Green cabs are particularly reckless. This is because despite identical numbers of Blue and Green cabs, Green cabs are involved in 85% of the accidents. Hence, the individual assigns a lower probability to Blue cabs being involved in the accident, which curbs their tendency to underweight the base rate of Blue cabs.

Bar-Hillel (1980) showed that subjects may combine information on base rates with other non-causal information to mitigate base rate neglect. For instance, in one modification of the cab problem, subjects were told that the hit-and-run cab was equipped with an intercom and intercoms are installed on 80% of the Green cabs and 20% of the Blue cabs. The mathematical structure of this problem is identical to the original cab problem, yet the median response was 0.48, not far from the Bayesian answer of 0.41.

A variety of factors have been identified that reduce base rate neglect. Individuals appear to pay more attention to base rate information, when they are instructed to think like statisticians rather than clinical psychologists (Schwarz, Strack, Hilton, and Naderer, 1991). Individuals with higher measured intelligence also underweight base rates less (Stanovich and West, 2000). Girotto and

¹⁴ For more evidence on the neglect of base rates, see Grether (1980) who found that likelihoods are more salient than base rates, although the latter were not altogether ignored. See also Grether (1992) for an extension of his earlier work.

Gonzalez (2001) find that if the attention of subjects is drawn to the computations required in a Bayes' rule calculation, then base rate neglect falls. Sloman et al. (2003) find that presenting the information in a diagram that highlights set inclusion also reduces base rate neglect.

Empirically it has been observed that presenting the information in a frequency format rather than a probability format reduces base rate neglect (Brase, 2002b; Cosmides and Tooby, 1996; Gigerenzer and Hoffrage, 1995; Pinker, 1997). Consider the following problem of *base rate neglect* used originally in Eddy (1982) and then in the experiments of Gigerenzer and Hoffrage (1995). The problem is expressed in probability terms as follows.

The probability of breast cancer is 1% for a woman at age forty who participates in routine screening [base-rate]. If a woman has breast cancer, the probability is 80% that she will get a positive mammography [hit-rate]. If a woman does not have breast cancer, the probability is 9.6% that she will also get a positive mammography [false-alarm rate]. A woman in this age group had a positive mammography in a routine screening. What is the probability that she actually has breast cancer?

The Bayesian solution is readily found. Let X be the event "positive mammography" and Y the event "breast cancer" and let $\sim X, \sim Y$ be negations of these events. Then

$$P(Y | X) = \frac{P(X | Y)P(Y)}{P(X | Y)P(Y) + P(X | \sim Y)P(\sim Y)} = \frac{0.008}{0.008 + 0.096(0.99)} = 0.0776.$$

Thus, the Bayesian response is that conditional on getting a positive mammography, the probability that the individual has breast cancer is 7.76%. In Eddy's (1982) original study, less than 5% of the respondents gave answers that conformed to the Bayesian solution. Gigerenzer and Hoffrage (1995) tested the same problem in the probability format and the natural frequency format. In the probability format they found that the choices of 16% of the respondents conformed to the Bayesian solution, but in the natural frequency format, 46% of the responses conformed to Bayes' rule.

A sample of the studies that use the frequency format is shown in Table 19.4, drawn from Barbey and Sloman (2007). The second column shows that when the problem is presented in a probabil-

Table 19.4 Percentage of responses consistent with Bayes' rule in different empirical studies. Sample sizes in parenthesis.

ity format, the percentage of subjects conforming to Bayes' rule is relatively small. However, there is much greater conformity with Bayes' rule when the information is presented in a frequency format (third column). The Cosmides and Tooby (1996) result is an outlier that Sloman et al. (2003) and Evans et al. (2000) could not replicate. Despite the rhetoric, in the presence of a frequency format, less than half of the subjects conform to Bayes' rule in this cross section of studies.

It is also likely that other factors could facilitate conformity with Bayesian reasoning when the natural frequency format is given (Cosmides and Tooby, 1996). These factors include, in particular, monetary incentives and controlling for the ability levels of students, e.g., hiring subject pools at top universities. It is argued that these factors lead to statistically significant differences in the facilitation role of natural frequencies relative to the probability format (Brase et al., 2006). But this also casts doubt on the evolutionary explanation, which lies at the heart of the facilitating role of natural frequency formats. At best, these results are suggestive of the relation between cognitive effort and cognitive ability with the facilitation role of natural frequencies in improving conformity with Bayes' rule.

When data is presented in natural frequencies, but the set inclusion relation is not made obvious (although it can be easily computed from the data), then the facilitation role of natural frequencies drops significantly (Giroto and Gonzalez, 2001). Furthermore, Brase (2002a) finds that the probability and the natural frequency format are both perceived to be equally very clear unless the probabilities are of a very low magnitude. This is difficult to reconcile with the claimed facilitating role of the natural frequency format.

Based on the evidence, the case for the natural frequency format in reversing base rate neglect appears overstated.

Why might problems expressed in terms of natural frequency facilitate Bayesian reasoning? Some of the competing theories considered by Barbey and Sloman (2007) are as follows. In the *mind as a Swiss army knife* view (Cosmides and Tooby, 1996; Gigerenzer and Selten, 2001), the brain comprises several modules. Each module is responsible for a specific set of functions and is not under the voluntary control of the individual. In this view, there is a specific module, with evolutionary origins, designed to process natural frequencies, but not probabilities. One natural advantage of the frequency format is that it preserves the sample size and makes transparent the subset relation between two sets (e.g., 1 out of every 100 women have breast cancer).

A second view is that the brain has a *natural frequency algorithm* (Gigerenzer and Hoffrage, 1995). This view makes no assumptions about the modularity of brain architecture. However, for all practical purposes, this is fairly similar to the first view. Barbey and Sloman's (2007) preferred explanation is based on a System 1, System 2 distinction. In this view, the frequency format is more consistent with the natural inputs required by System 2 to process information. As the peer commentary in the same issue of *Behavioral and Brain Sciences* makes clear, however, there is no consensus among psychologists on this issue.

19.7.2 *Conservatism*

Conservatism refers to the underweighting of the likelihood of a sample. We illustrate this using a problem in Camerer (1995), which is originally due to Edwards (1968). Suppose that there are two urns A and B, each of which contains only red and blue balls. Urn A has 7 red and 3 blue balls and urn B has 3 red and 7 blue balls. It is common knowledge that nature is equally likely to choose one of the two urns, so $P(A) = 0.5$ and $P(B) = 0.5$. A sample of 12 balls is drawn *with replacement* from one of the urns, but subjects do not know which one.

Suppose that the number of red balls in a sample of size 12 is $x \in \{0, 1, \dots, 12\}$. Consider the sample, 8 red and 4 blue balls, which does not exactly represent the proportions in any of the two urns. Hence, we cannot use the representativeness heuristic. Let p_A and p_B be the respective probabilities of drawing a red ball from urns A and B. Analogous to (19.2), the conditional probability of drawing x red balls in a sample of 12 balls from urn $i = A, B$ is

$$P(x | i) = \binom{12}{x} p_i^x (1 - p_i)^{12-x}; i = A, B \text{ and } x \in \{0, 1, \dots, 12\}. \quad (19.10)$$

The Bayesian posterior belief that the sample came from urn A is given by

$$P(A | x = 8) = \frac{P(x = 8 | A) P(A)}{P(x = 8 | A) P(A) + P(x = 8 | B) P(B)}. \quad (19.11)$$

We already know that $P(A) = 0.5$, $P(B) = 0.5$. Since $p_A = 0.7$, $p_B = 0.3$, we get from (19.10) that $P(x = 8 | A) = 0.231$, $P(x = 8 | B) = 0.008$. Substituting these numbers in (19.11), we get that $P(A | x = 8) = 0.967$. However, the typical response reported in Camerer (1995) is 0.7 to 0.8. Hence, subjects in experiments appear too conservative about sample likelihoods.

19.7.3 A reconciliation of conservatism and base rate neglect

It appears contradictory that in some cases the base rate is underweighted (as in the cab problem), while in others the sample information is underweighted (conservatism). We need a model that identifies circumstances when we are confident (underweighting base rates), and underconfident (conservatism). Griffin and Tversky (1992) show that these two phenomena can be reconciled by distinguishing between the *strength* and the *weight* of evidence. Consider two illustrative examples of these concepts.

1. Suppose that one is trying to evaluate a reference letter for a graduate student, written by an academic referee. The strength of the letter is the information that it provides about the student, for instance, how warm and positive the letter is, while the weight is the credibility/standing of the referee.
2. Suppose that we toss a coin n times to determine if it is biased. The strength of the evidence is the number of times it shows up as heads while the weight is the sample size.

While it is not always possible to neatly separate the strength and weight of evidence in every case, in many cases one may be able to do so. Griffin and Tversky (1992) argue that people give undue importance to strength as compared to the weight of the evidence, relative to what would be prescribed by standard statistical techniques. In particular, people begin by giving undue importance to the strength of the evidence and then adjusting insufficiently for the weight of the evidence. For instance, in the first example, we often see how warm the reference letter is and then adjust for the credibility of the writer. We feel underconfident when there is a moderately positive letter from a very credible referee. An overconfident judgment arises when strength is high relative to weight. Conversely, an underconfident judgment gives relatively more importance to the weight, particularly when the strength is low.

Consider the following experiment that Griffin and Tversky conducted with 35 students. A coin is tossed n times and the number of heads (H) and tails (T) is noted. Subjects are told that the bias of the coin is $3/5 = 0.6$, but they are not told the direction of the bias. Hence, subjects believe

that either $P(H) = 3/5$, or $P(T) = 3/5$. Denote the events, “head-biased coin” and “tail-biased coin,” respectively, by H_b and T_b . Prior probabilities of these mutually exclusive and exhaustive events are 50 : 50,

$$P(H_b) = P(T_b) = 0.5. \quad (19.12)$$

In the experiments, the sample size, n , varies from 3 to 33, while the number of heads varies from 2 to 19; see Table 19.5 for the results. Consider a sample of size n in which there are h_n heads and $n - h_n$ tails. Denote this sample by h_n . The posterior distribution $P(H_b \mid h_n)$ that the coin is head-biased, conditional on the sample h_n , is given by

$$P(H_b \mid h_n) = \frac{P(h_n \mid H_b)P(H_b)}{P(h_n \mid H_b)P(H_b) + P(h_n \mid T_b)P(T_b)}. \quad (19.13)$$

Using the formula for the binomial distribution, we can compute $P(h_n \mid H_b)$ and $P(h_n \mid T_b)$ and rewrite (19.13) as

$$P(H_b \mid h_n) = \frac{\binom{n}{h_n} \left(\frac{3}{5}\right)^{h_n} \left(\frac{2}{5}\right)^{n-h_n}}{\binom{n}{h_n} \left(\frac{3}{5}\right)^{h_n} \left(\frac{2}{5}\right)^{n-h_n} + \binom{n}{h_n} \left(\frac{2}{5}\right)^{h_n} \left(\frac{3}{5}\right)^{n-h_n}}. \quad (19.14)$$

The first three columns in Table 19.5 give the experimental data, and the final column gives the computation of posterior probabilities, based on (19.14).

In an analogous manner, we get

$$P(T_b \mid h_n) = \frac{P(h_n \mid T_b)P(T_b)}{P(h_n \mid T_b)P(T_b) + P(h_n \mid H_b)P(H_b)}. \quad (19.15)$$

Table 19.5 Probability that the coin is head-biased, conditional on the observations.

n	h_n	$n - h_n$	$P(H_b \mid h_n)$
3	2	1	0.60
3	3	0	0.77
5	3	2	0.60
5	4	1	0.77
5	5	0	0.88
9	5	4	0.60
9	6	3	0.77
9	7	2	0.88
17	9	8	0.60
17	10	7	0.77
17	11	6	0.88
33	19	14	0.88

Source: Griffin and Tversky (1992).

Dividing (19.13) by (19.15) and using (19.12), we get

$$\frac{P(H_b | h_n)}{P(T_b | h_n)} = \frac{P(h_n | H_b)}{P(h_n | T_b)}. \quad (19.16)$$

Recall that the sample h_n denotes h heads out of a sample of n iid draws from either a heads-biased coin ($P(H) = 0.6$) or a tail-biased coin ($P(T) = 0.6$). Since the successive tosses of the coin are independent, the likelihoods of the sample under, respectively, the heads-biased coin and the tail-biased coin, are given by

$$P(h_n | H_b) = (0.6)^{h_n} (0.4)^{n-h_n}; P(h_n | T_b) = (0.4)^{h_n} (0.6)^{n-h_n}. \quad (19.17)$$

Substituting (19.17) in (19.16) and denoting by $t_n = n - h_n$, the number of tails in the sample, we get

$$\frac{P(H_b | h_n)}{P(T_b | h_n)} = \left(\frac{0.6}{0.4} \right)^{h_n - t_n}.$$

Taking logs on both sides and multiplying and dividing the right hand side by n , we get the following form for Bayes' rule.

$$\log \left(\frac{P(H_b | h_n)}{P(T_b | h_n)} \right) = n \left(\frac{h_n - t_n}{n} \right) c; \text{ where } c = \log \left(\frac{0.6}{0.4} \right), \text{ a constant.} \quad (19.18)$$

We can now use (19.18) to further clarify the notions of strength and weight, using terms on the right hand side.

1. The first term, n , is the *weight* of the evidence.
2. The second term, the difference between the proportions of heads and tails in the sample, is the *strength* of the evidence for H_b and against T_b ; the experiment only considers the cases such that $h_n > t_n$.
3. The third term, c , is the *discriminability* of the evidence.

Taking logs on both sides of (19.18) we get

$$\log \log \left(\frac{P(H_b | h_n)}{1 - P(H_b | h_n)} \right) = \log n + \log \left(\frac{h_n - t_n}{n} \right) + \log c. \quad (19.19)$$

Griffin and Tversky (1992) estimate a regression of the following form:

$$y = \beta_0 + \beta_1 \log n + \beta_2 \log \left(\frac{h_n - t_n}{n} \right) + \beta_3 \log c + u \quad (19.20)$$

where $y = \log \log \left(\frac{P(H_b | h_n)}{P(T_b | h_n)} \right)$, u is a random error, and $\beta_0, \beta_1, \beta_2, \beta_3$ are the regression coefficients. To be consistent with Bayes' rule, (19.18), the predicted regression coefficients are: $\beta_1 = \beta_2 = 1$. However, for 30 out of 35 subjects, $\beta_2 > \beta_1$ and the difference is statistically significant. Across subjects, the median ratio $\frac{\beta_2}{\beta_1} = 2.2$, i.e., subjects weighted the strength more than twice as much as the weight.

Since the conditional probability function is also a probability function, $P(H_b | h_n) + P(T_b | h_n) = 1$. Fix $P(H_b | h_n)$ at some number in the open interval $(0, 1)$, so that the LHS of (19.19) equals a constant, $\bar{y}$. An example is the value of $P(H_b | h_n) = 0.77$ for $n = 3$ and 9 (see Table 19.5). Thus, (19.19) can be written as

$$\log \left(\frac{h_n - t_n}{n} \right) = (\bar{y} - \log c) - \log n. \quad (19.21)$$

We now ask, what combinations of strength, $\frac{h_n - t_n}{n}$, and weight, n , satisfy equation (19.21), given that $\bar{y} - \log c$ is a fixed number? A curve that expresses such combinations is known as an *equal-support line*. In $(\log n, \log \left(\frac{h_n - t_n}{n} \right))$ space, the equal-support line based on (19.21) has a slope -1 and an intercept that is increasing in $P(H_b | h_n)$ (because $\bar{y}$ is increasing in $P(H_b | h_n)$). So, for instance, if we fixed $P(H_b | h_n) = 0.77$, then, using Table 19.5, (19.21) is satisfied for the following two (strength, weight) pairs: $\left(\frac{h_n - t_n}{n}, n \right) = (1, 3), \left(\frac{1}{3}, 9 \right)$.

In Figure 19.6, we plot two equal-support lines that are consistent with Bayesian updating (i.e., $\beta_1 = \beta_2 = 1$). These are shown as the two dotted lines. The upper one corresponds to a higher value of $\bar{y} = y_H$, relative to the lower one, $\bar{y} = y_L < y_H$.

We can also derive the equal support lines from the estimated regression. Rewrite (19.20) as follows.

$$\log \left(\frac{h_n - t_n}{n} \right) = \frac{1}{\beta_2} (y - \beta_0 - \beta_3 \log c - u) - \frac{\beta_1}{\beta_2} \log n. \quad (19.22)$$

Figure 19.6 Determining the relative importance of the strength and the weight of evidence.

Since, empirically, subjects place greater salience on strength, relative to weight, $\frac{\beta_1}{\beta_2} < 1$, so the slope of the estimated equal-support line is flatter. Two such estimated equal-support lines are drawn for $y = y_H$ and $y = y_L$; these are shown as the two continuous lines.

Consider the intersection points e_H and e_L , where the Bayesian line intersects the estimated line. To the left of these intersection points (for any level of weight, $\log n$) the estimated strength is lower than the correct statistical (or Bayesian) strength. Individuals are said to be *underconfident* in this region. Conversely, to the right of these intersection points, estimated strength is greater than the Bayesian strength. Individuals are said to be *overconfident* in this region. Conservatism is a sort of *underconfidence* in the sample likelihood. On the other hand, base rate neglect arises when individuals are *overconfident* of the strength of the evidence. Hence, points such as e_H , e_L divide the space into regions where conservatism and base rate neglect arise naturally.

Consider an individual engaged in the stock market. When he hears isolated bits of news, he views the news as having low strength, so he does not find this information very useful (although it might have high weight; for instance, the news might be a report of an assessment by a leading expert). On the other hand, when the individual hears about a small sequence of good news about a company selling some stock, he might assign much higher strength to it as compared to a Bayesian. The individual might overreact to a sequence of good news based on an overweighted strength. However, the news might have little weight in predicting the future performance of the company.

19.8 Hindsight bias

Suppose that an individual is asked at time t to predict the outcome of an uncertain event, X , that will take place at some time $t + j$, $j > 0$. Denote the information set at time t by I_t . Then the conditional prediction, denoted by $E[X | I_t]$, reflects the individual's *predictive judgment*. Suppose that at time $t + j$, the realization of the random variable is x . Posterior to the observation of x , the individual is asked about the remembered prediction or the *postdictive judgment*. This is given by $E[E[X | I_t] | I_{t+j}]$, where I_{t+j} is the date $t + j$ information set, and $I_t \subseteq I_{t+j}$. In neo-classical economics, the typical assumption is $E[X | I_t] = E[E[X | I_t] | I_{t+j}]$. An individual is said to suffer from *hindsight bias*, or *creeping determinism* (Fischhoff, 1975), if the predictive and postdictive judgments differ, i.e.,

$$E[X | I_t] \neq E[E[X | I_t] | I_{t+j}], \quad (19.23)$$

and the postdictive judgment is biased in favour of the actual outcome. For instance, Camerer et al. (1989) incorporate hindsight bias by the following simple rule

$$E[E[X | I_t] | I_{t+j}] = \alpha x + (1 - \alpha)E[X | I_t]; \alpha \in [0, 1]. \quad (19.24)$$

The individual has no hindsight bias if $\alpha = 0$ and is fully-biased if $\alpha = 1$. Hindsight bias is sometimes termed as the “I knew it all along” effect; this is particularly obvious when $\alpha = 1$. Hindsight bias is quite distinct from learning. In learning, one learns to make better predictions of future events. However, under hindsight bias, the relevant issue is remembered past predictions, i.e., postdictive judgments.

19.8.1 *Empirical evidence on the hindsight bias*

In his pioneering work, Fischhoff (1975) ran six experiments in a between-subjects design; each experiment has a Before and After group. In each experiment, the Before group read a brief 150 word account of a historical or clinical event and then had to rate the probabilities of four possible mutually exclusive outcomes of which only one outcome actually occurred; this captures predictive judgment. The After group then read the same 150 word account, and was told that one of the four outcomes had occurred; all four outcomes were used in this stage, but each experimental group was given only one outcome and told that this was the real outcome. Based on this information, the After group was required to make a postdictive judgment.

Each of the six experiments used four events, A, B, C, and D, to construct the 150 word accounts. The events were chosen so that subjects were unlikely to know the actual outcome. For instance, event A used a historical account that was based on the British–Gurkha struggle. It was presented as follows (p. 305):

For some years after the arrival of Hastings as governor-general of India, the consolidation of British power involved serious war. The first of these wars took place on the northern frontier of Bengal where the British were faced by the plundering raids of the Gurkhas of Nepal. Attempts had been made to stop the raids by an exchange of lands, but the Gurkhas would not give up their claims to country under British control, and Hastings decided to deal with them once and for all. The campaign began in November 1814. It was not glorious. The Gurkhas were only some 12000 strong; but they were brave fighters, fighting in territory well-suited to their raiding tactics. The older British commanders were used to war in the plains where the enemy ran away from a resolute attack. In the mountains of Nepal it was not easy even to find the enemy. The troops and transport animals suffered from the extremes of heat and cold, and the officers learned caution only after sharp reverses. Major-General Sir D Ochterlony was the one commander to escape from these minor defeats.

The possible outcomes offered were: (1) British victory, (2) Gurkha victory, (3) military stalemate with no peace settlement, and (4) military stalemate with a peace settlement. The factually correct outcome was (3) but the After subjects were informed of one of the factual outcomes (1)–(4) as the correct one.

The average probabilities for each of the outcomes, 1–4, in the four events, A–D, are shown in Table 19.6. For each event, the first row gives the predictive judgment of the Before group. The next four rows give the postdictive judgments of the After groups, for each of the outcomes, 1–4, when told that outcomes 1, 2, 3, and 4, respectively, were the real outcome.¹⁵ Hindsight bias arises if the before probabilities (first row) and the after probabilities (along the diagonal of the matrix) differ and, in particular, the after probabilities are higher. This was true in all cases, and in 22/24 of the cases, the after–before difference was statistically significant at the 2.5% level. The mean difference between the after and before probabilities was 10.8%. At the level of the individual subjects, 70% of the After subjects assigned higher probabilities relative to the mean before probabilities.

¹⁵ Just to make sure that there is no confusion about Table 19.6, consider Event A (British–Gurkha struggle). On average, 33.8% of the before group assigns outcome 1 as the most likely outcome (predictive judgment). However, 57.2% of the after group that has been told that the outcome was 1, believes that the before group must have chosen outcome 1 as the most likely outcome (postdictive judgment); only 14.3% in the same group believe that the before group chose outcome 2. Similarly, 21.3% of the before group chooses outcome 2. However, 38.4% of the after group that was given outcome 2 as the actual outcome, believed that outcome 2 was chosen by the before group (postdictive judgment).

Table 19.6 Mean probabilities assigned to each of four outcomes, 1–4, in the four events, A–D. The actual outcomes for events A, B, C, and D were, respectively, 1, 1, 4, and 2.

Experimental group	n	Outcome provided	Outcome evaluated			
			1	2	3	4
Event A: British–Gurka struggle (English-speaking subjects)						
Before	20	None	33.8	21.3	32.3	12.3
After	20	1	57.2	14.3	15.3	13.4
	20	2	30.3	38.4	20.4	10.5
	20	3	25.7	17.0	48.0	9.9
	20	4	33.0	15.8	24.3	27.0
Event B: Near-riot in Atlanta (subjects with knowledge of statistics)						
Before	20	None	11.2	30.8	43.8	14.2
After	20	11	30.6	25.8	23.3	20.3
	20	2	5.5	51.8	24.3	18.5
	20	3	2.9	23.9	50.8	21.4
	20	4	16.7	31.9	23.4	27.9
Event C: Mrs Dewar in therapy						
Before	19	None	26.6	15.8	23.4	34.4
After	13	11	43.1	13.9	17.3	25.8
	17	2	26.5	23.2	13.4	36.9
	16	3	30.6	14.1	34.1	21.3
	17	4	21.2	10.2	22.6	46.1
Event D: George in therapy						
Before	17	None	27.4	26.9	39.4	6.3
After	18	11	33.6	20.8	37.8	8.0
	18	2	22.4	41.8	28.9	7.1
	20	3	20.5	22.3	50.0	7.3
	17	4	30.6	19.5	37.7	12.3

Source: Fischhoff (1975).

In order to address potential concerns about the between-subjects design of the earlier study, Fischhoff and Beyth (1975) used a within-subjects design. They asked Israeli subjects to make predictions about a set of 15 possible outcomes on the eve of President Nixon's visit to China and the USSR. Prior to the visit, the subjects filled in a prediction memory questionnaire. Following the actual visit of the President, subjects were asked to make postdictive judgments. Significant hindsight bias was discovered in the postdictive judgments.

In the context of the 9/11 tragedy in the US, Kahneman (2011) cites public reaction when it was revealed that on July 2001 the CIA had come across information to suggest that al-Qaeda might be planning an attack on the US. In this case, the CIA did not pass on the information to the President but did pass it on to the National Security Advisor. A former executive editor of the *Washington Post* wrote (p. 294): "It seems elementary to me that if you've got the story that is going to dominate history you might as well go right up to the President." However, in July 2001 nobody knew that this was going to make history.

A similar case of 20–20 judgment in hindsight is the proliferation of claims by experts following the 2008 financial crises that they had predicted the crash. From time to time, experts predict that a current economic situation may lead to a recession. However, in 2006/7 there was no widespread agreement among experts about the scale of the impending crash or certainty about the failure of Lehman Brothers. Kahneman (2011) infers from this that the crash was not *knowable*. Yet the postdictive judgment of many experts is that they knew it all along; this is an illustration of the *illusion of understanding*.

The hindsight bias has been found for all age groups from 3 to 95 (Bernstein et al., 2011). It has been found in many different contexts such as medical diagnosis (Arkes et al., 1988), accounting decisions (Anderson et al., 1993), football (Roese and Maniar, 1997), legal liability (Hastie et al., 1999; Goodwill et al., 2010), terrorist attacks (Fischhoff et al., 2005), the verdict in the O.J. Simpson criminal trial (Bryant and Brockway, 1997), and labor disputes involving firefighters (Pennington, 1981).

For attempts to debias subjects who suffer from hindsight bias, see Arkes (1991), Fischhoff (1982), Larrick (2004), and Harley (2007). The meta-study by Guilbault et al. (2004) suggests that expertise does not shield decision makers from the hindsight bias. Expertise is likely to mitigate a bias if experts receive continual feedback (weather forecasters, chess players, insurance firms) as compared to cases where less frequent feedback is available, or it is ambiguous (judges, stockbrokers, political experts); see, for instance, Kahneman and Klein (2009), McKenzie et al. (2008), and Tetlock (2006).

19.8.2 *Hindsight bias in legal situations*

The issue of hindsight bias is particularly important in legal situations. Consider a defendant who can take several possible actions; each action leads to a possible harm for others with some probability. Suppose that the chosen action of the defendant did indeed cause harm to a plaintiff, who then sues the defendant. A judge or a jury must now form a postdictive judgment of the reasonableness of the action taken by the defendant. In the presence of hindsight bias, the postdictive judgment is biased, so the defendant is more likely to be found guilty. Thus, liability is likely to be assigned in a biased manner, even if the defendant took the most reasonable action.

If potential defendants are forward looking, then anticipating potential future liability, they may take excessive precautions and engage in excessively risk averse behavior. For instance, doctors may prescribe more tests than they otherwise would have, or avoid minor surgical procedures, or be willing to pay for even more comprehensive and expensive insurance, which feeds into higher treatment costs.

Rachlinski (1998) argues that the legal system recognizes well the presence of hindsight bias and takes reasonable steps to mitigate it, as far as possible. For instance, in medical malpractice lawsuits, reliable ex-ante judgment of reasonable care is available; in this case, courts simply use this judgment as its legal postdictive judgment. Corporate law protects directors of corporations from liability for negligent business decisions. This eliminates the possibility of hindsight bias in legal judgment in this domain, enabling corporations to operate in an unfettered environment; this has its pros (fewer restrictions on business investments) and cons (socially irresponsible but privately optimal decisions). However, this does not apply to individuals in their private capacity, hence, the law views the negligence of private individuals as a form of strict liability; in this case, the outcome is third-best.¹⁶

¹⁶ Our usage follows the standard sense of the term in economics: The first best obtains if no harm is done, the second best occurs if a judgment can be passed in the absence of hindsight bias and the third best occurs if judgment is passed with hindsight bias.

In Kamin and Rachlinski (1995), subjects make predictive and postdictive judgments about a municipality's actions to engage in flood precautions. The damages from the flood are set at \$10⁷ and the cost of the precautions at \$10⁵; subjects were also provided with meteorological and anecdotal data. One group of subjects, group A, were asked to predict the probability of a flood in the absence of precautions. They were told that if they find the probability greater than 10% they should decide to take the precaution. Another group of subjects, group B, was asked to make the postdictive judgment. They were told that the precautions had not been taken and a flood had occurred. They were told that if their postdictive judgment is that the probability of a flood was greater than 10% they should find the defendant guilty. In Group A, 24% of the subjects thought that the precautions were merited, while 57% in group B found the defendant guilty.

19.8.3 What causes hindsight bias?

What causes hindsight bias? Kahneman (2011, p. 202) opines: "A general limitation of the human mind is its imperfect ability to reconstruct past states of knowledge, or beliefs that have changed. Once you adopt a new view of the world (or of any part of it), you immediately lose much of your ability to recall what you used to believe before your mind changed." Other explanations are that (i) people prefer to see a stable and predictable world and the hindsight bias is simply a coping mechanism in the face of an unpredictable world, and (ii) by exaggerating their ability to predict, individuals attempt to signal greater competence to others (Rachlinski, 1998).

19.8.4 Hindsight bias and the underestimation of financial volatility

We now show that hindsight bias can lead decision makers to reduce volatility estimates in financial markets and lead to insufficient revision of incorrect models (Biais and Weber, 2009). Consider the two equations (19.23) and (19.24); to simplify notation, let $E[X | I_t] = \mu$ and let $E[E[X | I_t] | I_{t+j}] = \hat{\mu}$. Then we can write (19.24) as

$$\hat{\mu} = \alpha x + (1 - \alpha)\mu. \quad (19.25)$$

Suppose that an investor at time t forecasts the average returns at time $t + j$ on an asset, or a portfolio of assets. When making the prediction at time t , the investor believes that $X \sim N(\mu, \sigma_L^2)$ with probability λ and $X \sim N(\mu, \sigma_H^2)$ with probability $1 - \lambda$, where $\sigma_L^2 < \sigma_H^2$. Thus, the density of X is given by

$$f(x | \sigma_i^2, \mu) = \frac{1}{\sqrt{2\pi\sigma_i^2}} \exp\left(\frac{-1}{2\sigma_i^2} (x - \mu)^2\right), i = L, H. \quad (19.26)$$

At the end of time period $t + j$, after observing the realization, x , of the random variable, X , the decision maker forms posterior beliefs about which model (i.e., variance σ_L^2 or σ_H^2) is likely to have generated x . However, at the end of time $t + j$, on account of hindsight bias, the remembered mean is $\hat{\mu}$, given in (19.25). Thus, the relevant density, ex-post, is $f(x | \sigma_i^2, \hat{\mu})$; this may be used to determine, ex-post, which of the two competing models is more likely to hold. Denote by $\hat{P}(a | b)$ and $P(a | b)$, respectively, the probability of a conditional on b in the presence of hindsight bias ($\alpha > 0$) and in the absence of hindsight bias ($\alpha = 0$).

Using Bayes' rule, we have

$$\hat{P}(\sigma_L^2 | x) = \frac{f(x | \sigma_L^2, \hat{\mu})\lambda}{f(x | \sigma_L^2, \hat{\mu})\lambda + f(x | \sigma_H^2, \hat{\mu})(1 - \lambda)}. \quad (19.27)$$

Using (19.26) to substitute the value of $f(x | \sigma_i^2, \hat{\mu})$, we can rewrite (19.27) as

$$\hat{P}(\sigma_L^2 | x) = \frac{1}{1 + \left(\frac{1-\lambda}{\lambda}\right) \frac{\sigma_L}{\sigma_H} \exp\left(\frac{-1}{2} \left(\frac{1}{\sigma_H^2} - \frac{1}{\sigma_L^2}\right) (x - \hat{\mu})^2\right)}. \quad (19.28)$$

Substituting $\hat{\mu}$ from (19.25) in (19.28), we get

$$\hat{P}(\sigma_L^2 | x) = \frac{1}{1 + \left(\frac{1-\lambda}{\lambda}\right) \frac{\sigma_L}{\sigma_H} \exp\left(\frac{-1}{2} \left(\frac{1}{\sigma_H^2} - \frac{1}{\sigma_L^2}\right) (1 - \alpha)^2 (x - \mu)^2\right)}. \quad (19.29)$$

In the absence of hindsight bias ($\alpha = 0$), we get the posterior probability, $P(\sigma_L^2 | x)$, as used in typical models in economics and finance

$$P(\sigma_L^2 | x) = \frac{1}{1 + \left(\frac{1-\lambda}{\lambda}\right) \frac{\sigma_L}{\sigma_H} \exp\left(\frac{-1}{2} \left(\frac{1}{\sigma_H^2} - \frac{1}{\sigma_L^2}\right) (x - \mu)^2\right)}. \quad (19.30)$$

Comparing (19.29) and (19.30), we derive the main implications of hindsight bias in this model. From (19.29), since $\frac{-1}{2} \left(\frac{1}{\sigma_H^2} - \frac{1}{\sigma_L^2}\right) > 0$, we have $\frac{\partial \hat{P}(\sigma_L^2 | x)}{\partial \alpha} > 0$, so as hindsight bias increases (α increases), $\hat{P}(\sigma_L^2 | x)$ increases. Thus,

$$\hat{P}(\sigma_L^2 | x) > P(\sigma_L^2 | x) \text{ and } \hat{P}(\sigma_H^2 | x) < P(\sigma_H^2 | x). \quad (19.31)$$

In finance, volatility is often defined as the standard deviation of returns. From (19.31), decision makers who are subject to hindsight bias infer, ex-post, that volatility is likely to be low rather than high. Furthermore, the degree of underestimation of volatility is increasing in the degree of hindsight bias, as captured by the size of α . Since hindsight-biased decision makers underestimate volatility, if they have to invest in the relevant asset/portfolio, they will invest more than they really should, particularly if they are risk averse. One may expect that the performance of hindsight-biased individuals will, therefore, be inferior to those who are not hindsight-biased.

Using a within-subjects design, Biais and Weber (2009) propose the following empirical measure of hindsight bias: $\phi = \frac{\hat{\mu} - \mu}{x - \mu}$. Using (19.25), we get that $\phi = \alpha$. They consider two treatments. In the first treatment, the experimenter informs subjects, ex-post, of their ex-ante prediction, hence, eliminating the hindsight bias. In the second treatment, the hindsight bias is not eliminated. Subjects were given the market price of five German stocks (BASF, IKB, EON, Postbank, Premiere), two commodities (oil and gold), and the euro-dollar exchange rate. They were then asked to predict the prices for one week ahead. Subjects were also asked to give the upper and lower bounds of prices, which were converted into standard deviations or *initial implied volatility estimates*. A week later, once the relevant prices had been realized, the first treatment group was simply reminded of their previous estimates of prices and volatility, while the second treat-

ment group was asked to make the postdictive judgments (i.e., give a best estimate of their earlier estimates).

The results are shown in Table 19.7. The first row shows the hindsight bias calculated in the second treatment (this is $\phi = \alpha$). There is a positive hindsight bias for all eight assets, which is significant at the 10% level for four of the assets. The second row calculates the ratio of their initial implied volatility estimates and the remembered volatility. For five of the eight assets, the median estimates exceed 1 and for four assets this is significant at the 10% level. For one asset, the ratio is slightly less than 1 but it is statistically insignificant.

Hindsight-biased decision makers appear not to be surprised because they act as if they knew it all along. To test this, the *true surprise*, based on the ex-ante measures is defined as $\left(\frac{x-\mu}{\sigma}\right)^2$, where σ is the initial implied volatility. Define *biased surprise* as $\left(\frac{x-\hat{\mu}}{\hat{\sigma}}\right)^2$, where $\hat{\mu}$ and $\hat{\sigma}$ are remembered mean and remembered volatility; this measure can only be computed in treatment 2. For treatment 2, the biased surprise is smaller than the true surprise; the difference is statistically significant for two cases—Gold and dollar.

At the second date, the subjects are asked, yet again, to forecast their volatility estimates for another week ahead. The upward revisions in volatility are stronger for treatment 1 subjects relative to treatment 2 subjects. This is consistent with hindsight-biased subjects not updating volatility estimates as much as they ideally should, in the absence of the bias.

In order to test the performance of hindsight-biased actual investors, data was used from the Frankfurt and London branches of a large investment bank. A between-subjects design was used because competitive traders might not wish to admit that they forecast the future in a biased manner. The questions asked were similar in nature to those that the traders encountered in their jobs. Traders in both offices were found to be almost equally hindsight-biased. The estimate of α in the London and Frankfurt offices was, respectively, 0.547 and 0.579. Traders are split into high, middle, and low earners. Those in the high earners category demonstrate a lower mean and median hindsight bias, relative to the other two categories. The median difference between the middle- and low-income categories is similar. For individual-level data, and controlling for age and experience, the very highest earners have the lowest hindsight bias.

19.9 Confirmation bias

Suppose that an individual holds some initial beliefs. If the individual interprets subsequent evidence in a manner that is biased towards supporting the initial beliefs, relative to a Bayesian, then the individual is said to exhibit *confirmation bias*. For instance, buyers of a new car find that the particular model they drive suddenly appears more numerous on the roads. Since this takes the form of a biased assimilation of information, another name for this phenomenon, often used in psychology, is *biased assimilation*; for a survey of psychological research on the phenomenon see Nickerson (1998), Lord and Taylor (2009), and Mercier and Sperber (2011).

Rabin and Schrag (1999) note that confirmation bias is more likely to arise when: (1) the evidence is ambiguous and bears alternative interpretations, (2) the collection and scrutinization of evidence is selective (*hypothesis-based filtering*), (3) people are asked to judge the correlation between temporally separated events, and (4) individuals need to aggregate information from various sources. Confirmation bias is not mitigated by greater cognitive abilities or open mindedness (Stanovich and West 2007, 2008a, b).

A natural implication of confirmation bias is that individuals may be too overconfident because they typically search for confirmatory evidence and ignore or underweight contradictory evidence.

Table 19.7 Median values across decision makers. p-values are given in parentheses.

Confirmation bias may also lead to the formation and hardening of prejudices and stereotypes. In the presence of confirmation bias, learning may lead asymptotically to the incorrect model of the world with probability 1. Rabin and Schrag (1999) distinguish confirmatory bias from a related phenomenon in which once subjects form strong beliefs about one hypothesis over competing hypotheses, they start being *inattentive* to new evidence for or against their preferred hypothesis.

The nature of confirmatory bias is beautifully captured in the following quote from Lord et al. (1979, p. 2099):

Thus, there is considerable evidence that people tend to interpret subsequent evidence so as to maintain their initial beliefs. The biased assimilation processes underlying this effect may include a propensity to remember the strengths of confirming evidence but the weaknesses of disconfirming evidence, to judge confirming evidence as relevant and reliable but disconfirming evidence as irrelevant and unreliable, and to accept confirming evidence at face value while scrutinizing disconfirming evidence hypercritically. With confirming evidence, we suspect that both lay and professional scientists rapidly reduce the complexity of the information and remember only a few well-chosen supportive impressions. With disconfirming evidence, they continue to reflect upon any information that suggests less damaging “alternative interpretations.” Indeed, they may even come to regard the ambiguities and conceptual flaws in the data opposing their hypotheses as somehow suggestive of the fundamental correctness of those hypotheses. Thus, completely inconsistent or even random data—when “processed” in a suitably biased fashion—can maintain or even reinforce one’s preconceptions.

19.9.1 *Empirical evidence for confirmation bias*

The typical experiments in confirmatory bias proceed as follows. The initial preference of subjects, or prior beliefs, for one hypothesis over another is elicited. For instance, do you support capital punishment or not (Lord et al., 1979); do you think nuclear technology is safe or unsafe (Plous, 1991); which football team do you support (Hastorf and Cantril, 1954); which party do you support in the US Presidential elections (Munro et al., 2002). The subjects are then given some information or evidence that supports one hypothesis over another and asked to form posterior beliefs. Confirmation bias arises when, relative to a Bayesian, the posterior beliefs of subjects adjust insufficiently from their priors. Such a bias was found in all the studies mentioned in this paragraph.

The initial beliefs of subjects in experiments can be created in the lab by providing them with anchoring information. Darley and Gross (1983) create two different profiles of a girl in two different treatments in a between-subjects design. In the first treatment, she is the daughter of college graduates who hold white collar jobs; a video clip shows the girl playing in a prosperous, middle class neighborhood. In a second treatment, she is the daughter of high school graduates who hold blue collar jobs; a video clip shows the girl playing in a poor, inner-city neighborhood. The subjects are divided into two sets; set A is used to elicit prior beliefs and set B to elicit posterior beliefs. Based on the information provided, the average estimate of set A individuals about the reading abilities of the girl (prior beliefs), in the first treatment, is slightly higher (4.29) as compared to the second treatment (3.90).

Subjects in set B are provided some evidence of the girl’s scholastic abilities; this takes the form of a video clip in which the girl answers a series of questions with varying degrees of success. The average posterior beliefs of individuals in set B about the girl’s reading abilities, in both treatments, were significantly different from the prior beliefs of set A. For instance, set B subjects in the second treatment (inner-city) rated the girl’s average ability to be 3.71 (posterior belief), which

is below the prior estimate of set A individuals, 3.90. The corresponding average posterior estimate of set B individuals in the first treatment (middle class) was 4.67, which is statistically higher than the prior estimate of set A individuals, 4.29. Despite the fact that subjects viewed identical videos, the girl's background has a significant influence on her perceived scholastic abilities. Girls from poor inner-city neighborhoods are assigned even lower ability levels while girls from more prosperous neighborhoods are assigned even higher ability levels. Thus, subjects exhibit the confirmation bias.

19.9.2 A formal model of confirmation bias and overconfidence

Rabin and Schrag (1999) propose a stylized model of confirmation bias that nicely illustrates the concept of confirmation bias and shows how it might lead to overconfidence. We consider this model below. Suppose that there are two mutually exclusive and exhaustive states of the world, $x \in \{A, B\}$; A and B may be thought of as competing hypotheses concerning a particular issue/event that an individual wishes to form beliefs about. The prior probability is $p(A) = p(B) = 0.5$. Time is discrete and denoted by $t \in \{1, 2, 3, \dots\}$.

At time t , the individual receives a signal, $s_t \in \{a, b\}$, that is correlated with the true state, A or B , of the world. Let $p(a | A)$ be the probability of receiving signal a if hypothesis A is true. Similarly, $p(b | B)$ is the probability of signal b if hypothesis B is true. The signals are temporally *iid* and $p(a | A) = p(b | B) = \theta$ and $0.5 < \theta < 1$. If the underlying hypothesis A is true, then $p(a | A) = \theta$ and $p(b | A) = 1 - \theta$; likewise if B is true then $p(b | B) = \theta$ and $p(a | B) = 1 - \theta$. After observing the signal, the individual uses Bayes' rule to update the beliefs about the relative likelihood of $x = A$ and $x = B$.

Confirmatory bias takes the form of misinterpreting signals that are in conflict with one's current beliefs about which of the two hypotheses is likely to be true. The signals perceived by the individual are given by $\sigma_t \in \{\alpha, \beta\}$. When α (respectively, β) is the perceived signal, the individual believes that the received signal is a (respectively, b). Signals that confirm the initial beliefs are correctly encoded, while signals that conflict with the initial beliefs are incorrectly perceived with probability $q > 0$.

Suppose, for instance, that at time t , the individual believes A is more likely than B . If the signal is $s_t = a$, then this is correctly encoded, i.e., $\sigma_t = \alpha$. But if $s_t = b$, then this is incorrectly perceived as $\sigma_t = \alpha$ with probability q and $\sigma_t = \beta$ with probability $1 - q$. Similarly if B is initially perceived to be more likely, then the signal $s_t = b$ is correctly perceived ($\sigma_t = \beta$) but $s_t = a$ is incorrectly perceived as $\sigma_t = \beta$ with probability q .

Confirmatory bias implies that although s_t is temporally *iid*, σ_t is not temporally *iid*. Denote the history of signals at the beginning of time t by $s^t = \{s_1, \dots, s_{t-1}\}$ and the history of perceived signals at the beginning of t by $\sigma^t = \{\sigma_1, \dots, \sigma_{t-1}\}$. Let $p(A | \sigma^t)$ and $p(B | \sigma^t)$ denote, respectively, the beliefs of the individual at the beginning of time t about hypotheses A and B .

Let θ^F be the probability that the individual perceives a signal σ_t that confirms his hypothesis, when it is *false* (i.e., the opposite hypothesis is, in fact, true), then

$$\theta^F = \begin{cases} p(\sigma_t = \alpha | p(A | \sigma^t) > 0.5, B) \\ p(\sigma_t = \beta | p(B | \sigma^t) > 0.5, A) \end{cases}, \quad (19.32)$$

where the conditioning expression $p(A | \sigma^t) > 0.5, B$ means that, conditional on the history of perceived signals, hypothesis A is thought to be more likely, when, in fact, B is true. Similarly the conditioning expression $p(B | \sigma^t) > 0.5, A$ means that conditional on the history of perceived signals, hypothesis B is thought to be more likely, when, in fact, A is true.

Consider the first row in (19.32). Suppose that conditional on the history of perceived signals at time t , σ^t , the individual believes A to be more likely, i.e., $p(A \mid \sigma^t) > 0.5$. How can he perceive $\sigma_t = \alpha$ when B is actually the correct hypothesis? Since B is the correct hypothesis, $p(b \mid B) = \theta$ and $p(a \mid B) = 1 - \theta$. If $s_t = a$, which, in this case, occurs with probability $1 - \theta$, the individual's beliefs are confirmed, so he perceives it correctly. However, with probability θ , the signal is b , which contradicts the initial beliefs about model A , so it is incorrectly perceived as α with probability q , hence

$$\theta^F = (1 - \theta) + \theta q. \quad (19.33)$$

Since the model is symmetric, the second row of (19.32) also leads to the same calculation reported in (19.33).

Let θ^T be the probability that the individual perceives a signal σ_t that confirms his hypothesis, when it is *true* (i.e., the opposite hypothesis is false), then

$$\theta^T = \begin{cases} p(\sigma_t = \alpha \mid p(A \mid \sigma^t) > 0.5, A) \\ p(\sigma_t = \beta \mid p(B \mid \sigma^t) > 0.5, B) \end{cases}. \quad (19.34)$$

Consider the first row in (19.34). Since A is the correct model in this case, $p(a \mid A) = \theta$ and $p(b \mid A) = 1 - \theta$; furthermore, the individual believes in model A over B , $p(A \mid \sigma^t) > 0.5$. The perception that $\sigma_t = \alpha$ can come about in two ways. First, if the signal is a (a probability θ event) it is perceived without error. Second, if the signal is b (a probability $1 - \theta$ event), it is perceived mistakenly as α with probability q . Putting these together we get

$$\theta^T = \theta + (1 - \theta) q. \quad (19.35)$$

Symmetry ensures that the second row in (19.34) leads to an identical calculation.

Definition 19.1 (*Unbiased Bayesian statistician*): An unbiased Bayesian statistician has $q = 0$, so $\theta^F = (1 - \theta)$ and $\theta^T = \theta$.

Definition 19.2 (*Confirmation-biased individual*): An extreme confirmation-biased individual has $q = 1$, so $\theta^F = 1$ and $\theta^T = 1$. Such an individual always misreads any contradictory evidence, hence, takes all evidence as supportive of his initial beliefs. Partial confirmation bias arises when $0 < q < 1$. In general, the degree of confirmation bias is increasing in q . All individuals who have $q \neq 0$ are said to be confirmation-biased.

Let us superscript variables belonging to a confirmation-biased individual by C and a Bayesian individual by B . Suppose that the individual observes n signals; n_α are perceived to be α and n_β are perceived to be β ($n_\alpha + n_\beta = n$). What are the posterior beliefs of a confirmation-biased individual that the true model is A ? Using Bayes' rule,

$$p(A \mid n_\alpha, n_\beta) = \frac{p(n_\alpha, n_\beta \mid A) p(A)}{p(n_\alpha, n_\beta \mid A) p(A) + p(n_\alpha, n_\beta \mid B) p(B)}. \quad (19.36)$$

The prior probabilities are $p(A) = p(B) = 0.5$. When the true model is A , the probability of n_α outcomes that are α and n_β outcomes that are β is $p(n_\alpha, n_\beta \mid A) = \theta^{n_\alpha} (1 - \theta)^{n_\beta}$. Similarly, we can compute $p(n_\alpha, n_\beta \mid B) = \theta^{n_\beta} (1 - \theta)^{n_\alpha}$. Substituting these calculations in (19.36), we get

$$p(A | n_\alpha, n_\beta) = \frac{\theta^{n_\alpha} (1 - \theta)^{n_\beta}}{\theta^{n_\alpha} (1 - \theta)^{n_\beta} + \theta^{n_\beta} (1 - \theta)^{n_\alpha}}.$$

Similarly computing $p(B | n_\alpha, n_\beta)$, we can determine the likelihood ratio of a confirmation-biased individual,

$$L^C(n_\alpha, n_\beta) = \frac{p(A | n_\alpha, n_\beta)}{p(B | n_\alpha, n_\beta)} = \left(\frac{\theta}{1 - \theta} \right)^{n_\alpha - n_\beta}. \quad (19.37)$$

Thus, conditional on the history, n_α, n_β , the confirmation-biased individual believes that A is more likely if $L^C(n_\alpha, n_\beta) > 1$ and B is more likely if $L^C(n_\alpha, n_\beta) < 1$. Since we have assumed that $0.5 < \theta < 1$, whenever $n_\alpha > n_\beta$, a confirmation-biased individual will assign greater probability to A being true relative to B . For instance, suppose that $n = 5$ and $n_\alpha = 3, n_\beta = 2$. Using (19.37), we have $L^C(n_\alpha, n_\beta) = \frac{\theta}{1 - \theta} > 1$. Hence, a confirmation-biased individual believes relatively more in A .

Relative to a confirmation-biased individual, denote the likelihood ratio formed by an unbiased Bayesian statistician by $L^B(n_\alpha, n_\beta)$. Suppose that the hypothetical unbiased Bayesian statistician knows that an individual suffers from confirmation bias and also misperceives signals in the manner outlined above. In general, we will have $L^B(n_\alpha, n_\beta) \neq L^C(n_\alpha, n_\beta)$. Since the perceived signals σ_t are not *iid* (although the actual signals s_t are *iid*), the order of the perceived signals received by a confirmation-biased individual influence the posterior beliefs.

Definition 19.3 Suppose that $n_\alpha > n_\beta$. The confirmation-biased individual is:

- (i) Overconfident if $L^B(n_\alpha, n_\beta) < L^C(n_\alpha, n_\beta)$. Such an individual believes that hypothesis A is more likely than can be justified by the evidence.
- (ii) Underconfident if $L^B(n_\alpha, n_\beta) > L^C(n_\alpha, n_\beta)$.

Example 19.1 (Overconfidence): Suppose that the sequence of perceived signals of the confirmation-biased individual is $\alpha, \alpha, \alpha, \beta, \beta$. What likelihood should an unbiased Bayesian statistician assign to A versus B ? We assume that our hypothetical unbiased Bayesian statistician knows that the individual suffers from confirmation bias and also misperceives signals in the manner outlined above.

The Bayesian likelihood ratio is

$$L^B = \frac{p(A | \alpha, \alpha, \alpha, \beta, \beta)}{p(B | \alpha, \alpha, \alpha, \beta, \beta)}.$$

Using Bayes' rule

$$p(A | \alpha, \alpha, \alpha, \beta, \beta) = \frac{p(\alpha, \alpha, \alpha, \beta, \beta | A) p(A)}{p(\alpha, \alpha, \alpha, \beta, \beta | A) p(A) + p(\alpha, \alpha, \alpha, \beta, \beta | B) p(B)}.$$

Writing the analogous expression for $p(B | \alpha, \alpha, \alpha, \beta, \beta)$ and noting that $p(A) = p(B) = 0.5$ we have

$$L^B = \frac{p(\alpha, \alpha, \alpha, \beta, \beta | A)}{p(\alpha, \alpha, \alpha, \beta, \beta | B)}. \quad (19.38)$$

Let us first compute $p(\alpha, \alpha, \alpha, \beta, \beta | A)$, i.e., what is the likelihood of getting the five perceived signals in the order given, conditional on the true model being A . Given the signals, since

$n_\alpha > n_\beta$, the individual always believes the true model is more likely to be A. Conditional on the true model being A (or $x = A$), the probability of the first α signal is θ . The second period signal could have been either $s_t = a$ (with probability θ) and correctly perceived to be $\sigma_t = \alpha$ or it might have been $s_t = b$ (with probability $1 - \theta$) and incorrectly perceived to be $\sigma_t = \alpha$ with probability q . This calculation is $\theta^T = p(\alpha \mid p(A \mid \sigma^t) > 0.5, A)$, the first line in (19.34). The third period perceived signal is α and gives rise to an identical calculation as in period 2. In period 4, the perceived signal is β . Now the relevant calculation is $1 - \theta^T$. An identical calculation is repeated in period 5. Thus,

$$\begin{aligned} p(\alpha, \alpha, \alpha, \beta, \beta \mid A) &= \theta (\theta^T)^2 (1 - \theta^T)^2 \\ &= \theta (\theta + (1 - \theta)q)^2 (1 - \theta)^2 (1 - q)^2 \text{ (using (19.35))}. \end{aligned} \quad (19.39)$$

Proceeding analogously, $p(\alpha, \alpha, \alpha, \beta, \beta \mid B) = (1 - \theta) (\theta^F)^2 (1 - \theta^F)^2$. Substituting the value of θ^F from (19.33) we get

$$p(\alpha, \alpha, \alpha, \beta, \beta \mid B) = (1 - \theta) ((1 - \theta) + \theta q)^2 \theta^2 (1 - q)^2. \quad (19.40)$$

Substituting (19.39), (19.40) in (19.38), the Bayesian likelihood ratio is

$$\begin{aligned} L^B &= \frac{\theta (\theta + (1 - \theta)q)^2 (1 - \theta)^2 (1 - q)^2}{(1 - \theta) ((1 - \theta) + \theta q)^2 \theta^2 (1 - q)^2}, \\ &= \left(\frac{\theta + q(1 - \theta)}{1 - \theta + q\theta} \right)^2 \frac{1 - \theta}{\theta}. \end{aligned}$$

It is now straightforward to show that $\left(\frac{\theta + q(1 - \theta)}{1 - \theta + q\theta} \right)^2 \frac{1 - \theta}{\theta} < \frac{\theta}{1 - \theta}$, hence, $L^B < L^C$. Thus, the confirmation-biased individual is overconfident.

Example 19.2 Suppose that the sequence of perceived signals of the confirmation-biased individual is $\beta, \beta, \alpha, \alpha, \alpha$. In this case, it can be shown that

$$L^B = \frac{(1 - \theta) (1 - \theta + q\theta) \theta^3}{\theta (\theta + q(1 - \theta)) (1 - \theta)^3} > \frac{\theta}{1 - \theta} = L^C. \quad (19.41)$$

Hence, the individual is underconfident.

19.10 Other judgment heuristics

We now briefly note some other judgment heuristics in this section. The aim is to provide no more than a minimum discussion of each heuristic without surveying the literature in any detail.

19.10.1 Regression towards the mean

Galton (1886) discovered that taller than average parents produce children who, on average, are shorter than them. Similarly, shorter than average parents produce children whose average height is greater than theirs. This phenomenon is known as *regression towards the mean*. Regression towards the mean always holds between two random variables whose correlation is different from 1 in absolute value.

Suppose that we measure test scores, or some other human performance measures, at two distinct points in time; each score is partly determined by random influences. Suppose that the test scores are random variables, X_1 and X_2 , which are identically distributed with common mean μ . Let us select from the first test scores, individuals whose scores deviate from the mean by more than $k > 0$, i.e., scores from the set $\{x : x - \mu > k, x \in X_1\}$. Suppose that we now track the performance of the same individuals on the second test where the test score is determined by the random variable X_2 . Denote the sample mean of the test scores of these selected individuals in the second test by μ_s . Then regression to the mean implies that $\mu_s - \mu < k$. Similarly, if we chose the original set of individuals from distribution X_1 who satisfy $\{x : \mu - x > k, x \in X_1\}$, then we must have $\mu - \mu_s < k$.

Consider the following interesting example of this phenomenon from the Israeli Air Force (Tversky and Kahneman, 1974; Kahneman, 2011). Air instructors found that when flight cadets were praised for particularly good performance, say a clean execution of an aerobatic maneuver, then their subsequent performance dropped. On the other hand, those flight cadets who were punished for poor performance, improved their subsequent performance. An inference was made that rewarding good performance was bad and punishing bad performance was good. However, this fits perfectly with an inability to appreciate the statistical phenomenon of regression to the mean.

On average, extreme performances on the aerobatic maneuver arise purely from luck. Flight cadets who were extremely lucky performed much better than the average while others did worse than the average. There is no causality between rewards/punishments and subsequent performance. The fluctuations in performance between two tests is purely random. It is of course true that low skilled pilots will continue to perform at a lower level, however, regression to the mean captures the variability in performance that arises from purely random factors.

The regression to the mean has been documented in other contexts. For instance, golfers with high scores on day 1 of a tournament typically report lower scores on day 2, while those who struggle on day 1, improve their average performances on day 2. Kahneman (2011) conjectures that people give inadequate attention to regression to the mean because the brain wishes to construct causal relations while regression is a purely statistical phenomenon that has an explanation but not a cause.

19.10.2 *False consensus effect*

The *false consensus* heuristic arises when people believe that their own behavioral choices and judgments are appropriate, and relatively common among others. Individuals walking on a tightrope across skyscrapers or launching a revolution do know that they are in a minority. Yet they also view their behavior as less deviant, relative to the behavior of others who do not engage in these behaviors (Ross et al., 1977).

The false consensus effect has some similarity with *evidential reasoning* or *projection bias*, and this is recognized in Ross et al. (1977). Under evidential reasoning, subjects ascribe diagnostic significance to their own beliefs when asked to guess the beliefs of others; see Part 4 of the book for a formalization of evidential reasoning (al-Nowaihi and Dhimi, 2015), and the experimental evidence (Robbins and Krueger, 2005).

In one experiment, Ross et al. (1977) asked Stanford University students whether they would be willing to walk around the campus for 30 minutes wearing a sandwich board inscribed with a message. For one group of students, the message read “Eat at Joe’s” and for another group it read “Repent.” When the message was Repent, those who agreed, estimated, on average, that 63.50%

of their fellow students would also agree, and those who refused, estimated that 76.67% of their fellow students would also refuse. For both messages combined, those who agreed to wear the board estimated that 62.2% of other students would also agree to wear it. Those who refused to wear the message board estimated that 67% would also refuse.

For a meta-study of 115 studies on the false consensus effect, see Mullen et al. (1985). Solan et al. (2008) show that laymen and judges alike are subject to the false consensus effect when interpreting contractual documents in insurance that have in the past led to different judicial outcomes. Leviston et al. (2013) find that individuals believe that their own views on climate are more widespread than they actually are. Those who thought that climate change was not happening believed that 43% of others thought likewise; the actual figure was 6%. Similarly, those who said “don’t know” thought that 34.1% of others believed likewise; the actual figure was less than 5%. Roth and Voskort (2014) document a false consensus effect for finance professionals in Germany. In an artefactual field experiment, finance professionals are asked to guess the risk preferences of others. A significant false consensus effect is found and professionals unduly project their own risk preferences to others. Indeed, the measured effect is strongest for experienced professionals.

19.10.3 *Confusion between necessary and sufficient conditions*

The distinction between *necessary and sufficient conditions* is critical for most inference in economics, yet people can find it difficult to make the distinction. Consider the following classic problem in Wason (1968). There are four cards labeled E, K, 4, 7 that are placed on a table. It is known that each card has a number on one side and a letter on the other. Subjects are invited to pick all the cards that can test the following rule. “*Every card with a vowel on one side has an even number on the other side.*”

Most subjects report that card E must be turned over while many report that both E and 4 must be turned over to test the rule. The rule can be written as the following logical statement:

$$\text{Vowel on one side} \Rightarrow \text{even number on the other side.} \quad (19.42)$$

Thus, a vowel on one side is sufficient for there to be an even number on the other side. But an even number on one side is only a necessary, but not a sufficient condition for a vowel on the other side. An implication of (19.42) is that

$$\text{not an even number on one side} \Rightarrow \text{not a vowel on the other side.} \quad (19.43)$$

Statement (19.42) dictates choosing card E, and (19.43) dictates choosing card 7. Choosing card 4 can never confirm (or falsify) the rule because an even number is not a sufficient condition for a vowel on the other side, yet about 65% choose card 4.

19.10.4 *Attribute substitution*

Kahneman and Frederick (2005) draw attention to the heuristic of *attribute substitution*. This occurs when one attribute of an object is substituted by another, perhaps because it comes more readily to mind. For instance, “similarity” might be substituted for “probability” in solving a prob-

lem. The usefulness of attribute substitution is that it simplifies difficult judgments by substituting easier ones in their place. The downside is, of course, that it may lead to incorrect inferences.

Consider, for instance, the following two questions asked of subjects in experiments (Strack et al., 1988). How happy are you with your life in general? How many dates did you have last month? When asked in this order, the correlation in the answers was low. However, when the order was reversed, the correlation rose to 0.66. Kahneman and Frederick (2005) propose the following explanation: “We suggest that thinking about the dating question automatically evokes an affectively charged evaluation of one’s satisfaction in that domain of life, which lingers to become the heuristic attribute when the happiness question is subsequently encountered.” Schwarz, Strack, and Mai (1991) replicate these results when marital satisfaction replaces the number of dates (the respective correlations were 0.32 when the questions were asked in direct order, and 0.67 in the reversed order). For a review of findings from similar experiments, see Schwarz and Bohner (2001).

19.11 Dual process models and judgment heuristics

In this section, we briefly outline some of the explanations for judgment heuristics and biases. Although our treatment is relatively condensed, this is an important area of research in psychology that has attracted a great deal of scholarship.¹⁷ Various judgment heuristics can be explained by taking a *two modules view* of the brain (Kahneman, 2011). The two modules have several distinct names in the literature such as “dual process theories” and “intuition and reason.” Following Stanovich and West (2000, 2002), we refer to the two modules as System 1 and System 2; these might not be the most illuminating terms but they are easiest to use and are popular.

System 1 is fast, automatic, and little mental effort is involved in using it. System 2, on the other hand, is much slower, deliberative, and requires cognitive effort. System 1 forms impressions, feelings, and intuitions for System 2. If System 2 endorses these intuitions, they turn into beliefs. System 2 typically springs into action when System 1 encounters a situation that is counter to its worldview. Table 19.8 gives the different usages of these terms, which illustrate nicely the distinction between the two systems, and the various features associated with them.

Kahneman (2011, p. 25) offers a very illuminating view of the two systems:

The division of labor between System 1 and System 2 is highly efficient: it minimizes effort and optimizes performance . . . System 1 is generally very good at what it does: its models of familiar situations are accurate, its short term predictions are accurate as well, and its initial reactions to challenges are swift and generally appropriate. System 1 has biases, however, and it is prone to making systematic errors in specified circumstances . . . it answers easier questions than the one it was asked and has little understanding of logic and statistics. One further limitation of System 1 is that it cannot be turned off.

It is important to note that the two systems are purely fictitious characters that provide a way of organizing our understanding of the brain. Indeed “there is no part of the brain that either of the systems would call home” (Kahneman, 2011, p. 29).

One explanation for judgment heuristics is that individuals save on cognitive effort by using the relatively less cognitively taxing and spontaneous System 1, as compared to System 2. This

¹⁷ The distinction between Systems 1 and 2 that we outline in this section is used extensively in formal economic models; see Part 6 of the book.

Table 19.8 Different usages of the System 1–System 2 terms.

	System 1	System 2
Dual-Process Theories:		
Sloman (1996)	associative system	rule-based system
Evans (1984; 1989)	heuristic processing	analytic processing
Evans & Over (1996)	tacit thought processes	explicit thought processes
Reber (1993)	implicit cognition	explicit learning
Levinson (1995)	interactional intelligence	analytic intelligence
Epstein (1994)	experiential system	rational system
Pollock (1991)	quick and inflexible modules	intellection
Hammond (1996)	intuitive cognition	analytical cognition
Klein (1998)	recognition-primed decisions	rational choice strategy
Johnson-Laird (1983)	implicit inferences	explicit inferences
Shiffrin & Schneider (1977)	automatic processing	controlled processing
Posner & Snyder (1975)	automatic activation	conscious processing system
Properties:	associative	rule-based
	holistic	analytic
	automatic	controlled
	relatively undemanding of cognitive capacity	demanding of cognitive capacity
	relatively fast	relatively slow
	acquisition by biology, exposure, and personal experience	acquisition by cultural and formal tuition
Task Construal	highly contextualized	decontextualized
	personalized	depersonalized
	conversational and socialized	asocial
Type of Intelligence	interactional	analytic (psychometric IQ)
Indexed:	(conversation and implicature)

is also known as the *cognitive miser* model. For instance, Tversky and Kahneman (1973) found that mathematical psychologists exhibited the law of small numbers. Despite being well trained in statistics, they used their fast and reactive System 1, thus neglecting basic statistical analysis.

System 1 is biased to look for confirmatory evidence that enables individuals to make sense of the world around them. Such a bias is also reflected in the desire of individuals to reduce or avoid *cognitive dissonance*. Cognitive dissonance arises from the psychological stress placed upon individuals when they hold different *mental models* of the world (see Section 19.13 on mental models). The individuals' response in such cases is to rationalize the world around them and reduce conflict between different mental models. The term "cognitive dissonance" was proposed by Festinger (1957) and a classic set of experiments can be found in Festinger and Carlsmith (1959).

The fact that the suppression of an incorrect response by System 1 requires cognitive effort on the part of System 2 can be illustrated by the *Stroop task*. The term Stroop task is now used for any generic task in which an automatic, highly practiced response, by System 1 is, in fact, incorrect. System 2 then attempts to control the incorrect response (successfully or unsuccessfully), which accounts for the hesitation in subject responses. In the classical example, subjects are asked to read names of different colors, but some of the names are printed in a different color, e.g., the word “green” may be printed in the color “red.” Subjects take longer to answer these questions and make more errors relative to the case where the names of the colors and the color in which they are printed, match.

System 1 is also associated with high levels of skill and achievement. For instance, expert chess players can quickly gauge the strength of their position without considering all possibilities. Indeed, considering all possibilities would be seriously taxing even for System 2 and deplete scarce cognitive resources. Kahneman and Frederick (2005) provide a list of factors that determine the relative usage of the two systems that we now outline. Unfamiliar tasks and those involving abstract concepts are likely to be dealt with by System 2. However, System 1 is likely to be used to a greater extent when the time available for deliberation is smaller, exposure to statistical training is lower, and some traditional measures of IQ are lower.

The relative use of the two systems might also depend on the moods of individuals. A representation of the data in terms of frequencies, rather than probabilities, can also influence the ability of System 2 to correct the errors of System 1. For instance, Kahneman and Frederick (2005) write: “the language of frequencies improves respondent’s ability to impose the logic of set inclusion on their considered judgments.” Indeed, we have reviewed a great deal of evidence above that in some cases, frequency information rather than probability information reduces some behavioral biases but the biases do remain, often for a majority of the subjects.

Higher cognitive ability might be associated with a greater and more efficient use of System 2. If this insight is correct, then we should see a lower prevalence of judgment errors among subjects in experiments whose cognitive ability is higher. Oechssler et al. (2009) test this idea. In order to measure cognitive ability, they use the *cognitive reflection test* (CRT) proposed in Frederick (2005). In this test, subjects are asked the following three questions.

1. A bat and a ball together cost 110 cents. The bat costs 100 cents more than the ball. How much does the ball cost?
2. If it takes 5 machines 5 minutes to make 5 widgets, how long would it take 100 machines to make 100 widgets?
3. In a lake, there is a patch of lily pads. Every day, the patch doubles in size. If it takes 48 days for the patch to cover the entire lake, how long would it take for the patch to cover half of the lake?

If one only engages System 1, then the answers to the three questions are respectively 10 cents, 100 min, 24 days. However, these answers are incorrect. The correct answers based on engaging System 2 are, respectively, 5 cents, 5 min, 47 days. The average number of correct responses was 2.05.¹⁸ As in Frederick’s (2005) sample, a lower CRT score is associated with greater risk seeking and greater impatience (higher discount rate).

There is a statistically significant difference in the error rates of individuals with high and low CRT scores. For the conjunction fallacy (the Linda problem), 62.6% of the low CRT group engaged in the fallacy, while only 38.3% of the high CRT group did. Now consider the conservatism problem, or the underweighting of the likelihood of a sample. In a problem given

¹⁸ In Frederick’s (2005) sample this score lies between the scores for the MIT and Princeton students.

to the subjects, the probability consistent with Bayes' rule was 0.967; however, the low CRT group reported a probability of 0.58, while the high CRT group reported a probability of 0.69. Interestingly cognitive ability did not turn out to have any effect on the anchoring heuristic. This suggests that the relative extent to which the heuristics are hardwired in the brain, differs. Some heuristics can be reduced with greater cognitive effort/ability, while others cannot be.

Bergman et al. (2010) find that as cognitive ability increases, the anchoring effect reduces but does not vanish. One reason for the difference in their findings from Oechssler et al. (2009) is that they do not use the CRT but rather a cognitive ability test (CAT) that is based on answering 44 questions in 20 minutes. Dohmen et al. (2009) find, using data from the German population, that cognitive ability and the number of years of schooling are positively related to better performance in probability judgment tasks, and a reduced incidence of the gambler's fallacy. For the relation between IQ and the extent of judgment biases, see Stanovich (1999) and Stanovich and West (2002).

A higher IQ can also be a doubled edged sword. On the one hand, a higher IQ can induce a more efficient system 2 that corrects for the mistakes of system 1. However, on the other hand, a high IQ can induce individuals to focus on a more plausible error rather than a random error; see for instance, Kahneman (2000).

19.12 Coarse thinking and persuasion

Persuasion is central to determining the outcomes in several forms of human interaction. Activities associated with persuasion include advertising, political campaigns, religious preaching, selling activities, media campaigns, and military propaganda. Of these, advertising as a form of persuasion, is the one that economists have focused on the most. A dominant strand in industrial organization insists that the objective of advertising is the dissemination of information (Stigler, 1987; Grossman and Hart, 1980; Milgrom, 1981).

In contrast, in psychology, persuasion is understood as the transference of information from one context to another (Kahneman and Tversky, 1982; Zaltman, 1997). Consider the following three examples of successful persuasion, taken from Shleifer et al. (2008).

1. American Express travelers cheques featured Karl Malden, an actor who played a detective in a well-known television show. The advertisements suggested that, for safety, people should carry American Express travelers cheques in preference to cash.
2. After the crash of the Internet bubble, the brokerage firm Charles Schwab launched an advertising campaign that featured judges, ship captains, crossing guards, doctors, grandmothers, and other steady and reliable individuals, each standing next to a Schwab investment specialist. The headline of one advertisement, depicting a Schwab professional standing next to a pediatrician, said: "Both are seen as pillars of trust."
3. Consider Arnold Schwarzenegger's memorable speech at the 2004 Republican National Convention. In the best remembered part of his speech, Schwarzenegger defended free trade: "To those critics who are so pessimistic about our economy, I say: Don't be economic girlie men! . . . Now they say India and China are overtaking us. Don't you believe it. We may hit a few bumps—but America always moves ahead. That's what Americans do."

All these examples illustrate a kind of thinking, known as *associative, analogical, or metaphoric thinking* in psychology. Information that has great relevance in one context is used in another context where it has much less, or worse, no relevance at all. Based on Mullainathan (2002),

Shleifer et al. (2008) make progress in formalizing these ideas by focusing on the concept of *coarse thinking*.

To explain *coarse thinking*, suppose that individuals are able to categorize a problem into one of n mutually exclusive categories. Any two problems in the same category have identical methods of solution. So, for instance, if there are two distinct problems in category $j \in \{1, \dots, n\}$, then they are solved using an identical model. The polar opposite of coarse thinking is known as *sophisticated thinking* in which different models may be suitable for each problem. Coarse thinking can be exploited by others for their benefit. So, for instance, a beautiful model or a well-known sports personality posing next to a car gives no information about the car, per se. However, individuals might, using associative thinking, transfer attributes they associate with the individual posing with the car, to the car itself.

Suppose that for some good, service, or information, a buyer needs to assess the level of quality, $q \in (-\infty, \infty)$. The buyer receives two possible messages $m \in \{\underline{m}, \bar{m}\}$, where $\underline{m}$ and $\bar{m}$ have the respective connotations of *bad* and *good* messages. The individual knows that there are two mutually exclusive *categories* or *situations* $s \in \{\underline{s}, \bar{s}\}$. Messages are only informative when $s = \bar{s}$; when $s = \underline{s}$ messages are completely uninformative. The joint distribution of quality, q , messages, m , and situations, s , is given by $p(q, m, s)$.

Example 19.3 Suppose that putting “silk” in shampoo has no effect on hair. Yet a shampoo company advertises putting silk in shampoo in the hope that associative thinking will persuade consumers to buy the shampoo. In this case, the message $\bar{m} = \text{silky}$, while $\underline{m}$ is any neutral message. One situation $\bar{s}$ is that a person is looking for a shampoo, and in a second situation $\underline{s}$ the person is not looking for a shampoo but simply assessing the quality of the plastic used in shampoo bottles; so $\bar{s} = \text{shampoo}$ and $\underline{s} = \text{bottle}$. The message $\bar{m} = \text{silky}$ is uninformative in the situation $\underline{s}$ but informative in the situation $\bar{s}$. A Bayesian thinker will simply avoid the shampoo ad in the first situation. However, a coarse thinker (see formal definition below) who lumps situations together in categories will give at least some weight to the shampoo advertisement.

Example 19.4 Consider the first of three examples of successful persuasion given above on American Express travelers checks. Here the message $\bar{m} = \text{Karl Malden advertisement}$, while $\underline{m}$ is any neutral message. The situations are: $\bar{s} = \text{an individual with travel plans}$ and $\underline{s} = \text{an individual who has no travel plans}$. Clearly the message on travelers cheques is only relevant to individuals with travel plans.

The assumptions are formally stated as follows.

A1: The distribution of quality, q , is independent of the situation, i.e.,

$$p(q \mid \underline{s}) = p(q \mid \bar{s}) = p(q). \quad (19.44)$$

A2: The average quality, $E[q] = 0$; using (19.44) this implies

$$E[q \mid s] = 0. \quad (19.45)$$

A3: Any message is possible under any situation

$$p(m \mid s) > 0; m \in \{\underline{m}, \overline{m}\}, s \in \{\underline{s}, \bar{s}\}. \quad (19.46)$$

A4: Messages are informative only in situation $s = \bar{s}$. In situation $\bar{s}$, the message $\overline{m}$ is good news about average quality, while the message $\underline{m}$ is bad news about average quality. Thus,

$$E[q \mid \underline{m}, \bar{s}] < E[q \mid \overline{m}, \bar{s}]. \quad (19.47)$$

By contrast, in situation $\underline{s}$, the message is uninformative, i.e.,

$$p(q \mid \underline{m}, \underline{s}) = p(q \mid \overline{m}, \underline{s}) = p(q \mid \underline{s}) = p(q). \quad (19.48)$$

The last equality uses (19.44).

From the definition of conditional probability, we know that

$$p(q \mid \underline{m}, \bar{s}) = \frac{p(q, \underline{m}, \bar{s})}{p(\underline{m}, \bar{s})} = \frac{p(q, \underline{m}, \bar{s})}{p(\underline{m} \mid \bar{s}) p(\bar{s})}. \quad (19.49)$$

Analogous to (19.49), we can write

$$p(q \mid \overline{m}, \bar{s}) = \frac{p(q, \overline{m}, \bar{s})}{p(\overline{m}, \bar{s})} = \frac{p(q, \overline{m}, \bar{s})}{p(\overline{m} \mid \bar{s}) p(\bar{s})}. \quad (19.50)$$

From the definition of a marginal probability distribution, we get that

$$p(q, \underline{m}, \bar{s}) + p(q, \overline{m}, \bar{s}) = p(q, \bar{s}). \quad (19.51)$$

Substitute $p(q, \overline{m}, \bar{s})$ from (19.50) in (19.51)

$$p(q, \underline{m}, \bar{s}) + p(q \mid \overline{m}, \bar{s}) p(\overline{m} \mid \bar{s}) p(\bar{s}) = p(q, \bar{s}). \quad (19.52)$$

Solve (19.52) for $p(q, \underline{m}, \bar{s})$ and substitute in (19.49) to get

$$p(q \mid \underline{m}, \bar{s}) = \frac{p(q, \bar{s})}{p(\underline{m} \mid \bar{s}) p(\bar{s})} - \frac{p(q \mid \overline{m}, \bar{s}) p(\overline{m} \mid \bar{s})}{p(\underline{m} \mid \bar{s})}. \quad (19.53)$$

But $p(q \mid \bar{s}) = \frac{p(q, \bar{s})}{p(\bar{s})}$, hence, (19.53) can be written as

$$p(q \mid \underline{m}, \bar{s}) = \frac{p(q \mid \bar{s})}{p(\underline{m} \mid \bar{s})} - \frac{p(q \mid \overline{m}, \bar{s}) p(\overline{m} \mid \bar{s})}{p(\underline{m} \mid \bar{s})}. \quad (19.54)$$

Multiply both sides by q and integrate both sides with respect to q to get

$$E[q \mid \underline{m}, \bar{s}] = \frac{1}{p(\underline{m} \mid \bar{s})} E[q \mid \bar{s}] - \frac{p(\overline{m} \mid \bar{s})}{p(\underline{m} \mid \bar{s})} E[q \mid \overline{m}, \bar{s}]. \quad (19.55)$$

From (19.45), $E[q | \bar{s}] = 0$, hence, we can write (19.55) as:

$$E[q | \underline{m}, \bar{s}] = -\frac{p(\bar{m} | \bar{s})}{p(\underline{m} | \bar{s})} E[q | \bar{m}, \bar{s}]. \quad (19.56)$$

On the other hand, in category/situation $\underline{s}$, using (19.45), (19.48) we get,

$$E[q | \underline{m}, \underline{s}] = E[q | \bar{m}, \underline{s}] = E[q | \underline{s}] = 0. \quad (19.57)$$

From (19.56), (19.57), a Bayesian uses the correct model for each category. In category $\bar{s}$, where the signals are informative, the Bayesian forms a different (and correct) posterior relative to category $\underline{s}$. We now describe how a coarse thinker infers quality, conditional on a message $m = \{g, b\}$.

We use the subscript “c” for a coarse thinker. So, p_c refers to the probability assigned by a coarse thinker to some event and E_c refers to the expectation computed by a coarse thinker. In the absence of a subscript, as in p , E , we refer to the analogous computations of a Bayesian who does not use categorization. We make the following assumption about a coarse thinker.

A5: A coarse thinker includes both situations $\underline{s}$ and $\bar{s}$ into the same category, hence, for any signal, s ,

$$p_c(q | m, s) = p(q | m, \underline{s}) p(\underline{s} | m) + p(q | m, \bar{s}) p(\bar{s} | m). \quad (19.58)$$

In (19.58), although the coarse thinker is able to observe the situation, the same model is used for both situations. A coarse thinker does not evaluate the informativeness of the message for the particular situation, but rather by the average informativeness across all situations in the category, $s \in \{\underline{s}, \bar{s}\}$.

Multiply both sides of (19.58) by q and integrate with respect to q to get

$$E_c(q | m, s) = E(q | m, \underline{s}) p(\underline{s} | m) + E(q | m, \bar{s}) p(\bar{s} | m). \quad (19.59)$$

Since $p(\underline{s} | m) + p(\bar{s} | m) = 1$ and $p(\underline{s} | m) \leq 1$, $p(\bar{s} | m) \leq 1$, it follows that the expected quality inferred by the coarse thinker is a linear combination of what a Bayesian would compute. Since $0 = E(q | m, \underline{s}) < E(q | m, \bar{s})$ it follows from (19.59) that

$$E(q | m, \underline{s}) \leq E_c(q | m, s) \leq E(q | m, \bar{s}). \quad (19.60)$$

This leads to the following straightforward implication.

Proposition 19.1 *Relative to a Bayesian, the coarse thinker overreacts when the signal is $\underline{s}$ and underreacts when the signal is $\bar{s}$.*

The intuition for the result in Proposition 19.1 is that the coarse thinker acts as a Bayesian who is unable to distinguish between the two situations. When the situation is completely uninformative, he still puts some weight on it being an informative situation, so he overreacts. This can explain the third example above; voters seem to put some weight on Arnold Schwarzenegger’s optimism of America’s ability to succeed under free trade. They transfer Arnold’s ability to win over strong characters in films into another context where such ability has apparently little relevance. Conversely, when the situation is completely informative, the coarse thinker puts some

weight on the situation being completely uninformative, so he underweights the information content of the message.

We now examine the incentives of a persuader to alter the message observed by an individual who might be persuaded. We make the following assumptions.

- A6:** The objective of the persuader is to maximize the expected quality as perceived by the individual. Presumably, an increase in the quality induces a buyer to buy more, or a politician to get more votes.
- A7:** Suppose that the true message is given by $m \in \{\underline{m}, \bar{m}\}$. Denote the message relayed by the persuader to the individual by $m' \in \{\underline{m}, \bar{m}\}$; we allow for $m' \neq m$. The persuader can distort the true message at some cost $c > 0$. The individual is a *face value individual* in the sense that any message given to the individual by the persuader is believed.¹⁹

In the light of A6, A7, the payoff of the persuader is given by

$$\begin{cases} E(q | m', s) & \text{if } m' = m \\ E(q | m', s) - c & \text{if } m' \neq m \end{cases}$$

We now examine the incentives of the persuader to distort the message.

Proposition 19.2 (*Bayesian individual*): When $s = \underline{s}$, the persuader always reveals the true message to a face value Bayesian and never incurs a cost of deception, c .

Proof: From (19.57),

$$E[q | \underline{m}, \underline{s}] = E[q | \bar{m}, \underline{s}] = 0,$$

hence, by altering a message there is no improvement in average quality. However, the persuader pays a cost, c , of altering the message. Hence, it is never optimal to do so. ■

Proposition 19.3 (*Coarse thinkers*): Suppose that $s = \underline{s}$. The persuader might not reveal the true message to a face value coarse thinker. In particular, if c is less than some critical value c^* , then the persuader will replace a bad message with a good message.

Proof: Using (19.57), the first term on the RHS of (19.59) is zero. Furthermore, using Bayes' rule we get that $p(\bar{s} | m) = \frac{p(m|\bar{s})p(\bar{s})}{p(m)}$, hence, from (19.58) we get that

$$E_c(q | m, s) = E(q | m, \bar{s}) \frac{p(m | \bar{s})p(\bar{s})}{p(m)}.$$

Using (19.56) we can derive the following expressions for the expected quality for a coarse thinker under the two possible messages $\bar{m}$ and $\underline{m}$.

$$E_c(q | \bar{m}, s) = E(q | \bar{m}, \bar{s}) \frac{p(\bar{m} | \bar{s})p(\bar{s})}{p(\bar{m})}. \quad (19.61)$$

¹⁹ One could alter this assumption to allow for strategic inference by the individual that takes into account the incentives of the persuader to distort the message. This is allowed for by Shleifer et al. (2008), but it does not alter the essential insights.

$$E_c(q | \underline{m}, s) = -E[q | \bar{m}, \bar{s}] \frac{p(\bar{m} | \bar{s}) p(\bar{s})}{p(\underline{m})}. \quad (19.62)$$

For the persuader, replacing the true message $\underline{m}$ with $m' = \bar{m}$ improves profits if

$$\begin{aligned} E_c(q | \bar{m}, s) - c &> E_c(q | \underline{m}, s). \\ \Leftrightarrow c &< E_c(q | \bar{m}, s) - E_c(q | \underline{m}, s). \end{aligned} \quad (19.63)$$

Substitute (19.61), (19.62) in (19.63) we get

$$c < c^* \equiv E[q | \bar{m}, \bar{s}] p(\bar{m} | \bar{s}) p(\bar{s}) \left(\frac{1}{p(\bar{m}) p(\underline{m})} \right), \quad (19.64)$$

which completes the proof. ■

We now give some comparative static results.

Proposition 19.4 *Suppose that c^* is as defined in Proposition 19.3. Then c^* is increasing in (1) the probability with which $s = \bar{s}$ occurs, i.e., $p(\bar{s})$, and (2) the informativeness of message $\bar{m}$ when $s = \bar{s}$, i.e., $E[q | \bar{m}, \bar{s}]$.*

Proof: Directly differentiate both sides of (19.64) successively with respect to $p(\bar{s})$ and $E[q | \bar{m}, \bar{s}]$. ■

From Propositions 19.3, 19.4, an increase in $p(\bar{s})$, $E[q | \bar{m}, \bar{s}]$ increases c^* , increasing the likelihood that the persuader lies by giving out good news ($\bar{m}$) when the news is actually bad. The intuition is as follows. From (19.61), (19.62), an increase in $p(\bar{s})$, $E[q | \bar{m}, \bar{s}]$ raises $E_c(q | \bar{m}, s)$ and reduces $E_c(q | \underline{m}, s)$. Thus, the marginal incentive of the persuader to lie and give out the message $\bar{m}$ increases.

DellaVigna and Gentzkow (2010) survey the non-experimental evidence on persuasion; there is much evidence that is supportive of persuasion. They consider four groups of individuals that are typically the target of persuasion: consumers, voters, donors, and investors. They consider questions such as: Are consumers affected by advertising? Is the voting decision of voters influenced by political campaigns? Do newspaper endorsements and endorsements by influential citizens persuade voters to vote differently? Does door to door campaigning for funds persuade donors to give more? Do analyst recommendations influence investment in stocks? The set of questions that falls within the domain of persuasion theories is wide and important. This continues to be an active area of research.

We do not address here the important issues of how and why these categories are formed and how/why they might change over time. These questions lie beyond the scope of the current model, but their resolution will ultimately determine the importance of this class of models. These observations are similar to those we made for *analogy-based equilibria* in Part 4. The issue of optimal categorization is considered in Mohlin (2014), Peski (2011), and Fryer and Jackson (2008). Mengel (2012) considers the evolution of coarse categorization. We close with an example of categorization, which speaks to the issue of racism in the workplace that arises despite the absence of social identity.

Example 19.5 (Fryer and Jackson, 2008) *Suppose that employees are either black or white. In a population of 100 workers, 90 are white and 10 are black (minority group). Workers' types*

are either high ability (H) or low ability (L). Half the workers in each race are of each type. Denote a black worker by 0, a white worker by 1, a low ability worker by 0 and a high ability worker by 1. Thus, there are four categories of workers: (0, 0), (0, 1), (1, 0), (1, 1). Suppose that the employer forms only three categories. Thus, at least one of the categories will contain either two different races, or two different types of workers, or both.

Suppose that the employer has previously interacted with a large number of workers in each of the categories, in proportion to their presence in the population. Since there are 10 black workers out of every 100 and half of those are low ability, so the employer must have interacted with 5 workers of type (0,0). Calculating in the same manner, the employer must have interacted with 5 workers of type (0,1), 45 workers of type (1,0) and 45 workers of type (1,1). The mean of any two categories that are grouped together is a population proportions weighted mean. So the mean of the categorization {(0,1), (1,1)} is (0.9, 1) while the mean of {(1,0), (1,1)} is (1, 0.5). The mean of any single category is the category itself; e.g., the mean of {(0,1)} is just (0,1). Let the objective of the employer be to minimize the “sum across categories of the total variation of the mean from each category”; clearly several other objectives are also possible. Fryer and Jackson show that the optimal categorization under such an objective is {(1,0), (1,1), {(0,0), (0,1)}}.

Thus, the optimal categorization groups together the two types of black workers in the same category. In this model, blacks are more coarsely sorted not because of racism, or malevolence, but simply because of the underlying objective function and the proportions of blacks in the population. Since the two types of black workers are put into the same category, the representative member of this category is viewed by the employer as $0.5(0,0) + 0.5(0,1) = (0,0.5)$. This is good news for a low ability black worker but bad news for a high ability black worker. Indeed if the decision to acquire human capital is endogenous, this is likely to reduce the incentive of black workers to acquire high ability.

19.13 Mental models

Under coarse thinking, individuals form categories such that all elements in a category are treated with an identical model. This economizes on the number of mental models required to analyze a large number of events, hence, it economizes on scarce cognitive resources. A useful working definition of *mental models*, based on Denzau and North (1994), is given in WDR (2015, p. 11): “When people think, they generally do not draw on concepts that they have invented themselves. Instead, they use concepts, categories, identities, prototypes, stereotypes, causal narratives, and worldviews drawn from their communities.” Chapter 3 in WDR (2015) gives an excellent introduction to mental models. The WDR (2015, p. 11) further writes: “There are mental models for how much to talk to children, what risks to insure, what to save for, what the climate is like, and what causes disease. Many mental models are useful; others are not as useful and may even contribute to the intergenerational transmission of poverty.”

Mental models are essential for people to make decisions by economizing on cognitive costs and can be passed down from generation to generation. Mental models can persist even when they are no longer useful, hence, while they economize on cognitive costs, they can lead to suboptimal decisions. An example of harmful mental models is stereotyping of other individuals and racial discrimination based on social group identities; see Chapter 7 and Example 19.5 above. Datta and Mullainathan (2014) document several examples of incorrect mental models that are detrimental to self-interest; let us consider some of these examples.

1. In many developing countries, there is a low take-up of the oral rehydration solution (ORS), a relatively cheap and effective mix of essential salts to treat diarrhea. However, 35% of poor women surveyed in India believed that the best response to diarrhea is to reduce, not increase, fluid intake; they possibly draw an incorrect analogy to a leaky bucket. Since ORS saves lives but does not alleviate the symptoms of diarrhea, it allows many people to hold on to an incorrect, and potentially fatal, mental model.
2. Farmers might overuse nitrogenous fertilizers because they believe that such fertilizers promote greener plants. This model works well for plants like spinach but not as well for grains, because it over-encourages green healthy leafs at the cost of lower crop yields.
3. Parents in Morocco and Madagascar pull their children out of school too early. In their incorrect mental model, education only pays if children go all the way up to secondary school. However, evidence shows that every extra year of schooling is equally valuable. Thus, while parents could afford to send their children to school for longer, doing so is inconsistent with their mental models (Banerjee and Duflo, 2011).

Insofar as undesirable outcomes are not simply the product of cognitive limitations but also of defective mental models, policy must address factors conducive for the formation of appropriate mental models.

Why do “bad” mental models persist? There is more than one potential cause. A range of judgment heuristics that we have already considered in this chapter may provide potential clues. Mental models may serve the purpose of *anchors* and the *availability heuristic* could ensure that existing mental models are the ones most likely to come to mind when taking decisions. *Confirmation bias* could ensure that individuals ignore information that contradicts their existing mental models. Social identity (see Chapter 7) too could play a role. By conforming to preexisting and shared mental models in a social group, individuals may wish to demonstrate that they belong to the group of insiders.

Existing mental models may also foreclose the choices that people could make to test the models (WDR, 2015). For instance, inadequate social exchange between communities that mistrust each other can allow mutual stereotypes to persist. Female genital mutilation may persist in parts of the world because contact with the non-mutilated genitalia may be perceived to be harmful. In the face of this incorrect model, individuals may be unwilling to experiment with alternative mental models, due to the high perceived costs of doing so (Mackie, 1996; Gollaher, 2000).

Although individuals can exhibit heterogeneity in mental models, shared mental models are essential to developing institutions. Indeed, there is a two-directional feedback between mental models and institutions. For instance, in Sierra Leone, the degree of competition for the role of paramount chiefs, who are elected for a lifetime, also determines the quality of governance (Acemoglu et al., 2013). In each area, the degree of competition is fixed because paramount chiefs can only come from families that were originally recognized by the British colonial authorities. Greater competition is found to be conducive to better governance. However, the persistence of the degree of competition in each area has influenced the mental models that people hold for respect towards authority. In areas with lower political competition, people are more respectful of authority and less likely to question the actions of leaders. This, in turn, perpetuates the existing degree of competition.

Some mental models are hardwired in humans due to their evolutionary history (e.g., fear of snakes and spiders; see Chapter 14 for more details). Historical accidents can also explain some mental models. For instance, the current low levels of trust in parts of Africa can be traced back

to the slave trade (Nunn, 2008; Nunn and Wantchekon, 2011). Black Africans required guns to protect themselves against capture by the slave traders. However, because they could not afford to buy guns, they kidnapped and sold other black Africans to slavery, in exchange for money that, in turn, financed guns. This eventually led to mistrust of strangers that still persists in some parts of Africa. In another example, the physical superiority of males gives them a comparative advantage in the use of agricultural implements, such as ploughs. Hence, gender inequities are more pronounced in societies with an agricultural past (Alesina et al., 2013).

Mental models are distinct from norms in that they are not enforced by social norms. Rather, mental models reflect “broad ideas about how the world works and one’s place in it” (WDR, 2015).

How does one get people to change incorrect mental models? Datta and Mullainathan (2014) argue that simply telling people that they hold the wrong mental model is unlikely to work. A more promising strategy is to provide evidence that falsifies the core beliefs in an incorrect mental model. For instance, a particularly potent method of getting people to pay attention to reducing a wasteful activity is by comparison with a reference social group or peers. For instance, when individuals are given information about a comparison of their electricity consumption relative to neighbors, they reduce consumption by as much as that caused by an 11–20% increase in the price of electricity (Allcott and Mullainathan 2010; Allcott and Rogers, 2014); a similar effect is documented for water consumption (Ferraro and Price 2013).

Villagers in poor countries are more likely to educate girls if greater information is provided on the availability of jobs for girls with high school degrees (Jensen, 2012). Long-running soap operas in Brazil that emphasized small family size led to reduced fertility, particularly for those of a similar age to the role models in the soap operas (La Ferrara et al., 2012). Exposure to cable TV in India led to a reduction in fertility, increase in women’s status, reduction in domestic violence, and an increase in children’s school enrollment, suggesting a change in mental models (Jensen and Oster, 2009). Legal or regulatory changes can also induce changes in mental models (Sunstein, 1996); this might have been the case in changes in attitudes towards slavery, wearing helmets, smoking, racism, and casteism.

19.14 Herbert Simon’s approach to bounded rationality

In neoclassical economics, individuals use subjective expected utility (SEU) to evaluate risky/uncertain situations and employ Bayes’ rule to update information. No cognitive limitations are placed on the individual, nor is the application of SEU dependent on the environment that an individual faces. The heuristics and biases approach shows that this view of human nature is often rejected. This has led some to argue that mainstream economic theory is based on an unrealistic picture of human decision making (Selten, 2001).

Rationality has several possible interpretations. A common view in economics is that individual behavior is rational if it can be interpreted as the solution to some optimization problem. Of course, the optimization problem must be a plausible one. Otherwise, it is possible to rationalize any behavior by assigning the utility function to take a value 1 for the action chosen by an individual and zero otherwise. The notion of the optimality of behavior, or the quality of the decision, has been termed as *substantive rationality* by Simon (1955). Classical economic theory focuses mainly on substantive rationality and does not give much attention to *procedural rationality*, or the quality of the process of decision.

Substantive rationality did not figure directly in the writings of classical economists. Simon (2000) interprets Voltaire's well-known saying "the best is the enemy of the good" as implying that "if you are too preoccupied with attaining the optimum, you won't even get an acceptable result." Indeed, much of the discourse in economics until well into the middle of the twentieth century used the notion of a *reasonable person* rather than that of a *utility maximizing rational person*.

Is the rationality hypothesis compelling on grounds of empirical evidence? The evidence is mixed at best, and success is mixed with well-documented and prominent failures. Börgers (1996) concludes that "Unfortunately, there are no striking examples of empirical regularities, which are well explained by the rationality hypothesis." Substantive rationality, as used in neoclassical economics, prescribes choosing on the basis of marginalist conditions; for instance, firms produce at the point where marginal revenues equal marginal costs. In his Nobel lecture, Simon (1978, p. 347) is very explicit on this issue: "But there are no direct observations that individuals or firms do actually equate marginal costs and revenues."

Furthermore, Selten (2001) writes. "However, there is overwhelming experimental evidence for substantial deviations for Bayesian rationality (Kahneman et al. 1982): people do not obey Bayes' rule, their probability judgements fail to satisfy basic requirements like monotonicity with respect to set inclusion, and they do not have consistent preferences, even in situations involving no risk or uncertainty." A more positive view of rationality is taken by Gintis (2009, p. 2) who argues for maintaining at least a minimum degree of rationality based on *preference consistency*; he argues that violations of preference consistency can be accounted for by changes in context, frames, and reference points.

The impact of the rationality assumption on other social sciences has not been profound. In evaluating the impact of such work, with particular reference to the collected works of Becker (1981), Simon (2000) says the following. "Perhaps its greatest failing was in not producing major insights into political and social processes that were not already well-known, if in somewhat less qualitative and less formalized statements."

In response to these concerns Herbert Simon proposed *bounded rationality* as an alternative approach. The term bounded rationality has become fashionable in a variety of contexts in economics and its usage and meaning have become variegated. To be specific, we follow the original usage of the term in Simon (1956, 1957). Simon used the metaphor of the two blades of a pair of scissors. One blade represents *cognitive limitations* of humans, while the second blade emphasizes the *structure of the environment*. To cut successfully, the scissors must use both blades, hence, for a proper approach to bounded rationality, one cannot choose to omit either cognitive limitations or the structure of the environment. By contrast, the practice in most of economics is to assume unbounded cognitive powers and underemphasize the structure of the environment, such as framing effects, context, and emotions.

Bounded rationality does not imply that individuals are irrational. Hence, bounded rationality is not synonymous with erratic human behavior. Boundedly rational individuals often solve some well-specified optimization problem. However, whether individuals should be modeled as optimizing agents is an open question. For arguments on both sides, see the "Forum on the Role of Bounded Rationality versus Behavioral Optimization in Economic Models" published in the June 2013 issue of the *Journal of Economic Literature*. The main difference between bounded rationality and substantive rationality (as used in neoclassical economics) is that, in the former, the optimization problem respects the cognitive bounds of the relevant economic actors and the structure of the environment. Bounded rationality is, thus, often concerned with *procedural rationality*. It tries to open up the black box of human decision making, and the steps that humans take to formulate and solve problems in different environments.

Bounded rationality has sometimes been interpreted as *optimization under constraints* because the information necessary for taking actions involves the costs of search. In one view, if one introduces constraints that capture the costs and benefits of search, then one could take account of bounded rationality (Stigler, 1961). However, the problem with this argument is that to estimate the costs and benefits of search, one would have to first estimate the costs and benefits of estimating the costs and benefits of search. One can construct an infinite regress of such search, which can be even more informationally demanding than the original problem. This compounds the very problem that these additional constraints were designed to address and makes the model even more psychologically implausible.

To see this slightly more formally, we can use the following intuitive construction in Selten (2001). He distinguishes between *familiar* and *unfamiliar* problems. For familiar problems, the decision maker *knows* the set of alternatives (or trivially knows where to find them) and also knows the *method* for choosing among these alternatives. For unfamiliar problems, the set of alternatives and methods for choosing among them are both unknown. Thus, in this case, the decision making process can be understood as being composed of the following two levels.

1. (Level 1) Find the set of alternatives to be chosen.
2. (Level 2) Find a method of making a choice among the set of alternatives.

A decision maker who is ignorant of what to do at Level 1, will also not know what to do at Level 2. Thus, we get:

3. (Level 3) Find an optimal method of solving the problem at Level 2.

Hence we get an infinite regress, with level k being:

- k . (Level k) Find the optimal method for solving Level $k - 1$.

While this is not a formal proof, it is strongly suggestive of the impossibility of classical optimization in limited time. In the words of Selten (2001) “Trying to optimize in such situations is like trying to build a computer that must be used in order to determine its own design.”

Simon (1978) in his Noble lecture is quite skeptical about theories that explicitly incorporate costly search and information. He offers the following sobering views (pages 358–9): “In none of these theories . . . is the assumption of perfect maximization abandoned. . . . Hence, the new theories do nothing to alleviate the computational complexities facing the decision maker . . . but simply magnify and multiply them. . . . Hence, to some extent, the impression that these new theories deal with the hitherto ignored phenomenon of uncertainty and information transmission is illusory. For many economists, however, the illusion has been pervasive.”

19.14.1 *Aspiration adaptation theory*

In an important class of bounded rationality models, the individual, or an institutional entity such as a firm, has a goal or a reference level, referred to as an *aspiration level* (Simon, 1957). Aspiration levels may refer, for instance, to the target profit of a firm, a target income for a consumer, or even a level of employment/growth rate for a government. A decision alternative is *satisfactory* if it meets or exceeds the aspiration level.

Decision alternatives are not exogenous but must be searched by the individual. To avoid an infinite regress problem, the decision maker can use a simple stopping rule. For instance, stop when an alternative (or the outcome from an alternative) exceeds the aspiration level. Such an

approach has also been called *satisficing* to distinguish it from *optimization*. The aspiration levels are not fixed, but evolve over time.

One simple method of updating aspiration levels is to adjust them downwards if successive alternatives fall below the aspiration level, much as one would reduce the sale price of a house that has been on the market for too long. As Simon (1978) puts it: “In a benign environment that provides many good alternatives, aspirations rise; in a harsher environment, they fall.” The individual has a well-defined optimization problem. Unlike the models in neoclassical economics that are based on substantive rationality, this model incorporates: (1) Limited cognitive abilities that are reflected in a simple stopping rule, and (2) the structure of the environment, as embodied in the formation of aspirations.

An early attempt at a formal model of *aspiration adaptation* was by Saurmann and Selten in 1962; an English version was published as Selten (1998). Consider the role played by aspirations in a symmetric two-player normal form stage game, denoted by $G(2, \{C, D\}, \{C, D\}, u_1, u_2)$, that is repeated over discrete time, $t = 0, 1, 2, \dots$ (Cho and Matsui, 2005). The two players are indexed by $i = 1, 2$, and player i has the strategy set $S_i = \{C, D\}$; think of these actions as, respectively, *cooperation* (C) and *defection* (D).

Denote the action of player i in period t by $s_{it} \in S_i = \{C, D\}$ and denote the action profile in any period t by $s_t = (s_{1t}, s_{2t})$. The respective payoffs of players 1, 2 in the stage game are denoted by u_1 and u_2 such that $u_i : \{C, D\} \times \{C, D\} \rightarrow \mathbb{R}$. We assume that players are sufficiently patient so that if both players were rational in the classical sense, then mutual cooperation (C, C) can be sustained as an equilibrium of an infinitely repeated game. However, we assume that players are boundedly rational.

In the spirit of Herbert Simon’s work, suppose that players are bounded rational and form aspiration levels. Since players do not have infinite cognitive abilities, it is assumed that they summarize the history of the game into a single number, the *aspiration level*, which is simply an average of past payoffs of the player; the precise sequence of outcomes and actions in the past is not relevant. Hence, the aspiration level of player i at time t , a_{it} , is given by

$$a_{it} = \frac{1}{t} \sum_{\tau=1}^t u_i(s_{\tau}), t = 1, 2, \dots \quad (19.65)$$

Rewriting (19.65), we get

$$a_{it} = a_{it-1} + \frac{1}{t} [u_i(s_t) - a_{it-1}]. \quad (19.66)$$

From (19.66), the aspiration level evolves in a manner that is reminiscent of *adaptive expectations*. Current aspirations are equal to lagged aspirations adjusted for the difference between the current actual payoff and lagged aspirations. Initial aspiration levels of the two players are exogenously given by $a_0 = (a_{10}, a_{20})$, and initial actions are also exogenously given by $s_0 = (s_{10}, s_{20})$.

The significance of the aspiration level a_{it} is that it is the payoff which the individual expects from the action s_{it} in the current period, conditional on the past payoffs. So, if past payoffs were high (low), then current aspirations are also high (low). Since player $i = 1, 2$ has only two actions, we denote the chosen action at time t by $s_{it}^+ \in S_i$ and the unchosen action by $s_{it}^- \in S_i$; for example, if the chosen action is C, then $s_{it}^+ = C$ and $s_{it}^- = D$. The individual uses the following *behavioral rule* to choose actions

	C	D
C	1, 1	-1, -1
D	-1, -1	0, 0

Figure 19.7 A coordination game to study the role of aspiration adaptation.

$$s_{it+1} = \begin{cases} s_{it}^+ & \text{if } u_i \geq a_{it} \\ ps_{it}^+ + (1-p)s_{it}^- & \text{if } u_i < a_{it} \end{cases}, \quad (19.67)$$

where $0 < p < 1$ and $ps_{it}^+ + (1-p)s_{it}^-$ is a mixed strategy that plays s_{it}^+ with probability p and s_{it}^- with probability $1-p$. The idea behind the behavioral rule is simple. If the current payoff from an action is at least as good as the current aspiration level ($u_i \geq a_{it}$), then continue playing the current action, s_{it}^+ . Otherwise, switch to the other action, s_{it}^- , with some probability $1-p$. Thus, p represents a measure of *inertia*. If $p = 0$, then the individual completely switches to the other action (no inertia) and if $p = 1$, then the individual never switches (full inertia). In order to make the problem interesting, we rule out both possibilities by assuming $0 < p < 1$. One possible cause of inertia is potential switching costs that we ignore for pedagogical reasons.

Given the initial aspiration levels, a_0 , and initial actions, s_0 , we can use the definition of aspirations in (19.66) and the behavioral rule in (19.67) to generate a time profile of aspiration levels and actions $\{a_\tau, s_\tau\}_{\tau=1}^\infty$.

Consider the coordination game in Figure 19.7. If both players coordinate at (C, C), they get the highest payoff of 1 each. Lack of coordination pushes them to the lowest possible payoff tuple $(-1, -1)$. However, if they both do not cooperate, then both get a zero payoff, corresponding to the strategy profile (D, D). Assume that the initial aspiration levels are given by

$$a_{10} = a_{20} = -0.1. \quad (19.68)$$

1. Suppose that the initial strategy profile is $s_0 = (C, C)$. Then, the payoffs of the two players at time $t = 0$ are given by

$$u_1(C, C) = u_2(C, C) = 1. \quad (19.69)$$

Since $u_i(C, C) > a_{i0}$, (19.67) implies that the strategy profile at $t = 1$ is $s_1 = (C, C)$. From (19.66), the aspiration levels in period $t = 1$ are given by $a_{i1} = a_{i0} + [u_i(C, C) - a_{i0}]$. Using (19.68), (19.69), $a_{i1} = 1$. Since $u_i(C, C) = a_{i1}$ in period 1, it follows from (19.67) that in $t = 2$, the equilibrium action profile is again (C, C). The aspiration level in period 2 is $a_{i2} = a_{i1} + \frac{1}{2}[u_i(C, C) - a_{i1}] = 1$. Repeating the usual steps, at $t = 3$, the action profile is again (C, C). Extending this argument, the prediction of the model is that if both players start by coordinating, they continue coordinating. The reason is that the payoff from (C, C) is always at least as good as the aspiration level, hence, the players never feel the need to experiment and choose a different action.

2. Suppose that the action profile (C, D) is played in the initial period; the game is symmetric, so the results with the profile (D, C) are identical. The payoffs of the two players at time $t = 0$ are given by

$$u_1(C, D) = u_2(C, D) = -1. \quad (19.70)$$

From (19.68), (19.70), $u_i(C, D) < a_{i0}$, so (19.67) implies that at time $t = 1$, each player switches to the alternative action with probability $1 - p$. Thus, the actions chosen by the two players at $t = 1$ are given by

$$s_{11} = pC + (1 - p)D. \quad (19.71)$$

$$s_{21} = pD + (1 - p)C. \quad (19.72)$$

We can now compute the payoffs of the two players in period 1 using the mixed strategies of the two players given in (19.71), (19.72). These can be calculated to be

$$u_1(s_{11}, s_{21}) = u_2(s_{11}, s_{21}) = (1 - p)(2p - 1) - p^2. \quad (19.73)$$

The payoffs of both players are equal because of the symmetry of the game.

Consider the polar case of no inertia, i.e., $p = 0$. Then at $t = 1$, using (19.71), (19.72), both players switch their actions, so that the time $t = 1$ action profile is (D, C) . Evaluating (19.73) at $p = 0$, we have $u_1 = u_2 = -1$. When $p = 0$, the aspiration levels of the two players at date $t = 1$ are given by $a_{11} = a_{10} + [u_1(D, C) - a_{10}]$ and $a_{21} = a_{20} + [u_2(D, C) - a_{20}]$. Using (19.68), (19.70),

$$a_{11} = a_{21} = -1. \quad (19.74)$$

Since $u_1 = a_{11}$ and $u_2 = a_{21}$, the behavioral rule in (19.67) implies that the actions at $t = 2$ are the same as those at $t = 1$, so the action profile remains (D, C) . A simple calculation shows that $a_{12} = a_{22} = -1$, so aspirations are not revised in the next period and payoffs do not change either. Thus, given an initial action profile (C, D) , if there is no inertia, the game settles at the profile (D, C) for all time periods, starting at $t = 1$. Analogously, one can show that, with $p = 0$, starting from (D, C) , the game settles at (C, D) from $t = 1$ onwards. Now consider the case when there is inertia, $p > 0$. In this case, from (19.66) and (19.73),

$$a_{11} = u_1 > -1, a_{21} = u_2 > -1 \quad (19.75)$$

for all $p \in (0, 1)$. The behavioral rule (19.67) implies that actions are not altered in the next period ($t = 2$), so s_{12} and s_{22} are given, respectively, by the mixed strategy profile in (19.71), (19.72). Utilities continue to be given by (19.73) in the second period also. The aspiration levels in the second period for $i = 1, 2$ are $a_{i2} = a_{i1} + \frac{1}{2}(u_i - a_{i1})$, where a_{i1} is given by (19.75), thus, $a_{i2} = a_{i1}$. Clearly, the mixed strategies in (19.71), (19.72) are played every period from $t = 1$ onwards. Identical results follow in the case where the initial action profile is (D, C) .

3. Suppose that the initial action profile is (D, D) . The first period payoffs are then $(0, 0)$. Since $0 > a_{i0} = -0.1$, both players' aspiration levels are met and they stick to the profile (D, D)

in period 1. One can use this argument repeatedly to show that the action profile (D, D) is followed in every period. The aspiration level improves in every period and converges eventually to zero, from below.

Based on this analysis, the following observations can be made.

The equilibrium of the game is heavily dependent on the initial state of play. Furthermore, the cooperative outcome can be sustained in an equilibrium of the aspirations adaptation game. For the parameter values chosen in the example, this outcome arises if players begin by cooperating in the initial period. Non-cooperation or defection, however, begets further rounds of non-cooperation. Finally, players might coordinate on the defection strategy and never cooperate again.

In a more general model, Cho and Matsui (2005) introduce other extensions. They introduce a small probability of players playing a different action; one interpretation is that players make a mistake with some positive, but small, probability. It turns out that the inefficient coordination outcome (D, D) is not robust to this perturbation and the only equilibrium which survives is the “good” coordination equilibrium.

It should be quite intuitive that this framework can be used to support the cooperative outcome in a range of games (Colman et al., 2010). For instance, in the prisoner’s dilemma game, if aspiration levels are sufficiently high, then the non-cooperative outcome results in payoffs that are lower than the aspiration level. Individuals then experiment with other actions (such as cooperation). If both players happen to cooperate at the same time, then the payoffs exceed the aspiration level, in which case there is no further need to experiment with other actions. These ideas can be formalized in different ways. Börgers and Sarin (2000) and Karandikar et al. (1998) are two such attempts. Both papers contain the idea that aspirations are updated slowly in the direction of the eventual cooperative payoffs. Karandikar et al. (1998), in addition, introduce a small probability of trembles in actions and demonstrate in 2×2 games that most players will cooperate most of the time.

Aspirations in these models are based on plausible adaptive processes. However, ultimately empirical evidence will determine the precise nature of the formation of aspirations, which might well be context and situation dependent. In one interesting experiment, Bernard and Taffesse (2014) randomly selected households in Ethiopia to watch inspirational videos based on the actual life stories of people who had successfully followed goals and achieved a higher socio-economic position. Six months later, these individuals had higher savings rates and higher aspirations, particularly about their childrens’ educational future. It is also well known that poverty depresses aspirations and engenders a feeling of greater hopelessness (Ray, 2006; Haushofer and Fehr, 2014). Similar results are found in richer countries where poorer students have relatively lower aspirations towards education and employment (Guyon and Huillery, 2014).

In the models above, there is a single goal, feedback is perfect, and the underlying economic environment is commonly understood. In actual practice, however, individuals, institutions, and governments, often try to achieve complex long-term goals. For instance, (i) individuals might be interested in long-term happiness, (ii) firms in long-term profits, and (iii) governments in long-term economic prosperity. Yet it might not be clear how to achieve these complex goals. On the other hand, there could be a set of short-term goals that the individual believes are correlated with long-term goals. Corresponding to the three long-term goals mentioned above, examples of relevant short-term goals could be: the individual practices daily meditation, the firm invests in short-term improvements in customer relations, and the government appoints a particularly capable central banker.

Selten et al. (2012) outline a formal model of the decisions taken by a monopolist, which has these features; an approach that they call *goal systems*. In this framework, economic entities face a complex problem whose solution is unlikely to be obtained by purely rational analysis, although a simulated solution is available by using specialized optimization software. Economic entities then choose among a set of goal variables that are essentially short-term feedback variables. For instance, the monopolist chooses short-term quality of the product and advertisement expenditure that contributes towards raising demand for a product in that period. For each goal, they set an aspiration level that they can adapt upwards or downwards. If no upward adjustments in aspiration levels are feasible, then no further attempts at adjusting aspiration levels is made. Their experiments confirm some of the basic predictions of the aspiration adaptation model.

19.14.2 *Fast and frugal heuristics*

Humans do not possess unlimited cognitive abilities, nor do they have unlimited time to solve problems. Thus, as Herbert Simon suggested, modeling *procedural rationality*, i.e., the cognitive process and the decision environment in which decisions are made is important.

Rubinstein (1998) provides several examples of procedural rationality. In chapter 11 of his book, titled *Final Thoughts* he provides a summary of his correspondence with Herbert Simon regarding his book. Simon objects to the lack of empirical support for the rationality procedures introduced by Rubinstein. Simon is quoted as saying “Facts do not come from the armchair, but from careful observation and experimentation” Rubinstein (1998, p. 188). Rubinstein’s own response is detailed in his chapter 11, but the following remark illustrates well his position. “The crowning point of making microeconomic models is the discovery of simple and striking connections between concepts (and assertions) that initially appear remote” (Rubinstein, 1988, p. 191). Clearly, Rubinstein’s approach, while important and timely in terms of its proposed formalism, is not in the same tradition as Herbert Simon’s. Indeed, there is a basic disagreement about the method and purpose of economic models; this book’s view has already been laid out in the introductory chapter.

An approach that is closer to Herbert Simon’s own views can be found in the work of Reinhard Selten and Gerd Gigerenzer and colleagues at the ABC Research Group, based at the Max Planck Institute of Human Development. Central to the work of this group is the intriguing metaphor that humans draw upon an *adaptive toolbox of heuristics*, conditional on the environment that they find themselves in. Two excellent summaries of this approach are Gigerenzer et al. (1999) and Gigerenzer and Selten (2001). This approach differs fundamentally from the heuristics and biases approach of Kahneman and Tversky.

The view taken by Gigerenzer and colleagues is, in many respects, similar to the *Enlightenment view*, associated with the names of Laplace, Boole, and Piaget; see Gigerenzer et al. (1999) for a representative position. In this view, the normative and descriptive models of human inference are the same as the relevant statistical models. So, for instance, in updating probabilities, the expectation is that humans will use the Bayes’ rule.

On the other hand, the work of Kahneman, Tversky, and others (see above) has shown a divorce between the normative view of humans and actual behavior (Kahneman and Tversky, 2000). So, for instance, the behavior of individuals might not conform to the predictions of subjective expected utility theory (SEU), or to the predictions of classical statistics. In his Nobel lecture, Simon (1978, p. 362) is very explicit about the implications: “On the basis of these and other pieces of evidence, the conclusion seems unavoidable that the SEU theory does not provide a good prediction—not even a good approximation—of actual behavior.”

Gigerenzer and colleagues take the position that human heuristics are not a *bad* but a *good*. They argue that these heuristics are the appropriate response by humans, with limited cognition and time, to their environment. This is reflected in the title of one of their books: *Simple Heuristics That Make Us Smart*. They argue that the heuristics used by humans can outperform other statistical approaches to solving problems. Gigerenzer and colleagues also challenge the Kahneman–Tversky inspired biases on several other grounds. For instance, they argue that if the problems are presented to subjects in a natural frequency format (as opposed to probabilities) and in a knowledge domain familiar to them, then the biases are significantly reduced or eliminated. We have already examined the evidence on some of these positions in the sections above; we postpone a further discussion of these issues to Section 19.15.

TWO EXAMPLES OF FAST AND FRUGAL HEURISTICS

We start with two examples that illustrate fast and frugal heuristics. The perceptive reader will note that there is no necessary conflict in the insights from these problems with the Kahneman–Tversky approach, an issue that we return to in Section 19.15.

Example 19.6 (*The problem of catching a ball*): Consider, as in Figure 19.8, the problem of catching a ball in cricket, baseball, or football (by a fielder in the first two cases and by the goalkeeper in the third). Suppose that the origin of the ball is at point A. It travels along the thick parabola and lands at point B. A catcher is stationed at point C. How does he catch the ball? The optimizing, fully rational, approach in economics would suggest the following algorithm.

Use the two-parameter equation of a parabola. Take the point of origin of the ball and the initial velocity as the initial conditions of the problem. In order to determine the two parameters of the parabola, take account of factors such as the wind speed, humidity, and spin on the ball. Also account for the fact that these conditions could create perturbations from the shape of an ideal parabola. Then design a machine (unless one is handy) that takes account of all this information in order to compute point B. Since the shortest distance between two points is a straight line, the prediction of the rational model is that the catcher runs in a straight line from C to B to successfully catch the ball.

Of course, a weaker position, and the one typically taken in neoclassical economics, is that the calculation process need not be taken literally. Individuals are expected to behave “as if” they can perform the appropriate calculations.

In either case, it is very easy to test this prediction. When the runs of successful catchers are observed, it turns out that they do not run in a straight line from C to B (McLeod and Dienes, 1996). Rather, they start running as soon as the ball leaves point A and take the curved, dotted, path shown in Figure 19.8. Hence, the prediction of the standard model is easily rejected in the strict and the weak interpretations.

McLeod et al. (2006, p. 139) describe why catchers behave in this manner: “the path of a fielder running to catch a ball is determined by the attempt to satisfy 2 independent constraints. The 1st is to keep the angle of elevation of gaze to the ball increasing at a decreasing rate. The 2nd is to control the rate of horizontal rotation necessary to maintain fixation on the ball.” The important feature of this heuristic is that it does not use all the available information. Hence, it is frugal in the use of information. Because it uses only two simple constraints, the heuristic is incredibly fast (the catcher starts running immediately).

Example 19.7 (*Dealing with heart attack patients*): Suppose that the emergency unit of a hospital receives a patient with chest pains and a suspected heart attack. How best should

Figure 19.8 The problem of catching a ball.

Figure 19.9 Classifying the degree of risk of suspected heart attack patients.

Source: Peter M. Todd and Gerd Gigerenzer (2000). "Précis of simple heuristics that make us smart." *Behavioral and Brain Sciences* 23: 727–41.

they deal with the patient? One possibility is to measure all the possible indicators of a heart attack. Then use some statistical procedure to aggregate this information into a number; when this number exceeds some critical value it is almost sure to correctly diagnose a heart attack. However, time, information and cognitive abilities are limited.

Breiman et al. (1993) suggest a simple decision tree, which is able to classify patients by the degree of risk that they face; see Figure 19.9. Only three variables are used. If the systolic blood pressure is below 91, the patient is immediately classified as high-risk and no further information is needed. If not, then patients older than 62.5 years and suffering from sinus tachycardia are classified as high risk. Otherwise they are low risk.

The distinguishing feature of this simple decision tree, which really is a heuristic to identify high-risk patients, is that it does not try to use all possible information that could have been used. Furthermore, it is simple in the following two respects. It uses qualitative information with binary answers to decision criteria. So, for instance, the absolute difference in one's actual age from 62.5 years is irrelevant; only the cutoff value of 62.5 years is important. The heuristic does not attempt to combine the three variables into a single index. Hence, this heuristic is also fast and frugal. But does it work? Breiman et al. (1993) show that it is actually more accurate

than some other complex statistical procedures that are currently used. Hence, fast and frugal heuristics are not necessarily inaccurate or inefficient, but they can be in other cases.

The main difference between *satisficing* in the sense of Herbert Simon, and *fast and frugal* heuristics is this: satisficing need not always be a fast and frugal heuristic. Some forms of satisficing might even be computationally challenging, while fast and frugal heuristics never are.

A distinguishing feature of the work on fast and frugal heuristics has been the attempt to (1) pit the predictions of such models against the data, and (2) test the efficiency of such heuristics in comparison with standard statistical procedures. As an illustration of this approach, we first consider some examples from Gigerenzer and Goldstein (1996).

THE RECOGNITION HEURISTIC AND THE TAKE-THE-BEST HEURISTIC

In this section we describe a prominent example of a fast and frugal heuristic. Gigerenzer and Goldstein (1996) ask how individuals might solve the problem of comparing the relative size of different German cities? For instance, which city has a higher population? (a) Hamburg (b) Cologne. They suggest the following procedure that uses limited knowledge and limited cognitive abilities to make a relatively fast decision.²⁰

Consider a *reference class* R of cities; this is just a list of cities. For $a, b \in R$ we ask the individual: which is bigger? In answering this question, individuals tap into some *knowledge base*. Essentially, a knowledge base, C , consists of *probability cues* $C_0, C_1, C_2, \dots, C_n$. We focus, here, on cues that take a binary value. For instance, the cue C_i could be: does the city have a football team? The answer is either yes, no, or don't know; we denote these three cases, respectively, by $+$, $-$, $?$. As an example, suppose that we have four reference cities and five cues, so $R = \{a, b, c, d\}$ and $C = \{C_0, C_1, \dots, C_5\}$. Let the first cue, C_0 , be the *recognition cue*, i.e., does one recognize a city? The individual can either recognize ($+$), not recognize ($-$), or does not know if he can recognize ($?$). The cue values for each of the four cities are shown in Table 19.9.

The table illustrates two features. First, it uses *limited information* (in actual practice many other cues could have been used). Second, it shows *limited knowledge*. This is shown by the large number of $?$ signs, which indicate that the cue value is uninformative. Notice that for city d , the recognition cue indicates that it has never been heard of by the individual. For this reason, for all other possible cues, d takes a value $?$. Let $C_i(x)$ denote the cue value taken by the i th cue when the city is $x \in R = \{a, b, c, d\}$. Let $t(x)$ be the question asked from the individual or the *target variable*; in this case this is the population of city x . Suppose that for any two cities $x, y \in R$ and

Table 19.9 The cue values for each of the four cities.

	a	b	c	d
C_0 (Recognition)	+	+	+	—
C_1	+	—	?	?
C_2	?	+	—	?
C_3	—	+	?	?
C_4	?	—	—	?
C_5	?	?	—	?

²⁰ This draws on earlier work on probabilistic mental models; for instance, Gigerenzer (1993), Gigerenzer et al. (1991).

using cue C_i we get that $C_i(x) = +$ and $C_i(y) = -$. Then we say that cue C_i is able to predict correctly which city has the larger population, i.e.,

$$C_i(x) = +, C_i(y) = - \Rightarrow t(x) > t(y). \quad (19.76)$$

Now suppose that over all $x, y \in R$ we compute the number of cases, N , where (19.76) holds. Let M be the number of cases where it does not hold, i.e., where, for instance, $C_i(x) = C_i(y) = +$ and $C_i(x) = C_i(y) = -$. Ignore the cases where a cue takes a value ? (“don’t know”) because no comparison can be made.

Two features of cues, *ecological validity* and *discrimination rates*, are important. These are defined below.

Definition 19.4 (*Ecological validity*): The ecological validity v_i of cue C_i is the frequency with which it predicts the target from among the choices in the reference set, i.e.,

$$v_i = \frac{N}{N + M}.$$

So, for instance, let R be the set of German cities with a population of at least 100,000. Let cue C_i check if the city has a football team. In 87% of the cases, the city with the football team has greater population. Thus, cue C_i has an ecological validity of 0.87. Applying similar calculations to all cues we can rank the cues in term of their ecological validity.

Ecological validity reflects the phenomenon of limited information but not limited knowledge; it does not take account of the ? values. Now suppose that there are a total of $\bar{N}$ pairs of cities $x, y \in R$ such that x, y are distinct. Also let $\hat{N}$ be the number of cases (among all $x, y \in R$) such that the cue is able to discriminate between two options, i.e., either $C_i(x) = +, C_i(y) = -$ or $C_i(x) = -, C_i(y) = +$.

Definition 19.5 (*Discrimination rates*): The discrimination rate, d_i , associated with some cue C_i is the relative frequency with which a cue discriminates among two objects in the reference class. Hence,

$$d_i = \frac{\hat{N}}{\bar{N}}.$$

As d_i increases, the *inferential usefulness* of the cue, C_i , increases because it is able to distinguish among a larger number of cases.

Reverting back to the data provided in Table 19.9, how will an individual make a choice? One possibility is for individuals to use the take-the-best algorithm. In this algorithm, the cues are ranked in terms of their ecological validity first.²¹ Following the recognition cue, the remaining cues are arranged in the following order. The cue with the highest validity (C_1) at the top (also called the best cue) and the one with the lowest validity (C_5) at the bottom. The basic principle of this algorithm is to take-the-best and “ignore the rest.” The steps followed in the take-the-best algorithm are shown in Figure 19.10.

²¹ Another heuristic, the *minimalist heuristic*, ranks cues in a completely random order.

Figure 19.10 Description of the take-the-best algorithm.

Step I. The first cue that is used is the recognition heuristic. In making a choice among two objects, if one of the objects is recognized and the other is not (+−), then choose the recognized object. If both objects are unrecognized (−−), then guess. If both are recognized (++), then go to step II.

Step II. Use the cue with the highest ecological validity. If this cue discriminates among the two options $x, y \in R$ (i.e., $C_i(x) = +, C_i(y) = -$ or $C_i(x) = -, C_i(y) = +$ or $C_i(x) = +, C_i(y) = ?$ or $C_i(x) = ?, C_i(y) = +$), then choose the option that has a value + for the cue. Otherwise, if the cue is unable to discriminate, examine the cue with the next highest ecological validity and repeat step II.

Step III. If one runs out of cues and none is able to discriminate between the two options, then simply guess.

These steps, the definitions of ecological validity, and Table 19.9 can be used to illustrate several examples.

Example 19.8 Which of the two cities, a, d , has more inhabitants? Using Step I, the recognition cue, city a is recognized while city d is not, hence, the choice is made at the first step of the algorithm: city a is chosen.

Example 19.9 Which of the two cities, a, b , has more inhabitants? Using Step I, the recognition cue is unable to discriminate between the two cities. Using Step II, we now move on to the cue with the next highest validity, i.e., cue C_1 .²² It immediately distinguishes between cities, a, b because $C_1(a) = +, C_1(b) = -$. Hence, city a is chosen.

Example 19.10 Which of the two cities, b, c , has more inhabitants? In Step I, the recognition cue is unable to distinguish between the two (both are recognized). Cue C_1 , with the next highest validity, is also unable to distinguish because the cue value for city c is unknown ($C_1(b) = -, C_1(c) = ?$). The cue with the next highest validity, C_2 , is able to distinguish ($C_2(a) = +, C_2(b) = -$), and on that basis, city b is chosen.

These examples share some common features. First, only a limited part of the total stock of knowledge is searched. Second, the stopping rule is simple: “stop when the first discriminatory

²² Cues C_1, C_2 , and C_3 have identical ecological validity in this example.

cue is found.” Third, no attempt is made to integrate all the available information, using classical statistical procedures. These are all distinguishing features of fast and frugal heuristics. The take-the-best algorithm is sometimes said to be *non-compensatory* because the discriminating cue with the highest validity determines the final choice; no combination of the other cues can overturn this choice.

The take-the-best algorithm has been used successfully in several contexts. These include: the *confidence frequency effect*, the *less is more effect*, and why the confirmation bias explanation of the overconfidence effect may not be supported by the evidence.²³

In order to test the take-the-best algorithm in the context of city size, Gigerenzer and Goldstein (1996) consider 83 German cities with at least 100,000 inhabitants. Population is the target variable; 9 binary ecological cues are used, so there are 9×83 cue values. These cues included the following: Is the city a national capital? Does the city have a football team in the major league? Is the city on the intercity train route? Is the city a state capital? Is the city home to a university? Is the city in the industrial belt? The ecological validity of the cues is decreasing in the order written above.

The point of the exercise is to compare the take-the-best heuristic with some other statistical procedures, all of which use more information, more time, and more computation power. The statistical procedures used include tallying, weighted tallying,²⁴ unit weight linear model, weighted linear model,²⁵ and multiple regression. The alternatives against which these heuristics are compared are chosen by the experimenter. There need not be universal agreement that these

²³ For the *confidence frequency effect*, see Gigerenzer et al. (1991); the original take-the-best algorithm is also presented in this paper. For the *confirmation bias explanation of the overconfidence effect*, see Gigerenzer et al. (1991).

²⁴ Under tallying, first arrange the cues in decreasing order of validity. The recognition cue is not used. The idea is to take account of the (positive) weight of the evidence for a decision. So, for instance, in comparing cities a , b , tally the positive cue values for each city across all cues. Then choose the city with the largest number of positive cue values. Thus, city a is chosen over city b if

$$\sum_{i=1}^n \phi_i(a) > \sum_{i=1}^n \phi_i(b).$$

where for any city $x \in R$,

$$\phi_i(x) = \begin{cases} 1 & \text{if } C_i(x) = + \\ 0 & \text{if } C_i(x) = - \\ 0 & \text{if } C_i(x) = ? \end{cases}$$

In the event that both numbers are the same, one simply guesses.

²⁵ In the weighted linear model, city a is chosen over city b if

$$\sum_{i=1}^n v_i \phi_i(a) > \sum_{i=1}^n v_i \phi_i(b),$$

where v_i is ecological validity, and for any city $x \in R$,

$$\phi_i(x) = \begin{cases} 1 & \text{if } C_i(x) = + \\ -1 & \text{if } C_i(x) = - \\ 0 & \text{if } C_i(x) = ? \end{cases}$$

In the event that both numbers are the same, one simply guesses.

are the best possible alternatives. This is an important drawback in the claimed superiority of fast and frugal heuristics over other possible solutions.

The main empirical results in Gigerenzer and Goldstein (1996) are as follows. Suppose that 100% of the cue values are known. In this case, the take-the-best algorithm generated as many correct inferences as any of the alternative algorithms under consideration. Now suppose that we consider the following percentages of known cue values: 10, 20, 50, 75, 100, and take the average number of correct inferences across all of them. Again, the take-the-best algorithm performs as well as any of the alternative algorithms used. This result is strengthened if we note that these figures ignore the costs of using the alternative algorithms. These costs include the relatively greater costs of acquiring and using additional information, and the greater computational time required relative to the fast and frugal take-the-best algorithm.

If only the recognition heuristic is used (i.e., choose the recognized object over an unrecognized object), then the accuracy across all pairs of choices is 65%, which is significantly above purely random choice. Finally, the authors find an intriguing *more is less effect*. Giving the decision maker more information (i.e., increasing the proportion of recognized objects) beyond some intermediate level reduces the accuracy of decision making.

Oppenheimer (2003) offers one criticism of the use of the recognition heuristic in the context of judging city size. He notes a problem with the original studies; they appeared to have conflated the size of the city with its recognition. For instance, Berlin is recognized and known to be large. The recognition heuristic predicts that in a comparison of the city size in which one city is recognized and known to be a small one, and the other city is unrecognized, the former should be chosen. By introducing names of fictitious cities so that many would not be recognized, Oppenheimer (2003) finds the opposite result: Namely, that the unrecognized cities are chosen over “recognized and known to be small cities”. This suggests a more careful consideration of the robustness of the method and the claims.

The work of Gigerenzer and Goldstein (1996) is related to the work of Payne et al. (1993) who tested the performance of several heuristics in a choice between various risky gambles. They mainly looked at the following two one-decision heuristics that are very similar to the take-the-best heuristic. (1) The LEX heuristic in which cue order is determined not necessarily by ecological validity, unlike in the take-the-best heuristic, but by some measure of importance. (2) The LEXSEMI heuristic, similar to LEX except that the difference between cue values must exceed a certain threshold for a cue to be able to discriminate.

They found that different heuristics performed best in different environments, hence, the use of heuristics is strongly dependent on the environment, as Herbert Simon had proposed. Both LEX and LEXSEMI performed quite well in comparison with the weighted additive model (similar to the weighted linear model described above). Under severe time pressure, the LEX normally outperformed the others because it requires fewer computational steps.

The explanation of advertising has puzzled economists for a long time; none of the existing explanations in neoclassical economics is completely persuasive. However, the recognition heuristic might provide one important clue to an explanation. If consumers use the recognition heuristic in choosing among alternative products, then it is worthwhile for companies to spend significant sums of money on, often uninformative, but recognition-enhancing, advertising. The high-profile publicity campaigns of politicians, cities, or travel destinations can perhaps also be explained in a similar manner.

Gigerenzer and Goldstein (1996) take the cues as given; indeed these are often experimenter provided. In many contexts, the cues must be found in the first place. How do individuals search

for cues. One possibility is that individuals use fast and frugal heuristics to undertake the search in the first instance; see Todd (2001) for examples.²⁶

In another intriguing study in the context of stock markets, Borges et al. (1999) pit the simple recognition heuristic against highly trained fund managers. Over the period 1996–1997, individuals were asked to invest in a variety of American and German stocks by using only the recognition heuristic. Namely, between two stocks, if one is recognized and the other is not, then choose the recognized stock; two of the four authors used their own money to fund this stock market experiment. In competition with the recognition heuristic were pitted several classical benchmarks for stock market selection such as mutual funds, market indices, and chance (or dartboard portfolios).

The authors found that the average level of stock market return on a randomly chosen portfolio was consistently below the return arising from the use of the recognition heuristic. Portfolios of highly recognized stocks outperformed those that were unrecognized. The performance of the recognition heuristic was also better (in six out of eight tests) relative to two major managed funds, the American Fidelity Blue Chip Growth Fund and the German Hypobank Investment Capital Fund. This is suggestive of a relationship between recognition, market share, and profitability of companies; Borges et al. (1999) also review some empirical evidence in this regard. These interesting results are only suggestive, and further empirical evidence is required. For instance, the results were obtained in a strong bull market and the time horizon for the performance of the stocks was only one year. These design features need to be relaxed in future work, certainly in a manner that most experimental economists will find persuasive.

Czerlinski et al. (1999) examine the performance of the take-the-best heuristic and the *minimalist heuristic* against statistical benchmarks such as the linear regression model. The minimalist heuristic is identical to the take-the-best heuristic except that at the first stage, the cues are not arranged in any particular order (such as ecological validity) but chosen randomly. They consider 20 different environments. One of these environments is the relative population sizes of two cities in a binary comparison (this is as in Gigerenzer and Goldstein, 1996). However, other environments include (all using US data): high school dropout rates, rate of homelessness, mortality rate, house prices, rents, and obesity.

In each of these environments, individuals are given sensible cues. For instance, when individuals were asked to predict the high school dropout rates in 57 Chicago public high schools, they were given the following cues: percentage of low-income students, percentage of nonwhite students, and average SAT scores. Take-the-best often outperformed multiple regression while employing only a third of the cues used by multiple regression. Even the minimalist heuristic came close to the accuracy of the multiple regression model. The relatively good performance of these simple heuristics seems to be the result of the excellent correlation of the cues with the target variable. However, the cues are experimenter determined and provided, which compromises the bite in the results.

Heuristics often appear to outperform multiple regression in a variety of contexts, and in particular, when one looks at out-of-sample prediction (Gigerenzer et al., 1999). The intuition is that multiple regression, while taking into account the salient features of the problem, also fits the noise in the sample. Consider an extreme case in which, outside the sample, such noise is absent or the nature of such noise is very different. Then there might be large prediction errors when an

²⁶ The example of a new colleague who joined our university from the US is instructive. He was interested in a broadband, TV, and telephone connection. He asked a few selected colleagues what they had chosen; the answers allowed him to immediately narrow down his search process quite substantially.

attempt is made to fit the multiple regression to out-of-sample points. On the other hand, simple heuristics do not respond to noise. By relying on the salient, they might be able to predict better outside the sample. However, this could also work to the detriment of the heuristics when there is no noise in the sample but much greater noise out of the sample.

In his “Mais lecture,” Mervyn King (2005), the then Governor of the Bank of England, makes a case for using fast and frugal rules in central banking. His argument is that fully optimizing rules are too complex to fit in with the evidence on limited human cognition. Furthermore, as the state of the economy and the state of knowledge in economics changes, often at a rapid rate, problems of limited cognition and limited time become even more severe. Hence, an appropriate response is for both actors, the central bank and individual forecasters in the economy, to employ useful heuristics.

The central bank could adopt the following heuristic, depending on the environment. In normal times, set interest rates such that the expected inflation in two years time is equal to an inflation target. However, when the economy has been hit with a large shock, then the heuristic is to bring inflation back to target over a longer period. Hence, in this approach, the inflation target provides a nominal anchor around which the understanding of such a heuristic might become common knowledge. King also suggests heuristics that might be ideal (from the central bank’s point of view) for the individual forecasters to use. The ideal heuristic is for individuals to expect inflation to equal its target. An example of a bad heuristic is that if inflation is different from the target, then it is expected to drift further away. These heuristics are fast and frugal, and expected to be relatively conducive to economic stability.

There is also a literature on using heuristics to make choices among objects with multiple attributes (Payne et al., 1993). Payne and Bettman (2001) consider the problem of choosing among several brands of cars with different attributes (e.g., reliability, price, safety, horsepower). A key part of the problem is that there is conflict among the various attributes, so none of the cars dominates the others on all attributes. Furthermore, decision makers could have several goals such as maximizing accuracy, ease of justification of the decision to others, minimizing cognitive effort, and negative decision-related emotions. Furthermore, decision makers seem to use different goals in different settings, and at different times. How should a decision maker choose?

Several strategies are considered in the heuristics literature. One possibility is the *weighted adding strategy* (WADD) in which the score of each car is added over all attributes using some subjective weights (Edwards and Tversky, 1967). Another heuristic that is computationally simpler is the *equal weighting strategy* (EQW) that assigns unit weights to all attributes. The LEX strategy (see above) simply chooses the most important attribute, say, reliability, and then chooses the car with the highest value on this attribute.

Simon’s (1955) *satisficing strategy* (SAT) can also be used to make a choice in this case. Start with a base vector of attribute values that summarizes the aspiration levels for each attribute. Then pick the first car that does better than the base vector on all attributes. The *elimination by aspects* (EBA) strategy combines the LEX and SAT strategies. In this case, first choose the most important attribute and set an aspiration level for it. Then eliminate all cars that fall below this attribute value. Repeat this step for the next most important attribute, and so on, until a unique choice remains; if the choice is not unique, then some tie breaking rule is used (Tversky, 1972).

Payne and Bettman (2001) find that the heuristic which performs best is heavily contingent on the environment. The WADD strategy is the most robust in terms of accuracy across the various environments. But there are environments where the LEX achieves about 90% of the accuracy of the WADD with only about 40% of the effort. For more examples of fast and frugal heuristics and their performance, relative to statistical benchmarks, see Gigerenzer and Gaissmaier (2011).

We now offer a critical assessment of this approach.

1. The evidence provided by Gigerenzer and colleagues does not establish the conditions under which the heuristics proposed, such as take-the-best algorithm, will outperform the relevant statistical procedures or optimization approaches. They argue that the heuristics used by humans can outperform other statistical approaches to solving problems. This may often occur when the optimal benchmark is unclear. No heuristic can outperform an optimal solution when the optimal solution is unambiguously known. For instance, when the demand and cost curves are known, no heuristic can do better than the optimal solution: marginal revenues equal marginal costs. However, things are less clear if these curves are unknown or when one is interested in predicting stock market prices; in these cases the optimal solution with which to compare a heuristic is unclear. Furthermore, these results neither include the costs of finding the cues or the additional costs of information collecting, integrating, and computing associated with statistical procedures that are not fast and frugal; the latter issue is often considered in the theoretical computer science literature (Martignon, 2001).
2. In most studies of fast and frugal heuristics, the heuristics are proposed by the researchers or experimenters themselves. However, it needs to be established if individuals actually use these heuristics in actual practice. Some progress was made in this direction by Goldstein and Gigerenzer (1999). They gave individuals additional information that contradicted the decision that would have been made on the grounds of the recognition heuristic. They found that, nevertheless, 92% of the choices made by the participants still agreed with the recognition heuristic. It remains an open question whether individuals do follow the other fast and frugal heuristics considered above. In contrast to this, the thrust of the Kahneman–Tversky approach was to discover the “actual” heuristics that people follow.
3. How do individuals decide on the cues in a particular environment? One possibility is that the cues are searched using some simple heuristics. Perhaps we engage in simple learning that associates past cues with the outcomes. This is the basis of models of reinforcement learning that we consider in Part 5 (Erev and Roth, 2001). But it is also possible that we have, over the course of human evolution, acquired the ability to generate simple cues and heuristics. The problem of catching a ball (see Example 19.6) is a nice example of this phenomenon. However, it is less clear how these insights can be used to solve economic problems such as the design of contracts, choice of pension plans, choice of a mortgage, and choice of a monetary policy, for which evolutionary experience may provide only limited help. It is not immediately clear which fast and frugal heuristics to use in these cases. Unless these issues are directly addressed, they will limit the scope, and practical usefulness, of this work for economists.

19.15 The great rationality debate

One objection raised by some critics of Kahneman and Tversky’s heuristics and biases program (henceforth, KT) is that it overly focuses on human biases and paints a pessimistic picture of human inference and prediction. By contrast, it is argued, the main thrust of the approach by Gerd Gigerenzer and colleagues (henceforth, G&C) is more positive because it shows that heuristics outperform more sophisticated forms of statistical reasoning. Kahneman and Tversky’s approach came under great criticism only a few years after publication; see, Cohen (1981),

Einhorn and Hogarth (1981), Lopes (1991), Gigerenzer (1991, 1993, 1994), and Gigerenzer and Hoffrage (1995).

This debate between KT and G&C has come to be known in academic circles in psychology as the *Great Rationality Debate*; for surveys, see Stanovich and West (2000) and Stanovich (2012). Within psychology, the debate has been extremely acrimonious. Consider the following list of comments by psychologists on Kahneman and Tversky's work, taken from Stanovich and West (2000, p. 649):

Many critics have insisted that in fact it is Kahneman and Tversky, not their subjects, who have failed to grasp the logic of the problem (Margolis 1987, p. 158).

If a "fallacy" is involved, it is probably more attributable to the researchers than to the subjects (Messer and Griggs 1993, p. 195).

When ordinary people reject the answers given by normative theories, they may do so out of ignorance and lack of expertise, or they may be signaling the fact that the normative theory is inadequate (Lopes 1981, p. 344).

In the examples of alleged base rate fallacy considered by Kahneman and Tversky, they, and not their experimental subjects, commit the fallacies (Levi 1983, p. 502).

What Wason and his successors judged to be the wrong response is in fact correct (Wetherick 1993, p. 107).

Perhaps the only people who suffer any illusion in relation to cognitive illusions are cognitive psychologists (Ayton and Hardman (1997, p. 45).

These comments are sharp, some even vituperative. The discussion in Stanovich and West (2000) and the commentary following their excellent article illustrates just how muddled the debate really is. Part of the deadlock on these issues in psychology arises from disagreement over (1) the precise transmission channels in the brain through which judgment heuristics manifest (e.g., whether it is dual process theories or something else?), (2) the normatively correct model (as opposed to the rational benchmark in economics). These issues are not critical in economics so we omit them; interested readers can consult Stanovich and West (2000) and Stanovich (2012). Instead, we consider the remaining sources of disagreement below.

KT and G&C address very different questions. KT ask if people behave in the manner prescribed by the rational benchmark in economics. The rational benchmark implies compliance with subjective expected utility theory, and the classical rules of statistics and probability theory. The main finding in KT, that we extensively review in this chapter, is that a significant percentage of people do not act in a manner that is consistent with the rational benchmark.

G&C ask if there exist fast and frugal heuristics that still do better than "some statistical benchmarks" that rely on much greater information and computational requirements? They find the answer in the affirmative. However, typically little evidence is provided in this literature that people do indeed employ the experimenter-provided fast and frugal heuristic in real life. It is also not always clear what the proper statistical benchmark is against which a particular fast and frugal heuristic is compared.

Consider, for instance, the work that pits the recognition heuristic against several statistical benchmarks (see above) to determine which method earns greater stock market profits (Borges et al., 1999). Given that the efficient markets hypothesis is often rejected, the relevant benchmark that best predicts actual stock market prices is not clear. Indeed, economists and financial firms will not necessarily agree with the benchmarks employed in this literature. Hence, declaring victory for the recognition heuristic in this context may be premature. The only sensible inference that can be drawn is that for the set of benchmarks chosen by the experimenter and for

the chosen year and stock portfolio, the recognition heuristic did better. On the other hand, the full-optimization statistical benchmarks, even if they are known to exist, are likely to be computationally complex and informationally demanding. This is not a problem for financial firms who possess the computational firepower. However, for individual stock market participants with limited cognition and resources, the G&C approach poses appropriate questions, hence, imparting great usefulness to the approach.

Given the very different nature of the core issues dealt with in the KT and G&C frameworks, it is staggering that so many of the leading researchers could take such strong positions and fish in very muddy waters. Indeed, it is very likely that both KT and a less rhetorical G&C view of the world are, in fact, correct. The following two quotes from Kahneman (2000, p. 682) show just how close the two sides in the debate really are: (1) “Contrary to a common perception, researchers working in the heuristics and biases (HB) mode are less interested in demonstrating human irrationality than in understanding the psychology of intuitive judgment and choice.” (2) “All heuristics make us smart, more often than not ...”

There are, however, other, non-core issues that have to do with the nature of the evidence, where a debate is possible. A good source for this debate is Kahneman and Tversky (1996) and Gigerenzer (1996a). Some of the arguments against KT can be dismissed easily.

1. It has been argued that experimental evidence involving probabilities based on *singular events* is suspect because the frequentist approach requires a large number of repetitions (Gigerenzer et al., 1989). For instance, whether Linda is a bank teller or a feminist is a singular event. Whether a particular candidate will win the next Presidential elections in the US is also a single event. In this case, strictly speaking, one can speak only about subjective probabilities in a Bayesian sense (Gigerenzer et al., 1989). The argument is made that since only subjective probabilities are involved, any subjective probability will do, so the experimental results are uninformative about the violation of a rationality-based model. Kahneman and Tversky (1996) note that this issue only applies to 2 out of the 12 biases that they highlight. Furthermore, the responses show systematic biases in one direction, which weakens the case for arbitrary subjective probabilities.
2. It has been alleged that KT ignore the context, content, and framing effects in their demonstration of biases (Gigerenzer et al., 1988; Gigerenzer, 1993). However, this appears to be a misperception. Kahneman and Tversky (1996, p. 583) write: “the assumption that heuristics are independent of content, task and representation is alien to our position, as is the idea that different representations of a problem will be approached in the same way.” Consider, for instance, the distinction between causal and non-causal base rates and their effect on the violations of base rate (see Section 19.7.1) that is explicitly recognized in Tversky and Kahneman (1980).
3. The argument has been made that subjects may simply be making errors, could be inattentive, or may be suffering from temporary lapses of judgment. Some of the suggestions that have been made to cast doubt on the KT program include temporary insanity of the subjects, difficult childhood of the subjects, and entrapment by the experimenter (Kahneman, 1981, p. 340). The pattern of biases discovered by KT does not describe random mistakes, but systematic mistakes, hence, these objections cannot be taken seriously. Furthermore, there is typically a great deal of heterogeneity among subjects who exhibit biases, which contradicts conformity with a single rational response. A more detailed discussion can be found in Stanovich and West (2000).
4. A popular criticism that Gilovich et al. (2002) describe as the “*we cannot be that dumb critique*” argues that stellar human achievements, e.g., discovering the structure of DNA

and space flights, are not consistent with the idea that we might be using simple judgement heuristics. This critique arises from a confusion about the nature and process of scientific discoveries. First, scientists might well be using simple heuristics to build initial intuition about their problems. Second, scientific progress is not judged against the standards of individual human judgment heuristics. Rather, it is delegated to an established scientific process that prescribes stringent empirical testing of theories. Hence, there is no essential contradiction between scientific progress and the use of judgment heuristics.

We now consider other criticisms of KT that require either a more detailed or subtle answer.

1. *Frequency versus probability format*: A prominent claim is that the biases identified by KT are eliminated to a large extent when data is presented in frequency format rather than probability format (Gigerenzer et al., 1988, Gigerenzer, 1991, 1994, 1996b). However, the distinction between the frequency and probability formats was first noted by Tversky and Kahneman (1983) themselves in the context of the conjunction fallacy. They found that the frequency format leads to very few conjunction errors; see Section 19.3. However, the conjunction bias is found to be sufficiently high in a between-subjects treatment, relative to a within-subjects treatment, even when data is presented in frequency format (Kahneman and Tversky, 1996).

The anchoring heuristic was also tested by KT in a frequency format; see, e.g., the example on the number of African countries in the United Nations due to Tversky and Kahneman (1973, 1974) in Section 19.6. Indeed, strong evidence of anchoring was found despite the data being presented in terms of natural frequencies.

In the context of base rate neglect, Table 19.4 in Section 19.7.1 shows that while the frequency format reduces base rate neglect, on average about 60% of the subjects in a cross section of studies nevertheless exhibit base rate neglect. Evans et al. (2000) report that the frequency format has been found, depending on the experiments, to worsen, improve, or leave unchanged, the quality of the judgments made.

Thus, the weight of the evidence shows that while the frequency format improves compliance with the rules of classical statistics in some problems (e.g., in the conjunction rule), high non-compliance remains for most problems. Although humans might have evolved to cope better with natural frequencies, casual empiricism suggests that crucial real-world economic data is presented in percentage terms. For instance, interest rates on mortgage borrowing are quoted in percentage terms; the forecasts of inflation and unemployment by central banks are typically made in percentage terms; various insurable risks are often presented to potential insurees in percentage terms; grade information on open days in educational institutions is often given out in percentage terms; and league tables are typically based on inputs that are stated in percentage terms. Thus, it is important to study human judgment and perception in probability tasks.

2. *Formal definitions and statements of heuristics*: Another criticism of KT is that because the heuristics are not stated formally, it is not clear what constitutes a refutation (Gigerenzer, 1991, 1996a; Gigerenzer and Gaissmaier, 2011). For instance, talking of representativeness and availability, Gigerenzer (1991, p. 102) writes that these are: “largely undefined concepts and can be post hoc used to explain almost everything.” Kahneman and Tversky’s (1996) response is that since representativeness can be elicited experimentally (see Section 19.2.1) there is no need to define it a priori.

However, an even better response is that we now have several models that formally define the exact bias in question and derive the formal implications. We have considered several

models in this growing class of models, above. These include: Rabin's (2002) model of inference by believers in the law of small numbers and Rabin and Vayanos's (2010) model of gambler's and hot-hands fallacies (see Section 19.2.3); the model by Biais and Weber (2009) on hindsight bias (see Section 19.8); and the model of Rabin and Schrag (1999) on confirmation bias (see Section 19.9). To this list must be added models of shrouded attributes and limited attention that consider explicit formalizations; see Sections 19.16, 19.17. We anticipate further progress in this direction.

3. *Narrow norms:* Gigerenzer (1996a) questions the appropriate statistical norms that apply to the problems in the experiments in KT; see also Koehler (1996). His argument is that the underlying model is not fully specified, which leaves the appropriate statistical prediction unclear. He writes (p. 592): "A convenient statistical principle, such as the conjunction rule or Bayes' rule, is chosen as normative, and some real-world content is filled in afterward, on the assumption that only structure matters. The content of the problem is not analyzed in building a normative model, nor are the specific assumptions people make about the situation."

This statement should surprise most economists. The analogy in economics is the following. Either one can test the axioms of expected utility theory, e.g., the independence axiom, separately and without reference to an economic model; this often takes the form of observing choice in pairwise lotteries. Or, one can test the predictions of a model that has at its core, the model of expected utility. The first option is scientifically equivalent to the second option because the axioms of rationality are necessary and sufficient for an expected utility representation of preferences. However, the first option is the easier of the two because contrary evidence achieved in the second option is a joint rejection of expected utility and other auxiliary assumptions in the model. Indeed the first option has been massively employed in the testing of expected utility in economics. The airframe of a proposed new airplane might be tested in a wind tunnel, without adding-on all the other components in the airplane. This is a scientific, acceptable and sensible procedure.

Thus, Gigerenzer, in this case, criticizes an appealing feature of the KT tests, i.e., clean unambiguous predictions. Most reasonable economists would be comfortable with the predictions ascribed to the relevant statistical models in the KT tests; although they might contest issues of experimental design such as the appropriateness of subject pools and the appropriate incentivization of the subjects.

The conclusion reached by Kahneman and Tversky (1996, p. 584) is blunt: "The position described by Gigerenzer is indeed easy to refute but it bears little resemblance to ours. It is useful to remember that the refutation of a caricature can be no more than a caricature of a refutation." However, on another count, G&C need to be commended for asking fundamentally important questions about the usefulness of heuristics and making important headway in this direction. KT are likely to agree with this position, although they would be dismayed at how muddled and contentious the debate between the two sides has become.

Both sides also advocate and vigorously debate models of the brain that may lead to biases relative to statistical benchmarks. Kahneman (2011) devotes the first one-third of his book to developing such models of the brain, in this case a model of Systems 1 and 2, that facilitates a deeper understanding of the biases.²⁷ For instance, the quick, reactive, and automatic System 1 is responsible for most errors. System 2 has been likened to a *lazy controller* in Kahneman (2011)

²⁷ However, there is no universal agreement among psychologists about the appropriate models of the brain in this context (Stanovich and West, 2000).

and when it is called upon to intervene in an unusual situation, the agenda (e.g., affective emotions, recalled memory, associations) is chosen by System 1. On p. 21 he writes: “Although System 2 believes itself to be where the action is, the automatic System 1 is the hero of the book.” System 1 tries to make sense of a situation even when the events may have been generated purely randomly. As Stanovich (1999) points out, System 1 has a tendency toward automatic contextualization of problems. This gives rise, for instance, to the law of small numbers, the gambler’s and hot hands fallacies, and overconfidence in the ability to explain the future from a hindsight-biased explanation of past events that were purely random.

There should be no presumption that evolution must have favored rationality, as defined in neoclassical economics. Natural selection chooses among a population phenotype and a mutant phenotype, on the basis of which of the two adapts better to the environment. Indeed traits like loss aversion, prosociality, hyperbolic discounting, and level- k reasoning might be favored in this selection process. There is no presumption that evolutionary mechanisms impart greater rationality to individuals, understood as subjective expected utility maximization, or conformity with the rules of probability theory (Stanovich, 2012).

19.16 Shrouded attributes

Attributes are *shrouded* when some characteristics of the goods that consumers buy are not directly observable. These hidden attributes can typically be discovered by the consumers at some cost, which can be a monetary cost or a purely cognitive search cost. For instance, while opening a bank account, an individual might not know the minimum balance fees or bank surcharges on using its cash machines, or bounced check fees. Neither does the bank make an attempt to easily provide this information, even on its website, although it is tucked somewhere in the fine print, or in some unexpected corner of the website. Manufacturers of printers shroud information on the costs of their patented ink cartridges that can, over the printer’s lifetime, cost several times as much as the cost of the printer.

In classical theory, the costs of *unshrouding* the shrouded attributes are either considered so small that all attributes are assumed to be visible to the consumer, or competition among firms leads to the unshrouding of attributes. Consumers who are rational will believe that shrouded attributes signal bad news and attempt to find other sellers. In response, firms will have an incentive to unshroud information (Jovanovic, 1982; Milgrom, 1981).

19.16.1 *Empirical evidence*

In actual practice, one observes that individual decisions are often visibly influenced by shrouded attributes, even when the cost of unshrouding them appears to be quite small. Consider, for instance, two state taxes on alcohol in the US. The *excise tax* is included in the price of alcohol, while the *sales tax* is not included in the tagged price but it is added at the point of purchase. In classical theory, both taxes should have identical effects on the demand for alcohol. However, the sales tax is shrouded, while the excise tax is unshrouded. Figure 19.11 shows that the elasticity of demand of alcohol with respect to the two taxes is very different. Indeed, as the reader might expect, demand is relatively less responsive to changes in the shrouded tax, relative to the more visible tax.

Consider another example. Hossain and Morgan (2006) conduct a field experiment on eBay auctions in the US in which they put CDs and Xbox games up for sale for different levels of

Figure 19.11 Variations in demand due to a visible excise tax (left panel) and a shrouded sales tax (right panel).

Source: Chetty et al. (2009) with permission from the American Economic Association.

shipping charges and initial bids. The expectation is that shipping charges are shrouded attributes. eBay auctions are an example of ascending bid English auctions and standard auction theory predicts an efficient outcome. Suppose that a bidder has a maximum willingness to pay of $\$x$ for an item. If shipping and handling were free, the bidder should be willing to pay up to $\$x$. Suppose that the minimum opening bid is $\$m$, and shipping and handling costs are $\$s$, and $x \geq m + s$, where $m + s$ is known as the *effective reserve price*. Then, the bidder would be willing to bid $\$b \geq \$m$ for the object, up to $b + s = x$. In particular, so long as these inequalities hold, the buyer should be willing to part with a total of $\$x$ for the object, even as m and s vary.

Two treatments were run. In one treatment, the effective reserve price, $m + s$, was low, and in another it was high, but in each case, $x \geq m + s$. In each treatment, different levels of m and s , keeping fixed $m + s$, were tried out. The predicted revenues of the seller are identical. In contrast to the predicted results, the main empirical finding is that in both treatments, low m and high s led to more bidders, earlier bidding, and higher revenues for both CDs and Xbox games. Thus, it appears that an increase in shipping and handling charges, keeping the effective reserve price constant, increases bidding and seller revenues. This is consistent with the view that many buyers treat shipping and handling charges as shrouded attributes. These results are not unique to eBay auctions in the US and have been replicated in leading online auction platforms in Taiwan and Ireland (Brown et al., 2010).

19.16.2 A theoretical framework

Gabaix and Laibson (2006) develop a general framework to model market competition when some attributes of a good may be shrouded. We have noted above that in the neoclassical case with rational consumers, no shrouding is predicted to take place in equilibrium. However, when not all consumers are rational in the neoclassical sense, we show that shrouding of attributes can take place in equilibrium. Furthermore, firms do not have an incentive, in equilibrium, to educate consumers about the shrouding practices of their rivals.

Consider the following example that nicely illustrates these claims. Suppose that there are two components of the price of a hotel room. The room price or the base price, p_b , and the price of add-ons, p_a , such as costs of parking, telephones, internet connections, and room service. The total price paid by the consumer is $p = p_b + p_a$. The hotel does not keep p_a secret from the public, but makes it sufficiently inaccessible that one needs to expend non-trivial search costs to find it.

The hotel sector is assumed to be perfectly competitive. Suppose that a fraction $\alpha \in [0, 1]$ of the customers is *myopic* (myopes) and the remaining fraction $1 - \alpha$ is *sophisticated*. Myopic consumers cannot observe shrouded information.²⁸ However, myopes exhibit heterogeneity in the presence of unshrouded information. Under unshrouded information, a fraction $\lambda \in (0, 1]$ of the myopes observes the information (informed myopes) and the remaining fraction $1 - \lambda$ (uninformed myopes) pays no attention to unshrouded information about add-ons. Sophisticates comprise a fraction $1 - \alpha$ of the consumers and take account of add-ons when they are unshrouded.

Suppose that one of the hotels is the Hilton and it costs \$100 for the hotel to supply the room. Assume that add-ons have zero costs to the Hilton but consumers typically spend \$20 worth of add-ons when they have to pay for them. In competitive markets, the Hilton will set $p_b = 80$ and $p_a = 20$ and make no profits. Thus, add-ons have the advantage that they subsidize the base price. Consider a competitor hotel, called the Transparent, that supplies free add-ons and also advertises/educates consumers about the add-on prices at its competitors. We assume throughout that education of consumers is costless to the firm. Since the Transparent operates in competitive markets, it must set $p_b = 100$ and $p_a = 0$, thus, the add-ons price cannot subsidize the base price. Let us consider the behavior of each kind of consumer.

1. Uninformed myopes: These consumers find the Hilton base price cheaper. Since they ignore the price of add-ons, they choose the Hilton.
2. Informed myopes and Sophisticates: These consumers benefit from the information that is provided by the Transparent. So they realize that they will spend an amount \$20 on add-ons at the Hilton. They might be able to arrange for these add-ons from the outside. For instance, take a taxi to the hotel to avoid paying parking and take a cell phone to avoid hotel call charges. Suppose that this substitution effort costs them $e = \$10$. These consumers will find it profitable to book a room at the Hilton and pay the base price of \$80 plus the substitution effort cost of \$10 for a total of \$90. This works out cheaper than the price of \$100 for booking a room in the Transparent hotel.

Thus, in equilibrium, the Transparent does not benefit from its policy of advertising about add-ons. By contrast, if the Transparent shrouds add-ons, uninformed and informed myopes may book rooms with it. Unlike the classical framework with purely rational consumers, the presence of myopic consumers allows some attributes to be shrouded in equilibrium.

Consider a formal version of the two-period problem given above in which competitive hotels are indexed, $i = 1, 2, \dots$

In period 1, hotel i offers a base good at a price p_b^i and the price of add-ons is denoted by p_a^i . Myopes comprise a fraction α of consumers, and a fraction λ of myopes are *informed myopes* who take account of add-ons if unshrouded. Unshrouding is costless to the firm and takes the

²⁸ One possibility is that myopic consumers simply do not pay enough attention. Empirical evidence is suggestive of the importance of consumers who exhibit limited attention; see, for instance, DellaVigna and Pollet (2009), Cohen and Frazzini (2008), Hirshleifer et al. (2009), Gilbert et al. (2012).

form of educating consumers about the add-ons. Sophisticates who comprise a fraction $1 - \alpha$ take account of add-ons when unshrouded.

Informed myopes and sophisticates form Bayesian posteriors, Ep_a^i , of add-ons. When add-ons are unshrouded, informed myopes and sophisticates can take account of add-ons, either by (i) choosing a firm that offers cheaper add-ons, or (ii) substitute away from the add-ons at a substitution cost $e : 0 < e < \bar{p}$; $\bar{p}$ can be thought of as the maximum price for add-ons that is allowed by government regulation. Informed myopes, like sophisticates, exert substitution effort only if $e < Ep_a$.

We only consider a symmetric price equilibrium. Denote by v_i , the surplus that a consumer gets by booking at hotel i , net of the opportunity cost of booking at the next best hotel. Variables corresponding to the next best alternative are starred. Thus, for informed myopes and sophisticates, the surplus is²⁹

$$v_i = (-p_b^i - \min\{e, Ep_a^i\}) - (-p_b^* - \min\{e, Ep_a^*\}). \quad (19.77)$$

By contrast, uninformed myopes do not take account of add-ons, so they never exert any substitution effort. Thus, their surplus is given by

$$v_i = (-p_b^i) - (-p_b^*) = p_b^* - p_b^i. \quad (19.78)$$

Let $x(v_i) \in [0, 1]$ denote the probability that a consumer books a room in hotel i ; it captures the demand by the consumer. We assume that $x'(v_i) > 0$, so if a hotel offers better value it is more likely to be chosen.

In period 2, consumers who have booked hotel i can purchase add-ons at a price p_a^i . If consumers have engaged in substitution efforts, then they do not purchase add-ons. We now state the main result.

Proposition 19.5 *Consider a symmetric equilibrium in which the belief of sophisticates and the informed myopes is that if hotel i shrouds add-ons, then $p_a^i = \bar{p}$.*

- (i) *Shrouded prices equilibrium: If $\alpha > \frac{e}{\bar{p}}$, then the price of the base good and the price of add-ons are given, respectively, by*

$$p_b^i = -\alpha\bar{p} + \frac{x(0)}{x'(0)} \text{ and } p_a^i = \bar{p}; i = 1, 2, \dots \quad (19.79)$$

In this equilibrium, only the myopes purchase add-ons.

- (ii) *Unshrouded prices equilibrium: If $\alpha < \frac{e}{\bar{p}}$, then the price of the base good and price of add-ons are given, respectively, by*

$$p_b^i = -e + \frac{x(0)}{x'(0)} \text{ and } p_a^i = e; i = 1, 2, \dots \quad (19.80)$$

All consumers purchase the add-ons in this equilibrium.

Proof: We sketch a part of the proof for (i) and leave the rest as an exercise. We are interested in computing a sequential equilibrium of the game. Thus, we need to check for (a) sequential

²⁹ We can, without loss of generality, include a benefit B of staying in a hotel, but it cancels out in the subsequent calculation (unless there is a hotel-specific benefit of booking a room).

rationality, and (b) consistency of beliefs and actions. If a firm chooses to unshroud (i.e., educate the consumers about the add-ons, so that the informed myopes behave like sophisticates), then the beliefs of the sophisticates and informed myopes are the announced value of p_a^i . Otherwise, if the firm chooses to shroud, then given the stated beliefs, sophisticates believe that $p_a^i = \bar{p}$, i.e., once a consumer is locked-in with a hotel it will be charged the maximum permissible price for the add-ons.

(i) Suppose that $\alpha > \frac{e}{\bar{p}}$ and all firms shroud. We need to check that no profitable deviations from the announced strategies are possible. Given the prices of other firms, p_b^* and p_a^* , if firm i shrouds, then the myopes do not show any awareness of add-ons, and given the stated beliefs, consumers believe that $p_a^i = \bar{p}$ for all firms. Then, from (19.77), (19.78), we get $v_i = p_b^* - p_b^i$ for sophisticates and myopes. Thus, the demand for firm i is given by $x(p_b^* - p_b^i)$ and the fraction α of myopes buy the add-ons. The profits of firm i , therefore, are given by

$$\pi = (p_b^i + \alpha p_a^i)x(p_b^* - p_b^i). \quad (19.81)$$

Firm i chooses p_b^i and p_a^i to maximize π , given in (19.81). The solution to p_a^i is directly obtained as the maximum possible value $\bar{p}$. Setting $p_a^i = \bar{p}$ in (19.81) we get $\pi = (p_b^i + \alpha \bar{p})x(p_b^* - p_b^i)$. Hence, the first order condition with respect to p_b^i is

$$-(p_b^i + \alpha \bar{p})x'(p_b^* - p_b^i) + x(p_b^* - p_b^i) = 0. \quad (19.82)$$

In a symmetric equilibrium, $p_b^i = p_b^*$. Substituting this in (19.82) we get $p_b^i = -\alpha \bar{p} + \frac{x(0)}{x'(0)}$. This is the solution given in (19.79). However, to prove that this is the optimal solution to the problem, a bit more work is needed. We need to consider the case where the firm chooses to unshroud (i.e., educate consumers of the add-ons). Unshrouding educates the sophisticates and the informed myopes who might or might not respond by engaging in a substitution effort, e , depending on whether the price of add-ons is higher or lower. Thus, in this case we need to consider two cases: $p_a^i > e$ and $p_a^i < e$. In particular, the fraction of myopes in this case is given by $\alpha_1 = (1 - \lambda)\alpha$ because the informed myopes (fraction λ of the total myopes) now behave like sophisticates. We leave it to the reader to consider these two cases and show that in each case, the profits of the firm are lower relative to the case of shrouding.

(ii) Proof left to the reader as an exercise. ■

Proposition 19.5 illustrates two different equilibria. In Proposition 19.5(i), firms choose to shroud and charge the maximum permissible price for add-ons, $p_a^i = \bar{p}$ and subsidize the base price relative to the unshrouded equilibrium in Proposition 19.5(ii). Empirical evidence for this prediction is reviewed in Gabaix and Laibson (2006) and Ellison (2005). The intuition for charging the maximum permissible price for add-ons is that shrouding induces the worst possible beliefs about the price of add-ons. Since $e < \bar{p}$, sophisticates engage in substitution effort. Thus, only the myopes buy add-ons, and once they book into the hotel, the hotel might as well charge them the maximum allowed for add-ons.

This is the sense in which the equilibrium in Proposition 19.5(i) is not efficient because only the myopes purchase the add-ons. Furthermore, the sophisticates take advantage of the subsidized base price to improve their surplus under shrouding relative to no shrouding.

Proposition 19.6 *The consumer surplus of the sophisticates is higher under shrouding relative to unshrouding when there is perfect competition among firms.*

Proof: Since perfectly competitive firms face an infinitely elastic demand curve, so $\frac{x(0)}{x'(0)} = 0$. From (19.79), (19.80) the optimal base price is $p_b^i = -\alpha\bar{p}$ under shrouding and $p_b^i = -e$ under unshrouding. Thus, the surplus of sophisticates under shrouding is $-p - e = \alpha\bar{p} - e$; since $e < \alpha\bar{p}$, the surplus is strictly positive. However, under unshrouding, the surplus is $-p - e = e - e = 0$. ■

The fact that sophisticated consumers prefer to engage with firms who shroud and charge high add-on prices but subsidize by offering low base prices is known as the *curse of debiasing*. An example is the low price of printers and the relatively high prices of patented printer cartridges. Sophisticated consumers, in this case, can buy unbranded low-priced printer cartridges on the Internet. In the neoclassical case with no myopes, advertising by firms will eliminate shrouding (Shapiro, 1995). However, the presence of myopes ensures that a captive set of consumers will pay a high price for add-ons in the presence of shrouding. We can see from Proposition 19.5 that if there are no myopes ($\alpha = 0$), then the condition $\alpha > \frac{e}{\bar{p}}$ required for the shrouded equilibrium in Proposition 19.5(i) is never satisfied.

By contrast, in Proposition 19.5(ii), the firm chooses to unshroud and chooses a price for add-ons that just makes consumers indifferent between substitution or not. We assume that the tie breaking rule is that in this case they purchase the add-ons (otherwise the price can be dropped by a penny to ensure that this occurs). This case arises when $\alpha < \frac{e}{\bar{p}}$, so the fraction of myopes is too low to make it worthwhile to extract sufficient consumer surplus by high prices of add-ons; this makes shrouding ineffective.

19.17 Limited attention

In this section, we consider the empirical evidence on *limited attention*. We also outline a general theoretical framework to model this phenomenon.

19.17.1 Limited attention and the poor

Why do individuals take payday loans with associated annual interest rates as high as 400%? Bertrand and Morse (2011) locate the reason in the limited attention of borrowers. They run several treatments in which potential borrowers are provided with a range of information on the real costs of payday loans. The information includes the weekly accumulation of fees (e.g., \$270 in 3 months on a \$300 loan), comparison of borrowing costs from other financial institutions, and refinancing using their credit card borrowing. These interventions succeeded in reducing the extent of borrowing; in the four treatments, the percentage reduction in borrowing was 5.9%, 12%, 16%, and 23%, respectively. These results suggest a potential role for legislation in making the provision of such information mandatory. However, the relatively small reductions in borrowing also indicates that limited attention alone does not account for the take-up of payday loans.

Stango and Zinman (2015) find that drawing attention to fees for overdrawn accounts, reduces overdraft fees for up to 2 years since the first reminders are sent out. The effects are more pronounced for individuals who have lower education and financial literacy. Limited attention might be expected to play a greater role when the number of options is greater. In an empirical study of the take-up of loans, Bertrand et al. (2010) find that reducing the number of options from four to one, increased loan take-ups; the effect is equivalent to a 2.3% reduction in the interest rate.

In Mexico City, only 39% of low-income individuals could spot the lowest cost credit product in bank brochures. However, 68% could spot the lowest cost product in a user-friendly summary sheet (Giné et al., 2014); limited attention and shrouded attributes are possible explanations. These examples also highlight the need for financial market regulation for framing information in a more transparent manner in the presence of limited information.

Limited attention is likely to reflect the cognitive costs of engaging in greater attention. These cognitive costs, which might take the form of depletion of scarce willpower required to exert greater attention, may create undesirable outcomes, especially for the poor. The poor may need to expend a disproportionate amount of scarce attention and willpower costs on important daily issues. These issues include arranging food for the table, dealing with debt, or arranging for clean drinking water; the associated willpower costs may be termed as a form of *cognitive tax* (Shah et al., 2012; Mullainathan and Shafir, 2013).

The result of this depletion in willpower is that the poor are more likely to engage their System 1 in making other potentially important decisions; the control exerted by System 2 on System 1 falls as willpower depletes. Thus, the poor may engage in insufficient deliberation on many important issues (Banerjee and Mullainathan, 2008); this is sometimes referred to as the problem of *low bandwidth*. Hence, poor individuals may make bad decisions, which perpetuate poverty that is the cause of the initial problem.

Indeed, the actions of the poor may not fully reflect their intentions; this is known as the *intention-action divide*. In the case of the poor, this problem is mostly caused by (1) intense willpower depleting focus on pressing current problems, and (2) present-biased preferences. Mani et al. (2013) find that farmers score much lower on cognitive ability tests before a harvest when they have high levels of financial stress. Measured IQ is 10 points lower before the harvest, relative to the period after the harvest.

Karlan et al. (2012) find that text messages sent out to individuals in Peru, Bolivia, and the Philippines, reminding them of their savings goals, actually improve savings by 16%. Presumably, these messages work because of issues of limited attention and procrastination (see Part 3 of the book). Furthermore, the most effective messages were the ones that emphasized a particular goal, for instance, purchase of a house or an appliance. Limited attention might also explain why many sophisticated financial literacy programs are not successful. Drexler et al. (2014) found that reducing the degree of sophistication of the financial programs, by emphasizing simple heuristics, improves financial literacy of firms and micro-entrepreneurs in the Dominican Republic.

The solutions to the problems of cognitive tax and low bandwidth can sometimes be surprisingly simple and offer a low-cost means of bringing about large welfare changes for the poor; Datta and Mullainathan (2014) term this as *low hanging policy fruit*. This suggests that poverty is not simply a problem of insufficient resources, so this offers a radically new perspective on the problem (WDR, 2015). Development policy could then play a key role in the timing of important decisions. For instance, sugarcane farmers have lower consumption in the months prior to the harvest and they may even pawn jewelry. However, if part of their harvest money could be put into an account with pre-specified withdrawal rates, then they may better smooth their consumption levels. Such default options have been shown to have important effects in the West for pensions and savings.

In the presence of limited attention and limited cognitive abilities, a benevolent or cunning third party might wish to frame the context within which individuals make decisions. This is known as the problem of *choice architecture*. Framing of context can take many forms; for instance, which information to make salient, which comparisons among options to highlight, which anchors to choose and so on. One example of choice architecture is Thaler and Sunstein's

(2008) idea of a *nudge*. For instance, on account of limited attention, if the healthiest snacks are put at eye level, they are more likely to be chosen; these issues are considered in more detail in Part 8.

19.17.2 Limited attention and taxes

Does consumer demand respond more to easily observed taxes relative to less salient taxes? For instance, sales taxes may be (i) posted on price stickers in shops, or (ii) not posted on the price sticker but added at the sales register at the point of sale. If demand or its responsiveness turns out to be different in the two cases (see Figure 19.11), then two competing explanations arise.

First, consumers may be unaware of the sales tax. Second, hidden fiscal attributes are less salient. Chetty et al. (2009) surveyed consumers at a grocery store where the sales tax was displayed for some but not other consumer goods. They found that the median consumer was able to successfully identify the sales tax on seven out of eight products on the survey. This finding, and the fact that consumers could easily inquire about the level of sales tax from the shop attendant if they wished, suggests that taxes that are not displayed on price stickers reduce tax salience.

Consider a simple model of consumer demand. Suppose that there are two consumer goods, x and y . Good y is an untaxed good whose price is normalized to 1. The pretax price of good x is p and the post-tax price is $q = (1 + \tau)p$, where τ is an ad-valorem sales tax. Consumers observe the pre-tax price on the posted price stickers in shops, but the sales tax, τp , is not included in the posted price.

Denote the solution to the consumer's optimal demand for x by $x(p, \tau)$. In traditional public finance theory, the consumer takes account of the post tax price, q , even if the sales tax is not posted on the price sticker. Thus, we have $x(p, \tau) = x((1 + \tau)p, 0)$, so there is no need to separately observe the sales tax if the consumer already takes account of the post tax price. In this formulation, an increase in the post tax price, q , whether it is caused by an increase in τ or an increase in p , has identical effects on the demand for x .

Let $\epsilon_{x,p}$ and $\epsilon_{x,1+\tau}$ denote, respectively, the elasticity of demand for x with respect to p and $1 + \tau$. Under classical public finance theory we should, by definition, observe that

$$\epsilon_{x,p} \equiv -\frac{\partial \log x}{\partial \log p} = \epsilon_{x,1+\tau} \equiv -\frac{\partial \log x}{\partial \log(1 + \tau)}. \quad (19.83)$$

In contrast to (19.83), Figure 19.11 shows that $\epsilon_{x,p} > \epsilon_{x,1+\tau}$. One way of representing limited attention to taxes that are not displayed on price stickers is to write $x(p, \tau)$ in a log-linear form.

$$\log x(p, \tau) = \alpha + \beta \log p + \theta \beta \log(1 + \tau). \quad (19.84)$$

In (19.84), the coefficients β and $\theta\beta$, respectively, give the two elasticities defined in (19.83). Thus,

$$\theta = \frac{\frac{\partial \log x}{\partial \log(1+\tau)}}{\frac{\partial \log x}{\partial \log p}} = \frac{\epsilon_{x,1+\tau}}{\epsilon_{x,p}}. \quad (19.85)$$

If $\theta = 1$, then we have the classical case in (19.83). However if $\theta < 1$, then we get the observed result in Figure 19.11. If one could uncover independent variation in p and τ , then $\epsilon_{x,p}$ and $\epsilon_{x,1+\tau}$ can be estimated separately to compute θ .

Chetty et al. (2009) conducted an experiment in a supermarket for three weeks in 2006. Initially, all products in the store excluded the sales tax on the price sticker; the sales tax was added later at the point of purchase. The price tags on a selected list of 750 products were altered to separately display the pre-tax price and the sales tax of 7.375% in order to increase the salience of the sales tax. The products included three groups: cosmetics, deodorants, and hair care accessories. The posting of the tax on the price stickers reduced demand by 8% relative to two control groups: other products in the store and similar products in two nearby stores.

The reduction in demand was statistically significant. One can reject the null hypothesis that posting of the sales tax on price stickers has no effect by using a t-test and non-parametric permutation tests. The effect of tagging products with the sales tax caused a fall in demand that was identical to a 7.373% increase in price. Hence, consumers pay limited attention to taxes that are not displayed on price stickers. θ is estimated to be 0.35. A separate survey conducted on supermarket shoppers showed that the median shopper was aware of the level of sales tax. Hence, the observed effect on demand was not the result of dispelling of ignorance, but an increase in the salience of the sales tax.

In a second study, the authors consider separately the effect of different kinds of indirect taxes on alcohol consumption. They considered the effect of excise duties that are included in the alcohol price and sales taxes that are only included at the point of sale, hence, these are shrouded; see Figure 19.11. The main empirical result is that, based on data over the period 1970–2003, excise taxes (more visible) reduced alcohol consumption far more than sales taxes (shrouded).

Goldin and Homonoff (2013) find that attention to sales taxes levied at the sales register differs among low-income consumers (who pay greater attention) relative to high-income consumers. This can be exploited by the fiscal authorities to reduce the degree of perceived tax regressivity by taxing goods consumed by the rich, relatively more.

Results of a similar nature have been obtained elsewhere. For instance, the earned income tax credit (EITC) is the largest cash transfer program in the US that transfers income to low-income families. However, evidence suggests that the marginal incentives implied by the program, e.g., should one work an extra hour, are not salient, hence, they would be ignored by individuals with limited attention. The EITC program appears to have had a relatively small impact on the intensive margin, i.e., hours worked, relative to the extensive margin, i.e., the decision to participate or not in the labor force (Hotz and Scholz, 2003).

Chetty and Saez (2013) arrange for tax experts to provide information on the intensive margin for potential EITC beneficiaries. Information provision takes several forms: a verbal description; a graph that reveals the behavior of the EITC as earnings change; and a table that lists key information on the EITC. Furthermore, potential beneficiaries were given advice that was particularly tailored to their personal circumstances. For instance, they were told if it would pay for them to work more or not. Yet, despite these attempts, the average behavior of the potential beneficiaries along the intensive margin did not change. One potential reason why providing information does not work in this case is that this problem is relatively more cognitively challenging relative to simply adding a sales tax on the price tag. Another reason is that the intensive margin may be determined by factors entirely outside this model.

Buchanan (1967) and Brennan and Buchanan (1980) note the potential link between tax salience and the size of the government. The basic idea is that governments can expand by increasing taxes that are not salient, ruling out adverse electoral consequences for political parties.

Finkelstein (2009) confirms these findings by examining the effect of electronic toll collections (ETC) in car plazas that automatically deduct the relevant toll; there is no manual exchange of cash between two parties in this case. Comparing customers who pay by manual tolls and by ETC, she finds much less awareness of the level of the toll among the ETC customers.

She also finds that there is an increase in the toll rates (the analog of an increase in the size of the government) following the introduction of an ETC. Indeed, toll rates are 20–40% higher in the presence of ETC as compared to manual toll collections. Furthermore, the timing of ETC increases is less sensitive to the electoral calendar relative to manual tolls, suggesting that politicians are less concerned about its electoral implications, most likely because people pay limited attention to these changes.

19.17.3 *Biased numerical attention*

It has been noted that people might unduly focus on the leftmost digit of a multi-digit number, relative to the digits on the right (Korvost and Damian, 2008). This appears to be a form of imperfect attention to some digits over others; we may term it as the *left-digit bias*. Basu (1997, 2006) explained the prevalence of prices ending in the digit 9; for instance, a price of $\$x.99$ (where x is a whole number), rather than an integer price of $\$x + 1$; e.g., a price of $\$39.99$ rather than $\$40$. He shows that in a rational expectations equilibrium, all firms choose prices ending in 99 cents and consumers, rationally, do not benefit by observing the full price (say, $\$3.00$, when the quoted price is $\$2.99$). This explanation is quite distinct from the one that ascribes such biases to limited attention arising from cognitive limitations.

Lacetera et al. (2012) explore the presence of the left-digit bias in the wholesale used car market. Potential buyers may exhibit the left-digit bias when presented with information on the odometer readings of cars. In particular, they find that there are discontinuous drops in the retail prices of cars at 10,000 mile thresholds. For instance, cars with odometer readings 79,900–79,999 miles sell for (i) $\$210$ more than those with odometer readings in the range, 80,000–80,100, yet only (ii) $\$10$ less than those with odometer readings 79,800–79,899. There are also discontinuities at the 1000 mile thresholds but these are smaller and we shall ignore them here. Furthermore, there are spikes in the volume of cars presented for sale just before they hit these odometer thresholds, suggesting awareness of this bias among car sellers. These results are also shown to hold for the retail used car market (Busse et al., 2013).

Buying a car is a large stakes decision and odometer readings are easily observed. Hence, this evidence is an important demonstration of the presence of heuristics in real markets. As with all heuristics, individuals commit systematic biases relative to the benchmark of classical statistics. The left-digit bias may be a useful heuristic in the fast-and-frugal sense, and this needs to be explored in future work. For instance, buying a car just below the threshold is costly because it will soon cross the threshold but the benefit might arise if this information is generally correlated with other useful characteristics of the car.

Consider a formal model of left-digit bias that illustrates the limited attention aspect of the bias. Suppose that the reading on the odometer is a k digit number, denoted by $m = d_1 d_2 \dots d_k$, where d_1 is the leftmost digit and d_k , the rightmost digit; each digit belongs to set $\{0, 1, \dots, 9\}$. Suppose that m , the actual odometer reading, is a positive whole number less than or equal to 100,000. A potential buyer perceives the odometer reading as $\hat{m}$, where³⁰

³⁰ A slightly different formula applies when $m > 100,000$ because the changes in this case are not to the leftmost digit until m exceeds 200,000. The reader may wish to think about the necessary modifications in the formula.

$$\hat{m} = d_1 10^{k-1} + (1 - \theta) \sum_{j=2}^k d_j 10^{k-j}, \quad (19.86)$$

where $\theta \in [0, 1]$ is the *inattention parameter*; thus the weight put on the leftmost digit, 1, is greater than the weight that is put on any of the other digits, $1 - \theta < 1$. The classical case corresponds to full attention, $\theta = 0$. An individual is maximally inattentive if $\theta = 1$, in which case, only the leftmost digit is salient. For instance, for $m = 4326$, (19.86) implies that $\hat{m} = 4 \times 10^3 + (1 - \theta) (3 \times 10^2 + 2 \times 10^1 + 6 \times 10^0)$. Whenever $0 < \theta \leq 1$ we have $\hat{m} < m$, i.e., the perceived mileage is lower than the actual mileage.

The actual value of the car is $V = V(m)$. However, the perceived value of the car is $\hat{V} = V(\hat{m})$, which takes a linear form

$$\hat{V} = V(\hat{m}) = v - \alpha \hat{m}, \quad (19.87)$$

where $v \geq 0$ is the component of valuation that is independent of the mileage, and $\alpha \geq 0$ is a measure of how quickly the car is perceived to depreciate. As consumers become maximally inattentive, $\theta = 1$, $V(\hat{m})$ becomes a step function.

Consider the change in perceived value for any two odometer readings m_1 and m_2 such that $m_1 - m_2 = 1$. Two cases arise.

- (i) m_1, m_2 do not straddle two different thresholds, e.g., $m_1 = 43,246$ and $m_2 = 43,245$.
- (ii) m_1, m_2 straddle different thresholds, e.g., $m_1 = 50,000$ and $m_2 = 49,999$.

For these two cases, (i) and (ii), a simple calculation, using (19.86), shows that

$$\hat{m}_1 - \hat{m}_2 = \begin{cases} 1 - \theta & \text{Case (i)} \\ 1 + \theta \times 9999 & \text{Case (ii)} \end{cases}. \quad (19.88)$$

Using (19.87) and (19.88), we get $V(\hat{m}_1) - V(\hat{m}_2) = -\alpha (\hat{m}_1 - \hat{m}_2)$, thus,

$$V(\hat{m}_1) - V(\hat{m}_2) = \begin{cases} -\alpha(1 - \theta) & \text{Case (i)} \\ -\alpha(1 + \theta \times 9999) & \text{Case (ii)} \end{cases}. \quad (19.89)$$

Clearly, there is a discontinuous drop in the perceived value of the car as we move from Case (i) to Case (ii). Consider Case (ii). From the second row in (19.89), we can write $V(\hat{m}_1) - V(\hat{m}_2) = -\alpha [(m_1 - m_2) + \theta \times (10000 - (m_1 - m_2))]$. Thus,

$$\lim_{m_2 \rightarrow m_1} [V(\hat{m}_1) - V(\hat{m}_2)] = -\alpha \theta \times 10000,$$

gives the discontinuous drop in car value at a threshold.

These predictions are nicely summarized in the self-explanatory Figure 19.12 for $50,000 \leq m \leq 100,000$. Since we have assumed a constant rate of depreciation, embodied in a constant value of α , the discontinuous downward jumps at each threshold are of the same size. However, comparing cars of different makes or models that have different rates of depreciation, more rapidly depreciating cars (higher α) will have larger discontinuous jumps at the thresholds.

The data for testing these predictions comes from wholesale markets in used cars. A simple theoretical model can be sketched that the reader might wish to formalize further. Suppose that

Figure 19.12 Predictions of a model of limited attention on used car values.

Source: Lacetera et al. (2012) with permission from the American Economic Association.

there are N consumers with unit demands for cars and whose perceived value for a car is given in (19.87). Cars are sold in a competitive retail market by dealers who, in turn, purchase their cars from auctions. The auctions are either second price auctions or ascending-bid English auctions. There are $M \leq N$ cars in the auctions; each car displays an odometer mileage, and its reserve price is zero. Since the market for dealers is competitive, they make no profits. Hence, in the auction market, they bid as if they had the valuations of the buyers in (19.87). Given these assumptions, the auction produces an efficient outcome, so for a car of any mileage, m , the auction price equals $V(\hat{m})$.

Figure 19.13 shows the raw prices of cars based on data for 22 million cars sold during the sample period, 2002–2008, at one of the largest wholesale car price auctions in the US. In the figure, the mileage is rounded to the nearest 500 (so, e.g., 42,315 is rounded to 42,500). The vertical lines in the figure represent each of the 10,000 mile thresholds from 0 to 125,000 miles. Average prices decline with mileage. Within two consecutive threshold values, the decrease in price is continuous. However, at each threshold value, there is a discontinuous downward jump in price, as predicted by models of limited attention.

Repeating the same analysis by netting out the effects of various fixed effects, such as the model, make, year, body style of cars, and plotting the price residuals gives a result very similar to Figure 19.13; the price plot is even smoother in this case but the price discontinuities survive. There are spikes in the volume of cars brought to the auctions with odometer readings just short of the 10,000 mile thresholds; this is most noticeable at thresholds starting at 60,000 miles. This suggests that car sellers are aware of the problem of limited attention on the part of car buyers. Thus, the left-digit bias is a feature of the demand side of the market rather than the supply side.

Using data from German used car markets, Englmaier et al. (2014) replicate the results above about the fall in the value of used cars when the odometer hits critical threshold values. However, they also find support for an additional and plausible factor in explaining discontinuous drops in used car values, the vintage or year of registration of the car. The left-digit bias cannot be used

to account for the vintage effect, so they propose a slightly different theoretical model to account for both effects

19.17.4 A theoretical framework

In neoclassical economics, an individual may be expected to take account of a very large number of variables in solving a problem. However, cognitive limitations may allow limited attention to some factors and greater attention to more salient factors; variables given limited attention might be substituted by default values. The choice of which factors to treat as salient may be an endogenous one. Once the individual decides on the set of salient factors, he proceeds as in neoclassical models in economics. Models with these features, where the decision is made in a manner that is consistent with neoclassical models of rationality, are sometimes known as *rational inattention models*. Our main focus in this section is on the *sparse max operator* model of Gabaix (2014) that we consider to be psychologically better grounded, and more tractable. We offer some brief comments on other models at the end.

Consider the classical problem of maximizing utility $\max_{x \in X} u(x, \theta)$, where $X \subset R^k$ is the k dimensional real domain of choices under consideration, and θ is a vector of parameters drawn from some set of parameters $\Theta \subset R^n$. We wish to adapt this problem to reflect limited attention by defining a *sparse max* operation,

$$s \max_{x \in X} u(x, \theta). \quad (19.90)$$

Denote $\theta = 0$ as the *default parameter* and the corresponding optimal action $x^d = \max_{x \in X} u(x, 0)$ as the *default action*. We assume that u is concave in x and twice continuously differentiable around $(x^d, 0)$. Suppose that the parameter θ is a linear combination of n other parameters $\theta_1, \theta_2, \dots, \theta_n$.

$$\theta = \sum_{i=1}^n \mu_i \theta_i, \text{ and } \forall i, \mu_i \in R, \theta_i \in \Theta.$$

Limited attention is captured as follows. The perceived value, $\hat{\theta}_i$, of the parameter θ_i is given by

$$\hat{\theta}_i = a_i \theta_i, i = 1, \dots, n, \quad (19.91)$$

where $a_i \in [0, 1]$ is the attention given to θ_i and $a = (a_1, a_2, \dots, a_n)^T \in [0, 1]^n$ is known as the *attention vector*; superscript T denotes the transpose. $a_i = 1$ corresponds to the case of full attention in neoclassical economics. At the other extreme, when $a_i = 0$, the parameter θ_i is given no attention. Once the optimal attention vector $a^* = (a_1^*, a_2^*, \dots, a_n^*)^T$ is endogenously determined, we can calculate the perceived or sparse parameter

$$\hat{\theta}(a^*) = \sum_{i=1}^n \mu_i \hat{\theta}_i = \sum_{i=1}^n \mu_i a_i^* \theta_i.$$

The individual then solves the following problem

$$x^* \in \arg \max_{x \in X} u(x, \hat{\theta}(a^*)). \quad (19.92)$$

The first order condition is $u_x(x^*(\hat{\theta}(a^*)), \hat{\theta}(a^*)) = 0$, where $x^*(\hat{\theta}(a^*))$ is the optimal solution. Substituting the optimal solution, $x^*(\hat{\theta}(a^*))$, in the direct utility function, u , we get the indirect utility function

$$v(a) = u(x^*(\hat{\theta}(a^*)), \theta). \quad (19.93)$$

Using the implicit function theorem on the first order condition and evaluating derivatives at $(x, \theta) = (x^d, 0)$, we get

$$x_{\theta_i} \equiv \frac{\partial x}{\partial \theta_i} \big|_{(x^d, 0)} = - \frac{u_{x\theta_i}}{u_{xx}} \big|_{(x^d, 0)}. \quad (19.94)$$

Thus, x_{θ_i} is the change in the optimal action when θ_i increases by one unit at the default option.

Consider, henceforth, the special case of quadratic utility and $x \in \mathbb{R}$.

$$u(x, \hat{\theta}) = \frac{-1}{2} \left(x - \sum_{i=1}^n \mu_i a_i^* \theta_i \right)^2. \quad (19.95)$$

In this case, the optimal solution is

$$x^* = \sum_{i=1}^n \mu_i a_i^* \theta_i. \quad (19.96)$$

We now model the optimal determination of attention. Suppose that attention is cognitively costly and the cost function of attention to θ_i is given by

$$C(a_i) = ca_i^\alpha, c > 0, \alpha \geq 0. \quad (19.97)$$

When $\alpha = 0$, there is a fixed cost of attention equal to c . In classical game theory, attention is costless, so $c = 0$. Suppose that the vector θ is drawn from some distribution $g(\theta)$ such that the means of the marginal distributions are zero ($E\theta_i = 0$), the standard deviations are $\sigma_i = E[\theta_i^2]^{1/2}$, and the covariances are given by $\sigma_{ij} = E[\theta_i\theta_j]$. The total cost of attention is given by

$$C(a) = \sum_i C(a_i).$$

The individual wishes to choose the attention vector, a , in order to maximize the expected value of indirect utility in (19.93), net of the cost of effort given in (19.97). Thus, the individual's problem is

$$\max_{a \in [0,1]^n} Ev(a) - C(a).$$

To simplify the problem we take a Taylor expansion of $v(a)$ around $a \equiv i = (1, 1, \dots, 1)^T$, where i is a vector of ones.

$$v(a) \approx v(i) + Dv(i)(a - i) + \frac{1}{2}(a - i)^T D^2v(i)(a - i), \quad (19.98)$$

where $Dv(i)$ is the matrix of first order partial derivatives of v and $D^2v(i)$ is the matrix of second order partial derivatives. $(a - i)$ is a row vector with the j th element $a_j - 1$. Using the definition of indirect utility in (19.93), $v(a) = u(x^*(\hat{\theta}(a)), \theta)$, and (19.91), differentiating once with respect to a_i we get $v_{a_i} = u_x x_{\hat{\theta}_i} \theta_i$. Since $E\theta_i = 0$ we have $EDv(i)(a - i) = 0$ (this is the zero vector). Differentiating v_{a_i} with respect to a_j we get $v_{a_i a_j} = x_{\hat{\theta}_i} u_{xx} x_{\hat{\theta}_j} \theta_j$ (recall that utility is quadratic, (19.95), and the optimal solution is (19.96), so the cross partials are zero). Taking expected values we get $Ev_{a_i a_j} = E[\theta_i \theta_j] x_{\hat{\theta}_i} u_{xx} x_{\hat{\theta}_j} = \sigma_{ij} x_{\hat{\theta}_i} u_{xx} x_{\hat{\theta}_j}$. Using these results, and taking the expected value in (19.98) we get

$$E[v(a) - v(i)] \approx \frac{-1}{2}(a - i)^T \Lambda (a - i),$$

where Λ is the *cost of inattention matrix* such that

$$\Lambda_{ij} = -\sigma_{ij} x_{\hat{\theta}_i} u_{xx} x_{\hat{\theta}_j}. \quad (19.99)$$

Thus, an individual who uses the sparse max operator will choose the vector of attention a to

$$\text{maximize}_{a \in [0,1]^n} \frac{-1}{2}(a - i)^T \Lambda (a - i) - C(a). \quad (19.100)$$

We summarize this in a formal definition.

Definition 19.6 (*Unconstrained sparse max operator*): The individual undertakes the following two-step optimization exercise.

- (1) Choose optimal attention, a^* , to solve (19.100). This gives the sparse representation of θ_i , $\hat{\theta}_i = a_i^* \theta_i$, $i = 1, \dots, n$.
- (2) The individual then solves the optimization problem in (19.92) giving rise to the vector of optimal choices, x^* .

Consider a simple one-dimensional example, $k = 1$, $n = 1$, quadratic utility, and $c = 1$. In this case, the analog of (19.100) is

$$\max_{a \in [0,1]} \frac{-1}{2} (a - 1)^2 \sigma^2 - a^\alpha. \quad (19.101)$$

The optimal values of a for three different values of $\alpha = 0, 1, 2$, denoted, respectively, by a_0^* , a_1^* , and a_2^* , are given by

$$a_0^* = \begin{cases} 0 & \text{if } \sigma^2 < 2 \\ 1 & \text{if } \sigma^2 \geq 2 \end{cases}.$$

$$a_1^* = \begin{cases} 0 & \text{if } \sigma^2 < 1 \\ 1 - \frac{1}{\sigma^2} & \text{if } \sigma^2 \geq 1 \end{cases}.$$

$$a_2^* = \frac{\sigma^2}{2 + \sigma^2}.$$

A plot of the optimal values against σ^2 (in bold) is shown in Figure 19.14; a_0^* (left panel), a_1^* (middle panel), and a_2^* (right panel). It is obvious that a_0^* , a_1^* induce sparsity. In both cases, there is a range of values for which the optimal attention is 0; a_1^* is continuous but a_0^* is not continuous at $\sigma^2 = 2$. In these cases, the individual is rationally inattentive in the sense that he takes account of the costs of attention as well as the stochastic structure of the problem. However, a_2^* never induces sparsity. We leave the proof of the next proposition for the reader.

Proposition 19.7 (Gabaix, 2014): Suppose that $\sigma_{ij} = 0$ for all $i \neq j$. Then the optimal attention, a_i^* , is increasing in σ_i^2 , x_{θ_i} , and decreasing in c .

Optimal attention is increasing in σ_i^2 and x_{θ_i} because these factors increase the loss in utility from imperfect attention (see (19.99)). An increase in c increases the cost of paying attention (see (19.100)), hence, it reduces optimal attention.

Gabaix (2014) offers plausible psychological interpretations of his model. For instance, Step 1 in Definition 19.6 may be considered to be a System 1 operation that decides how much attention to

Figure 19.14 Determination of the optimal attention parameters as a function of the variance of the underlying parameter. The horizontal axis in each of the three panels is σ^2 . The vertical axes in the three panels are: a_0^* (left panel), a_1^* (middle panel), and a_2^* (right panel).

give to a problem. Once this problem is solved, then Step 2 appears akin to a System 2 problem. The case of no attention, $a_i^* = 0$, may be considered to arise when System 1 operates under intense time pressure, and so assigns the default option $(x^d, 0)$. One may also consider this as an anchoring and adjustment model in which one begins at the default option $(x^d, 0)$ and then slowly adjusts towards the optimum (x^*, a^*) although this often falls short of the full attention optimum $(x, 1)$.

Once this is accepted, the model can be extended to constrained optimization. Suppose that now the problem is to optimize, as in (19.90), subject to the constraint $f(x, \theta) \geq 0$. Define the Lagrangian

$$L = u(x, \theta) + \lambda^d f(x, \theta), \quad (19.102)$$

where λ^d is the Lagrangian multiplier.

Definition 19.7 (*Constrained sparse max operator; Gabaix, 2014*): In the constrained problem, the sparse max operation, $s \max_{x \in X} u(x, \theta)$, subject to $f(x, \theta) \geq 0$, is defined as follows. The individual undertakes the following two-step optimization exercise.

- (1) Choose optimal attention, a^* , to solve (19.100), but instead of (19.99), using $\Lambda_{ij} = -\sigma_{ij} x_{\hat{\theta}_i} L_{xx} x_{\hat{\theta}_j}$ and $x_{\hat{\theta}_j} = -\frac{L_{x\theta_j}}{L_{xx}} |_{(x^d, 0)}$ where x^d solves $\arg \max_x L(x, 0)$. This gives the sparse representation of θ , $\hat{\theta}_i = a_i^* \theta_i$, $i = 1, \dots, n$.
- (2) Define the function $x(\lambda) = \arg \max_x [u(x, \hat{\theta}) + \lambda f(x, \hat{\theta})]$. Now solve the problem

$$\lambda^* \in \arg \max_{\lambda} u(x(\lambda), \hat{\theta})$$

subject to

$$f(x(\lambda), \hat{\theta}) \geq 0.$$

The solution to this optimization problem gives rise to the vector of optimal choices, $x^*(\lambda^*)$.

Gabaix (2014) uses this framework to re-derive basic results in consumer theory in microeconomics and in competitive equilibrium. Some of these results include the following. Individuals optimally exhibit money illusion. This can arise because consumers are inattentive to an increase in price but attentive to an increase in their incomes. The Slutsky matrix may not be symmetric under limited attention, and a behavioral analog of the Edgeworth box is derived. The weak axiom of revealed preference may also not hold.

Overall, this is an important contribution that is better psychologically founded than many of the other theoretical contributions. But, in the spirit of the approach in the rest of this book, it must await stringent testing before it gains greater acceptance. For that it must address questions such as the following. Is imposing a stochastic structure on the unknown parameters of the utility function the most attractive approach to modeling limited attention? What are the experimental/field analogs of σ_i^2 , x_{θ_i} , and c ? In several of the examples that we considered above, such as a fall in demand when sales taxes (known to people) are made salient, or changes in the pattern of Internet shopping when the less-salient delivery charges (known to people) are varied, the observed environments appear to be non-stochastic. How should we model limited attention in these cases? One may expect much progress to be made in future years on these questions.

In a popular class of models of rational inattention, information is modeled as a reduction in uncertainty. Uncertainty, in turn, is modeled as a reduction in *entropy*. Finally, an upper limit on the flow of information is imposed (Sims, 1998, 2003, 2006). Consider the simple exposition of the basics of this approach in Wiederholt (2010). Suppose that a random variable Y is distributed normally with mean μ_Y and variance σ_Y^2 . The *unconditional entropy* of Y is given by

$$S(Y) = \frac{1}{2} \log_2(2\pi e \sigma_Y^2). \quad (19.103)$$

The *conditional entropy* of Y , conditional on another normally distributed variable Z , is given by

$$S(Y | Z) = \frac{1}{2} \log_2(2\pi e \sigma_{Y|Z}^2), \quad (19.104)$$

where $\sigma_{Y|Z}^2$ is the conditional variance. A measure of the information that the random variable Z contains about Y is given by

$$\Delta S = S(Y) - S(Y | Z).$$

Observing Z reduces uncertainty about the variable Y . In this literature, limited attention is modeled as an upper bound, $b > 0$, on the information flow

$$\Delta S \leq b. \quad (19.105)$$

Using (19.103), (19.104) in (19.105) we get $\log_2 \left(\frac{2\pi e \sigma_Y^2}{2\pi e \sigma_{Y|Z}^2} \right) \leq 2b$, or

$$\frac{\sigma_Y^2}{\sigma_{Y|Z}^2} \leq 2^{2b}. \quad (19.106)$$

We may think of Z as a noisy signal of Y so that $Z = Y + \varepsilon$ where $\varepsilon \sim N(0, \sigma_\varepsilon^2)$. In this case, (19.106) can be written as

$$\frac{\sigma_Y^2}{\sigma_\varepsilon^2} \leq 2^{2b} - 1. \quad (19.107)$$

Thus, in this literature, limited attention imposes bounds on the signal to noise ratio in a purely statistical manner. These ideas have been used successfully in physical communication channels such as characterizing the rate of information flow in modems and Internet connections. It is an open question if these statistical techniques also describe similar information flows for humans. In rational inattention models, one minimizes two kinds of costs: departures of decisions from an optimum and the cost of paying attention, subject to a constraint such as (19.107). One criticism of the earlier models in this tradition is that they cannot model source-dependent inattention but recent work has attempted to address this criticism (Maćkowiak and Wiederholt, 2009; Woodford, 2012). Gabaix (2014, p. 1696) argues that these models still lack the tractability and generality of the sparse max operator.

19.18 Do experts exhibit biases?

Does market experience eliminate behavioral anomalies? The evidence gives a strongly negative answer, although experience may lessen some anomalies. In this section, we look at expert-bias in the context of judgment heuristics.

Existing empirical work suggests that experts are not immune to biases. Tetlock (2002) looks at the prediction of experts of political events. His results are sufficiently striking to justify a detailed quote.

Across all seven domains, experts were only slightly more accurate than one would expect from chance Most experts thought they knew more than they did. Across all predictions that were elicited, experts who assigned confidence estimates of 80% or higher were correct only 45% of the time . . . Expertise thus may not translate into predictive accuracy but it does translate into the ability to generate explanations for predictions that experts themselves find so compelling that the result is massive over-confidence.

Most evidence shows that experts are typically more overconfident relative to lay people who lack experience (Heath and Tversky, 1991; Frascara, 1999; Glaser et al., 2007a,b) and that overconfidence increases with experience (Kirchler and Maciejovsky, 2002). The predicted distributions of stock market returns by senior finance professionals, in a large dataset, are too narrow, and realized returns are within their 80% confidence intervals, only 36% of the time (Ben-David et al., 2013).

In this chapter, we have reported many empirical findings that demonstrate several kinds of expert-bias that we quickly summarize now. For surveys, see, for instance, Gilovich et al. (2002), Kahneman (2003), Kahneman (2011), and Tetlock (2006). Tetlock (2010) is a useful response to alternative critical views. Mathematical psychologists exhibit the law of small numbers (Tversky and Kahneman, 1973). The affect heuristic determines experts' perceived riskiness of various hazardous substances (Slovic et al., 1999) and the expert-assigned likelihood of offending of recently discharged mental patients (Slovic et al., 2000). Clinical psychologists underweight the base rate relative to a Bayesian decision maker (Meehl and Rosen, 1955). Expertise does not shield decision makers from the hindsight bias, as shown in a meta-study (Guilbault et al., 2004). Traders in a large investment bank, in both its international branches, were found to be hindsight-biased (Biais and Weber, 2009).

People are often willing to pay a premium for expert services that are mistakenly perceived to be competent (Powdthavee and Riyanto, 2015). Evidence supports the important role of anchoring on a list price by estate agents (Northcraft and Neale, 1987) and in legal judgment (Chapman and Bornstein, 1996; Englich and Mussweiler, 2001; Englich et al., 2006). The false consensus effect is exhibited by judges (Solan et al., 2008). Finance professionals also exhibit a false consensus effect by imputing on others, their own risk preferences (Roth and Voskort, 2014).

Experts, such as physicians and World Bank staff, exhibit framing effects, often of a similar magnitude to those observed with student populations. When presented with identical options, expert responses can flip depending on whether the outcomes are framed as gains or losses relative to a reference point (McNeil et al., 1982; Kahneman and Tversky, 1984; WDR, 2015). There is evidence of limited attention in wholesale car markets by wholesale car dealers (Lacetera et al., 2012).

In the experiments of Redelmeier and Shafir (1995), physicians were given a case study in which a patient suffers chronic hip pain. The physician, in the case study, is on the verge of referring the

case to an orthopedic consultant. At this point, the physician in the case study learns new information about drugs that the patient has not tried. In one treatment, physician-subjects learn that the patient has not yet tried Ibuprofen, and in the second treatment they learn that the patient had not yet tried Ibuprofen and Piroxicam. In the first treatment there were two choices: Ibuprofen+referral and plain referral. In the second treatment, in addition to these two choices, an extra choice was added: Piroxicam+referral. In the second treatment, despite more choices (three instead of two), 72% of the physician-subjects chose plain referral as compared to 53% in the first treatment.

Being subject to judgment heuristics and framing effects, experts can make systematic errors just like anyone else. Thus, market experience does not eliminate non-standard behaviors. But these are not the only reasons that experts exhibit potential biases. Moskowitz and Wertheim (2011) argue that the home ground advantage in sports arises not just from insider-knowledge of home players but also from expert-biases. The experts, in this case, are the match referees. Even if the referees are completely impartial and honest, they are subject to a natural human tendency to avoid the displeasure of those in the proximity. Thus, their discretionary authority typically tends to be exercised in favor of the home team, as for instance, in adding discretionary injury time minutes at the end of a football game. The idea of “home ground advantage” in sports is also used to explain the behavior of experts in the 2008 financial crises by Barth et al. (2013). Many financial experts held senior private sector positions in the financial sector before holding similar senior positions in the US Fed. The home team, in this case, becomes the private financial sector and the away team, the dispersed individual investors in the financial sector, whose interests were insufficiently protected.

In an admirable piece of work, the WDR (2015) documents several kinds of biases among its professional staff. These include confirmation bias, susceptibility to sunk costs, and the influence of framing. The WDR (2015, p. 18) is candid in its assessment of expert-bias: “This finding suggests that development professionals may assume that poor individuals may be less autonomous, less responsible, less hopeful, and less knowledgeable than they in fact are.” The WDR also suggests potential solutions to the problem of expert-bias. These include *dogfooding* (experts signing up and playing their own programs for real) and *red teaming* (having an adversarial outside team test that tests the proposals).

CHAPTER 20

Mental Accounting

20.1 Introduction

The idea of *mental accounting* is an essential part of behavioral economics with wide-ranging implications. Thaler (1999, p. 186), who has done more than anybody else to bring mental accounting to the center-stage in behavioral economics writes: “*I wish to use the term ‘mental accounting’ to describe the entire process of coding, categorizing, and evaluating events.*” Elsewhere (p. 183), he provides a definition of financial mental accounting: “*mental accounting is the set of cognitive operations used by individuals and households to organize, evaluate, and keep track of financial activities.*”

Many readers of this book are unlikely to have formally encountered the mental accounting literature. For this reason, the introduction is split into two parts. The first part gives some examples of mental accounting, while the second part gives an introduction to the chapter.

20.1.1 Some examples of mental accounting

Mental accounting is best motivated by the following insightful series of three examples that demonstrate how individuals create a system of mental accounts.

Example 20.11 (Thaler, 1999, p.183): *A former colleague of mine, a professor of finance, prides himself on being a thoroughly rational man. Long ago he adopted a clever strategy to deal with life’s misfortunes. At the beginning of each year he establishes a target donation to the local United Way charity. Then, if anything untoward happens to him during the year, for example an undeserved speeding ticket, he simply deducts this loss from the United Way account. He thinks of it as an insurance policy against small annoyances.*

Example 20.12 (Thaler, 1999, p.183): *A few years ago I gave a talk to a group of executives in Switzerland. After the conference my wife and I spent a week visiting the area. At that time the Swiss franc was at an all-time high relative to the US dollar, so the usual high prices in Switzerland were astronomical. My wife and I comforted ourselves that I had received a fee for the talk that would easily cover the outrageous prices for hotels and meals. Had I received the same fee a week earlier for a talk in New York though, the vacation would have been much less enjoyable.*

Example 20.13 (Thaler, 1999, p.184): *A friend of mine was once shopping for a quilted bedspread. She went to a department store and was pleased to find a model she liked on sale.*

The spreads came in three sizes: double, queen and king. The usual prices for these quilts were \$200, \$250 and \$300 respectively, but during the sale they were all priced at only \$150. My friend bought the king-size quilt and was quite pleased with her purchase, though the quilt did hang a bit over the sides of her double bed.

Classical economics assumes that individuals derive utility only from final levels of wealth.¹ In Example 20.12, the final wealth is the same whether the fee is received a week ago or after the talk (discounting is hardly an issue over such a small time interval), hence, if liquidity constraints do not bite, neoclassical economic theory cannot directly explain the stylized facts in the example.

In Example 20.13, the individual needed a queen sized quilt but purchased the oversized quilt because they are priced the same. Assuming that the individual derives greater utility from a better fitting quilt, why did she buy the oversized quilt?

Suppose that individuals have a system of *mental accounts*. Let us think of mental accounts, at the moment, as simply the assignment of transactions to different exogenously created categories, and money is not fully fungible across these categories. Classical economics assumes that one has a global financial account that simply aggregates all the individual accounts using the assumption of perfect fungibility of money. This makes the individual accounts redundant. Consider two salient properties of these mental accounts, supported by the evidence, that can explain Examples 20.11, 20.12.

1. Money is not fungible across mental accounts.
2. The individual does not exclusively focus on maximizing overall financial wealth. For instance, the objective might also be to limit the size of losses in individual accounts.

In Example 20.11, the Professor has an *account for unexpected losses* that is initially, and notionally, debited with some level of contribution to the charity. As unexpected losses occur, the contributions to charity are reduced to offset them so that the unexpected losses account does not show up a loss. In Example 20.12, the Thalers create a separate account for their visit, the Swiss mental account, that includes only incomes and expenditures from the Swiss trip. If the fee had been received a week earlier, it would not have been credited to this mental account. Within the Swiss mental account, the receipt of the fee offsets the loss arising from an appreciation of the franc. The explanation of Example 20.13 requires the concepts of *acquisition* and *transaction* utility that we develop later. We consider two more examples to illustrate the range of mental accounting phenomena.

Example 20.14 *In Kenya, many households do not invest sufficiently in health care prevention such as buying insecticide-treated mosquito nets. While credit constraints of households are part of the explanation, the bednets are not prohibitively expensive either. Dupas and Robinson (2013) apply mental accounting techniques to design a simple intervention. In the baseline intervention, individuals are provided with a lockable box with padlock, keys, and a passbook that they can use to keep track of the cash deposited in the lockable box. In three other treatments, they vary the degree of self-control by not providing the keys, or exerting a degree of social pressure. This intervention facilitates the creation of a mental account for health emergencies and is extremely effective in the take-up of the relevant health prevention. After 12 months, the take-up rates were between 66% and 97% in the four treatments.*

¹ Reference dependence can be readily incorporated into the classical subjective expected utility framework. However, without a theory of how human behavior differs in the domains of gains and losses, this adds little value; see Part 1 of the book for a discussion. In contrast, prospect theory offers a fundamentally different view of human nature in the two domains.

Example 20.15 *One might use mental accounting to categorize different sources of income. In the context of one-shot dictator games,² Cherry (2001) finds that the offer proposed by dictators depends on the source of money. When dictators are proposing a split over earned money, they exhibit self-regarding behavior 76% of the time. However, if they are using experimentally allocated money, they exhibit self-regarding behavior only 26% of the time. In this case, earned income resides in a mental account that has a different degree of flexibility towards supporting prosocial behavior.*

20.1.2 An introduction to the chapter

Section 20.2 briefly considers *framing effects* as a simple form of mental accounting. Under framing, informationally equivalent ways of presenting identical information that highlights different information cues, elicits different responses by the subjects. Since this phenomenon is pervasive and examples abound in this book, our discussion is brief and based on two classic experiments (McNeil et al., 1982; Kahneman and Tversky, 1984).

What kind of theoretical framework is suitable for an analysis of the wide diversity of mental accounting phenomena? One of Thaler's (1999) important insights is that Kahneman and Tversky's (1979) prospect theory can explain several mental accounting phenomena. Section 20.3 presents a general framework for when to segregate or integrate outcomes and applies this insight to the following simple example of a mental accounting problem. Consumers are more likely to travel to get a discount of \$5 on an item that costs \$15 as compared to a more expensive item that costs \$125. In each case, the saving is identical, which makes it difficult for neoclassical economics to account for the result.

Section 20.4 considers the *behavioral life-cycle model* (Shefrin and Thaler, 1988, 2004; Thaler and Shefrin, 1981; Thaler, 1980, 1985). The classical life-cycle model assumes perfect fungibility of money across all financial accounts. In contrast, evidence suggests that individuals code financial transactions into separate mental accounts and money is imperfectly fungible across all accounts. So, for instance, one might put aside money in a separate account for childrens' education. This would be unnecessary if money were fully fungible across accounts. Furthermore, the evidence suggests that the marginal propensity to consume out of these accounts is different. Thus, one might be less willing to raid the childrens' education amount relative to say, a mental account for drinking and leisure expenses.

If the marginal propensity to consume across distinct mental accounts differs, then the effect of salary composition, for instance, between wage and bonus, could have an effect on one's savings. Hence, the savings implications of defined pension contribution plans could be quite different from those suggested by the life-cycle model. The behavioral life-cycle model can also account for the reluctance of households to consume out of home equity, for the dependence of mandatory pension programs on demographic composition, and for the differential savings effects of small and large windfalls and of bonuses.

Why does the ticking of the taxi meter reduce one's pleasure from the taxi ride? Why do we normally prefer to prepay for a vacation? At the opposite extreme, why do we often prefer to buy consumer durables on installments? The life-cycle model in economics does not directly answer these stylized facts. For instance, delaying payments is preferable in the presence of time discounting, but in experiments with zero interest rate, subjects still prefer to prepay for vacations.

² A one-shot dictator game is a two-person game. In this game, a proposer (or dictator), proposes a division of a given sum of money between himself and a passive receiver who has an empty action set.

In Section 20.5, we use the *red* and *black* of mental accounting to address this class of questions (Prelec and Loewenstein, 1998). People prefer to have their mental accounts in the black (debt free) rather than in the red (under debt); this is a form of *debt aversion*.

We combine this insight with other insights from mental accounting. For instance, consumption that has already been paid for can be enjoyed as if it were free in the current period (*prospective accounting*). Furthermore, there is a *coupling* of benefits and costs. The thought of an impending payment reduces the current flow of utility from a good (ticking taxi meters). These insights allow us to explain the prepayment and postpayment for different kinds of goods, growing use of debit cards, use of tokens at casinos, dependence of mortgage payments on property values, popularity of fixed fee payment schemes, Club Med vacations, and gift giving among couples.

Individuals tend to break down complex problems into simpler ones that only require a subset of the information. These issues are examined in Section 20.6, under the rubric of *choice bracketing* (Read et al., 1999). An army general who focuses only on the battle at hand (*narrow bracketing*) might lose sight of winning the war (*broad bracketing*). Recall the problem of finding a taxi on a rainy day in New York that we considered in Part 1. One possibility is that taxi drivers set a daily target for earnings (narrow bracketing) rather than an income target over a longer period (broad bracketing). Narrow bracketing, in this case, leads to a backward bending labor supply curve (Camerer et al., 1997). Choice bracketing can also explain strategies used in “alcoholics anonymous,” i.e., set a daily target of relative abstinence (narrow bracketing) relative to a long-term target (broad bracketing). Other applications of choice bracketing include the desire for risk aggregation (Samuelson, 1963), and the equity premium puzzle (Benartzi and Thaler, 1995).

In classical economic theory, actual choices arise from well-defined initial preferences and well-defined subjective probability distributions over uncertain events. Contrary evidence has long been recognized in the work on *constructed preferences* (Slovic, 1995) and anchoring on irrelevant anchors (Tversky and Kahneman, 1974). Section 20.7 focuses on the experimental results from novel situations in which individuals are unlikely to have well-defined initial preferences (Ariely et al., 2003).

These results show that initial anchors have an inordinate effect on initial preferences. In this sense, initial preferences are *arbitrary*. However, once these preferences are embedded, subsequent preferences are *coherent*, for instance, in the sense that individuals display a well-defined demand curve; hence, the term *coherent arbitrariness*. These results can also explain the initial hype before mega sporting events, reluctance of firms to cut wages and inter-industry wage differentials, among others.

Section 20.8 considers the implications of sunk costs. In classical theory, sunk costs are irrelevant to current decisions. In actual practice, sunk costs often have an important bearing on current decisions (Kahneman and Tversky, 1984; Thaler, 1999; Shafir and Thaler, 2006). The reason is that individuals create a mental account for a particular category of expenditure. Sunk costs push this mental account into the red, which is aversive. Individuals then take actions to avoid closing accounts that are in the red. There is also some evidence that individuals react differently to sunk costs when they take the form of dollar amounts as compared to costs in terms of time (Soman, 2001). Empirical work also supports the idea that individuals have mental accounts for time (Rajagopal and Rha, 2009).

In Section 20.9, we consider an assortment of other mental accounting phenomena. In Section 20.9.1, we consider the distinction between *transaction utility* and *acquisition utility*. Transaction utility is salient when we make a purchase. The distinction between the two concepts can explain why we might buy less appropriate items at a sale, simply because they are cheaper, as in

Example 20.13. Section 20.9.2 answers the question of when to close an account (Thaler, 1999). The ideas developed here can explain the tendency to hold on to loss making stocks for too long and sell winners too early (Odean, 1998).

Section 20.9.3 shows that under mental accounting, *in-kind transfers* can dominate equivalent *cash transfers*. We give an illustrative example from the food stamps program in the US. The rationale for the existence of this program is in contrast to a standard result in neoclassical economics that demonstrates the dominance of cash transfers over in-kind transfers.

Section 20.9.4 extends loss aversion to a dynamic context using the observation that prior gains in casinos can induce individuals to take greater subsequent risks; this is known as the *house money effect* (Thaler and Johnson, 1990). However, no clear pattern on subsequent risk taking emerges in the case of prior losses. We also briefly comment on the relation between narrow bracketing and stock prices (Barberis and Huang, 2001).

In Section 20.9.5, we consider the *diversification heuristic* (Simonson, 1990; Read and Loewenstein, 1995). Diversification is generally good practice and consistent with rationality. However, in the presence of complex choices, individuals appear to engage in a naive form of diversification. For instance, when presented with an option to invest their wealth in n different options, individuals might diversify equally among the options. This is known as the $\frac{1}{n}$ *diversification heuristic* and has important implications for actual choices. For instance, in the domain of pension portfolios, it may lead people to choose portfolios that are dominated by stocks or by company assets (Benartzi and Thaler, 2001).

Section 20.9.6 considers the *mental accounting of goals*. Individuals often set goals and targets, e.g., completing term papers, quitting an addiction, losing a pre-specified amount of weight by a certain date, and so on. A literature that we consider in more detail in Part I, emphasizes the positive effects of goals (Locke and Latham, 1990). However, goals that are too ambitious are likely to be missed and can be counterproductive (Soman and Cheema, 2004); this is predicted by our model in Part I and supported by the evidence. Finally, we examine the *behavioral economics of retirement savings* in Section 20.9.7, and consider the role of several behavioral factors such as default options (opt-in or opt-out), initial contribution rates, and automatic escalation (Thaler and Benartzi, 2007; Benartzi and Thaler, 2013).

20.2 Framing and mental accounting

Mental accounting is used to describe the entire process of coding, categorizing, and evaluating events (Thaler, 1999). *Framing*, i.e., the presentation of a problem in informationally equivalent ways that highlight different information cues, is a form of mental accounting. Framing is not hard to demonstrate.

Example 20.16 (Kahneman and Tversky, 1984): *Imagine that the US is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows:*

Positive Framing: If program A is adopted, 200 people will be saved. If program B is adopted, there is a one-third probability that 600 people will be saved and a two-thirds probability that no people will be saved. Which of the two programs would you favor?

Negative Framing: If program C is adopted, 400 people will die. If program D is adopted, there is a one-third probability that nobody will die and a two-thirds probability that 600 people will die. Which of the two programs would you favor?

Under positive framing, the programs are framed in terms of *lives saved*. The result was that 72% of the respondents chose A, the safe option, and 28% chose B, the risky option. Under negative framing, only 22% chose the safe option, C, and 78% chose the risky option, D. The corresponding options (A and C; B and D) in each of the two frames are identical. Thus, in neoclassical economics, if A is preferred to B, then C must be preferred to D (or vice versa). The results show that individuals are risk averse for gains and risk loving for losses, which is an essential feature of prospect theory (see Part 1); the results also show that framing matters.

These results have been replicated for experienced professionals. For instance, when these experiments were conducted with World Bank staff, the outcome was similar. In this case, 75% chose the safe option under positive framing and 66% chose the risky option under negative framing (WDR, 2015, pp. 181–2).

Consider the following problem in which experienced physicians took part. Subjects in experiments received statistical information on the outcomes of two different treatments for lung cancer. Two different frames, the survival frame (positive framing) and the mortality frame (negative framing), were used. Both frames had identical information content that, in neoclassical economics, is not predicted to affect the outcomes.

Example 20.17 (McNeil et al., 1982): *In the “survival frame,” the choices were as follows:*
Surgery: Of 100 people having surgery 90 live through the postoperative period, 68 are alive at the end of the first year and 34 are alive at the end of five years.
Radiation therapy: Of 100 people having radiation therapy all live through the treatment, 77 are alive at the end of one year and 22 are alive at the end of five years.
In the “mortality frame,” the choices were as follows:
Surgery: Of 100 people having surgery 10 die during surgery or the post-operative period, 32 die by the end of the first year and 66 die by the end of five years.
Radiation therapy: Of 100 people having radiation therapy, none die during treatment, 23 die by the end of one year and 78 die by the end of five years.

The two informationally identical frames have a significant effect on outcomes. In the survival frame, 18% of the respondents favored radiation therapy. But in the mortality frame, this rose to 44%. The framing effect was exhibited equally by experienced physicians, statistically sophisticated business students, and clinic patients. Clearly, expertise does not mitigate mental accounting.

20.3 Prospect theory and mental accounting

Prospect theory is a convenient vehicle for modeling several aspects of mental accounting (Thaler, 1985). The central concepts in prospect theory such as reference point, loss aversion, and different attitudes to risk in the domain of gains and losses, can aid in the explanation of several mental accounting phenomena. Consider the following well-known experiment.

Example 20.18 (Tversky and Kahneman, 1981, p. 457): *Imagine that you are about to purchase a jacket for (\$125)/[\$15] and a calculator for (\$15)/[\$125]. The calculator salesman informs you that the calculator you wish to buy is on sale for (\$10)/[\$120] at the other branch of the store, located 20 minutes drive away. Would you make the trip to the other store? Two versions of the problem are given—in one version the figures in parentheses are given (\$125 for the jacket, \$15 for the calculator, and \$10 for the calculator in the sale) while in the other*

version, figures in square brackets are given (\$15 for the jacket, \$125 for the calculator, and \$120 for the calculator in the sale). At a price of \$15(\$125), 68%(29%) of subjects are willing to travel.

Let us now develop a framework to explain the finding in Example 20.18, as well as other similar findings. Denote wealth by y , and the reference point by r . Define $x = y - r$ as the increment in wealth relative to the reference point. Then, the power form of the utility function, v , in prospect theory (see Part I of the book for details) is given by

$$u(x) = \begin{cases} x^\beta & \text{if } x \geq 0 \\ -\lambda(-x)^\beta & \text{if } x < 0 \end{cases}. \quad (20.1)$$

Let us use the experimentally observed values of the parameters of the utility function: $\beta = 0.88$ and $\lambda = 2.25$ (Tversky and Kahneman, 1992). Using the properties of the prospect theory preferences, all of which are encapsulated in (20.1), Thaler (1985) gives the following plausible mental accounting conjectures.

1. *Multiple gains are segregated:* The utility function for gains under prospect theory is strictly concave. Hence, if there are several positive gains, they should not be combined (because the marginal utility of a larger amount is smaller). Instead *gains should be segregated*, perhaps temporally. The following analogy is helpful: If one receives a box of sweets one typically does not finish it in one go but tries to savor the enjoyment over time. Also, we typically do not like to wrap all Christmas presents in one box. As a numerical example, if $x = 100$, then one prefers to split it up into two equal gains of 50 each; using (20.1) we get

$$(100)^{0.88} < (50)^{0.88} + (50)^{0.88} \Rightarrow 57.544 < 62.535,$$

which is true. This result holds more generally for a strictly concave function v in gains such that $v(0) = 0$. Let $a > 0$ and $b > 0$ be two strictly positive outcomes, expressed relative to the reference point. Then strict concavity of v in gains implies that $v(b+a) - v(a) < v(b) - v(0)$, which can be rewritten as $v(b+a) < v(a) + v(b)$. Thus multiple gains are segregated.

2. *Multiple losses are integrated:* The utility function under prospect theory is strictly convex for losses. Hence, using the converse argument to the previous case, *losses should be integrated*. For instance, if $x = -100$, then the decision maker will prefer to integrate two equal losses of 50; using (20.1), we get

$$-2.25(100)^{0.88} > -2.25(50)^{0.88} - 2.25(50)^{0.88} \Rightarrow -129.47 > -140.7,$$

which is true. More generally, consider two strictly positive outcomes, $a > 0$ and $b > 0$, expressed relative to a reference point. Suppose that v is strictly convex in losses and $v(0) = 0$, then $v(0) - v(-a) > v(-b) - v(-(b+a))$ or $v(-b) + v(-a) < v(-(b+a))$. Thus, it is optimal to integrate losses. Consequently, sellers will attempt to lump together items for sale; for instance, adding options to a car at the time of purchase. It is as if the additional options have an inelastic demand, once they are combined with a larger purchase.

3. *Mixed net gains are integrated:* Individuals using prospect theory exhibit *loss aversion*. So the absolute value of the disutility arising from a small loss is equivalent to the utility arising from a larger gain. Insofar as individuals do not like their mental accounts to go into the

“red” (see Section 20.5), they should *integrate small losses with larger gains*. Thus, using (20.1), a loss of \$5 can be offset against a gain of 12.565 because

$$-2.25 (5)^{0.88} + (12.565)^{0.88} = 0.$$

This is also sometimes known as the *principle of cancellation*; one can cancel the smaller loss against a larger gain. If the two outcomes (12.565, -5) are integrated for a net outcome of 7.565, then the utility is $(7.565)^{0.88} > 0$. Consider any outcome pair $(b, -a)$, where each outcome is measured relative to a reference point. Let $0 < a < b$, so $b - a > 0$ (net gain), then we have $v(b) + v(-a) < v(b - a)$. The proof is straightforward. By the definition of loss aversion, we have $v(a) < -v(-a)$, thus,

$$v(b) + v(-a) < v(b) - v(a). \quad (20.2)$$

But v is strictly concave in gains, so

$$v(b) - v(a) < v(b - a) - v(0). \quad (20.3)$$

$v(0) = 0$ due to reference dependence, thus, from (20.2), (20.3) we get

$$v(b) + v(-a) < v(b - a),$$

as claimed.

4. *Mixed net losses and the silver lining principle*: Consider any outcome pair $(b, -a)$, where each outcome is expressed relative to a reference point such that $0 < b < a$, so $b - a < 0$ (net loss). In this case, $v(b) + v(-a) \leq v(b - a)$, so, in general, we cannot say anything about integration/segregation of outcomes. If b is small relative to a , for instance, the pair (40, -6000), then we have large net losses $b - a$. In this case, we are likely to have $v(b) > v(b - a) - v(-a)$, provided that the curvature of the utility function is not too flat or the net loss is very large. Suppose that the parameter of the utility function in (20.1), $\beta = 0.75$, then for the pair (40, -6000), the condition $v(40) > v(40 - 6000) - v(-6000)$ requires that

$$(40)^{0.75} > -2.25 (5960)^{0.75} - (-2.25 (6000)^{0.75}),$$

or $15.9 > 7.7$, which is true. In this case, one should *segregate large losses from small gains*; this is known as the *silver lining principle*. At the other extreme, when b is not too different from a , as in the pair (40, -50), then integration ($v(b) + v(-a) < v(b - a)$) may be optimal. For the pair (40, -50), integration is optimal if $v(40) + v(-50) < v(40 - 50)$. Applying the prospect theory utility function with $\beta = 0.75$, we get

$$(40)^{0.75} - 2.25 (50)^{0.75} < -2.25 (10)^{0.75}$$

or $-26.4 < -12.7$, which is true.

Let us revisit Example 20.18 in the light of the silver lining principle. Consider the outcome pair $(b, -a) = (5, -125)$; the item is expensive and costs \$125, and one can save \$5 by travelling to the other store. So $0 < b < a$, but b is small. From the silver lining effect, in this case, one

segregates the large loss from the small gain, so one does not travel to get the extra discount. In terms of the prospect theory utility function with $\beta = 0.75$,

$$(5)^{0.75} > -2.25(120)^{0.75} - (-2.25(125)^{0.75}),$$

or $3.3437 > 2.5362$, which is true. In the other case of the cheaper product that costs \$15, we have $(b, -a) = (5, -15)$, the converse arguments show that integration is optimal, and one undertakes the trip to the other store to save \$5. The usual calculation in this case is

$$(5)^{0.75} - 2.25(15)^{0.75} < -2.25(10)^{0.75},$$

or $-13.806 < -12.653$, which is true.

20.4 The behavioral life-cycle model

A central assumption in various versions of the life-cycle model in economics is that money is fungible across various accounts. This assumption allows one to write the intertemporal budget constraint in the following well-known form: The present discounted value of consumption is bounded above by the present discounted value of income from all sources. In a series of papers, Shefrin and Thaler (1988, 2004), Thaler and Shefrin (1981), and Thaler (1980, 1985) have questioned this assumption.

Another important feature of their critique, in relation to the life-cycle model, is to model the self-control problems that one's own future selves might have and how, in anticipation of these problems, one's previous selves take remedial measures. The previous selves are encapsulated in the form of a *planner*, who cares for the utility of all the subsequent selves. All subsequent selves, one for each time period, termed as the *doers*, are myopic in that they care only about maximizing their own utility.³ Shefrin and Thaler describe models with these features as *Behavioral Life-Cycle Models* (BLC).

We have found it more useful to separate the issues arising from a planner–doer framework and those that arise from mental accounting. The planner–doer framework and issues of self-control are treated in Parts 3 and 6 of the book. In this chapter, we focus on life-cycle considerations that arise when one takes into account issues of mental accounting.

20.4.1 *Mental accounting and the life-cycle model*

In the dynamic context, as in the static context, empirical evidence suggests that individuals create a system of accounts such that money is not fully fungible across the accounts. Evidence suggests fairly detailed and disaggregated mental accounting. However, for tractability, we consider disaggregation into the following three main mental accounts (Shefrin and Thaler, 2004). A *current income account* (*I*), a *current asset account* (*A*), and a *future wealth account* (*F*). A distinguishing feature of these accounts is that some are more tempting to invade than others. In particular, accounts that are considered “wealth” are less tempting than those that are considered as “income”.

³ The idea that future selves have potential self-control problems that a current self might correct (the two-self models) can also be found in Elster (1979), Margolis (1982), and Schelling (1984).

In classical economic theory, there is no issue of “invading” financial accounts. However, much empirical evidence indicates that individuals have present-biased preferences (see Part 3 of the book); such individuals are particularly susceptible to invade financial accounts.

Suppose that an individual has a stream of income over T periods, given by $y_1, y_2, \dots, y_T$. The individual retires in period T , so $y_T = 0$. There are perfect capital markets and the interest rate is zero. Suppose that the individual saves a fraction, λ , of income each period for retirement; perhaps the individual takes part in a pension scheme that deducts a fraction of income in each period. In time period $0 \leq t < T$, the account position is as follows.

The *current income mental account* is given by

$$(1 - \lambda)y_t \equiv I_t. \quad (20.4)$$

The *current asset mental account* is given by the cumulative sum

$$\sum_{\tau=1}^{t-1} [(1 - \lambda)y_{\tau} - c_{\tau}] \equiv A_t, \quad (20.5)$$

where $(1 - \lambda)y_{\tau} - c_{\tau}$ is the discretionary, or non-pension, savings made in period $\tau \leq t - 1$. The *future wealth mental account* is given by

$$\sum_{\tau=t+1}^T (1 - \lambda)y_{\tau} + \sum_{\tau=1}^T \lambda y_{\tau} \equiv F_t. \quad (20.6)$$

The first term on the LHS in (20.6) gives the disposable income (after pension deductions have been made) summed across all future periods and the second term gives the pension wealth over the lifetime.

It is easiest for the individual to spend from the current income account, more difficult to invade the current asset account, and most difficult to invade the future wealth account. The current asset account is sometimes disaggregated into sub-accounts. For instance, a childrens' education account could be designed to finance a child's education; such an account would be very difficult for an individual to invade.⁴

There is also evidence that small windfalls are coded by individuals as part of the current income account while larger windfalls are coded as part of the current asset account (Milkman and Beshears, 2009). Home equity is treated by some individuals as part of the current asset account, while others might treat it as part of the future wealth account. Asset income is usually kept in the current asset account but there is some evidence that dividend income might be kept in the current income account (Shefrin and Statman, 1984). Shefrin and Thaler (2004, p. 401) write: “While the mental accounting system described here may seem bizarre to economists, it is remarkably similar to the accounting systems used by most private universities.” Graham and Isaac (2002) present survey evidence, which supports this mental accounting practice.

The difference in the degree of difficulty of invading various accounts suggests that the individual has an *account specific marginal propensity to consume*. Shefrin and Thaler (2004) report an experiment with MBA students in Santa Clara University that provides support for this view.

⁴ A long-standing co-author of mine has a practice of keeping a book account. His large, and constantly growing, book collection is a testament to the effectiveness of such accounts.

Courant et al. (1986) find that the marginal propensity to consume out of the current asset account is about 0.25, but the marginal propensity to consume out of the future wealth account is significantly smaller.

Individuals are also likely to code labor income as current income and capital income as current asset income. Holbrook and Stafford (1971) find that the marginal propensities to consume out of labor and capital income are, respectively, 0.9 and 0.7. When the marginal propensity to consume is account-specific and constant, we get that consumption, c_{tj} , at time t , financed from account $j = I, A, F$ is given by

$$c_{tI} = \alpha_I I_t, \quad (20.7)$$

$$c_{tA} = \alpha_A A_t, \quad (20.8)$$

$$c_{tF} = \alpha_F F_t, \quad (20.9)$$

where $\alpha_I, \alpha_A, \alpha_F$ are, respectively, the constant marginal propensities to consume from the income, current asset, and the future wealth mental accounts. Shefrin and Thaler (2004) interpret the empirical evidence as suggesting the following magnitudes

$$\alpha_I \approx 1; 0 < \alpha_A < 1; \alpha_F \approx 0. \quad (20.10)$$

Levin (1998) used the Longitudinal Retirement Survey for individuals in their late 50s or older and distinguished between ten consumption categories and finds support for the pattern of marginal propensity to consume given in (20.10).

Using (20.7) to (20.10), one expects that

$$c_{tI} \approx I_t; c_{tA} = \alpha_A A_t; c_{tF} \approx 0. \quad (20.11)$$

One role of mental accounting is to act as a mechanism of self-control (Thaler, 1999). But how does the individual decide which mental accounts to create? Is it always clear which mental account a new item of expenditure should be assigned to? It is quite possible that there is some ambiguity with respect to both questions. Is it possible that an individual might engage in creative book-keeping or try to find loopholes to sidestep the very controls that were initially designed to help in the self-control problems? These sorts of questions are posed by Cheema and Soman (2006). They cite the following example from Mark Twain. “Having limited himself to one cigar a day, he started shopping for bigger and bigger cigars until he had each made to such proportions that he ‘could have used it as a crutch.’” This is an example of a loophole in the original mental account (1 cigar a day) that did not specify the size of the cigar.

Elsewhere, Soman and Cheema (2001) ask which mental accounts should unexpected windfalls be classified into? Because such windfalls are unexpected, there is potential ambiguity about which mental account they could be classified into. It is shown that this gives an opportunity for individuals to use such gains to clear accounts that are in the red. For instance, such gains could be used to write off sunk costs.

20.4.2 *Some predictions of the mental accounts model*

We now examine some of the predictions arising from the application of mental accounts to the life-cycle model.

(1) *Pensions and savings*: Choi et al. (2009) document evidence consistent with mental accounting from the 401(k) pension plans in the US, based on a change in rules in 2003. In contrast to the assumption of perfect fungibility across accounts, they found that individuals do not adequately consider the spillover effects across various accounts in their portfolios. Thus, they act as if they considered these accounts to be separate, as in the mental accounting literature.

Suppose that an employee pension scheme makes it mandatory to contribute an extra dollar of income. Thus, the total contribution to the pension scheme is now the sum of the initial contribution, λy_t , and the extra dollar, for a total of $1 + \lambda y_t$ dollars in contribution. What can we say about the effect on the total saving made by the individual? The prediction of the standard life-cycle model is that aggregate savings are unaffected. This is because money is fungible across accounts and the individual offsets one unit of private savings to make up for the extra unit of mandatory saving towards the pension account. These arguments are routinely used to illustrate neutrality effects in fully funded pension plans in the classical life-cycle model.

Now suppose that in the presence of mental accounting, the marginal propensities to consume differ across the three main accounts (I , A , and F). The method of financing extra pension contributions will now affect the amount of private savings that are offset. If the extra dollar of income comes out of the current income account, then, from (20.7), (20.11), consumption falls by one dollar so private savings are unaffected. If the extra dollar of pension contributions comes out of the current asset account, then it is shared between a fall in consumption and a fall in savings; the respective shares depend on the size of α_A ; evidence supports this prediction (Diamond and Hausmann, 1984; King and Dicks-Mireaux, 1982). Insofar as the young have a higher marginal propensity to consume out of the current asset account, α_A , relative to the old, the implications of mandatory pension programs are also contingent on the demographics of a society.

In neoclassical theory, the mix between dividends and capital gains is irrelevant for consumption. However, empirical evidence suggests that dividend and capital gains incomes are not fungible and realized dividends have a larger, positive, impact on consumption (Baker and Wurgler, 2007). Thus savings of individuals are lower if they receive a greater fraction of their income as dividends, relative to capital gains. Furthermore, dividends are withdrawn from the household portfolio at a relatively larger rate than capital gains, which is consistent with the predictions of the mental accounting model.

(2) *Housing wealth*: What are the implications of rapidly rising house prices on the consumption and savings behavior of households? The mental accounts approach would first attempt to uncover evidence on how households code an increase in equity income arising from an increase in house prices. Evidence suggests that households code housing wealth somewhere in between the current asset account and the future wealth account, so the marginal propensity to consume out of an increase in housing equity is relatively small; evidence indicates it is not statistically different from zero (Skinner, 1989). This result contrasts with the life-cycle model in which individuals should interpret an increase in housing equity as an increase in the present discounted value of income. Thus, they should have the same marginal propensity to consume out of it as they have out of current income. Evidence, however, suggests that even the elderly are reluctant to consume out of housing equity. The possibility that such behavior on the part of the elderly simply reflects the bequest motive can be ruled out (Hurd, 1987).

(3) *Bonuses and windfalls*: In the life-cycle model, bonuses are one component of income, so whether a part of one's income is received as bonuses or otherwise has no effect on consumption and savings behavior. However, in the Thaler–Shefrin framework, bonuses are coded as a part of the current asset account. Therefore, the marginal propensity to consume out of bonuses is lower than that of regular income. The implication is that bonuses increase the savings of individuals.

Thaler and Shefrin (2004) report supportive evidence from an empirical study based on Japanese data.

What about windfall income? The prediction of the mental accounting model depends on the size of the windfall income (Thaler, 1990). When windfalls are small relative to income, they are coded as part of the current income account where the marginal propensity to consume is 1. However, large windfalls are coded as a part of the current asset account where the marginal propensity is relatively lower. Landsberger (1966) considered the receipt of money received by Jewish families as restitution from Germany after World War II. Consistent with the prediction of the mental accounting model, those who received the largest windfalls as a fraction of their incomes, had the smallest marginal propensity to consume.

Further evidence supportive of mental accounting in the domain of small windfalls is presented in Heilman et al. (2002), Milkman and Beshears (2009), and Abeler and Marklein (2013). Milkman and Beshears compared the consumption behavior of online grocery store consumers when they were given small vouchers to spend at the store (about \$10) and when they were not given such vouchers. Controlling for customer fixed effects, they found that a \$10 voucher increased spending by \$1.59. Furthermore the target of the increase were items that consumers would typically not buy from the store. By contrast, since these small windfalls comprise a negligible fraction of total lifetime income, they should leave current consumption unaffected in the classical model; this is rejected by the evidence.

The source of the windfall matters too. Income from the sale of a security is typically coded as a part of the current income account, hence, the marginal propensity to consume is 1 (Summers and Carroll, 1987). However, unrealized capital gains are treated as a part of the current asset account, hence, relatively less likely to be reflected in current consumption (Hatsopoulos et al., 1989). Whether windfalls are anticipated or unanticipated is reflected in consumption-effects that exceed those that one would expect from the neoclassical life-cycle model (Arkes et al., 1994).

20.5 The red and black of mental accounting

Prelec and Loewenstein (1998) distinguish between two binary states of mental accounts. A mental account is said to be in the *red* if it is in debt and in the *black* if it is debt free. Evidence indicates that individuals derive satisfaction if their accounts make a transition from red to black. In other words, individuals behave as if they have *debt aversion*.

The standard model of discounted utility in discrete time proceeds as follows. Suppose that the consumer makes a purchase and T_b , T_c , respectively, are the sets of discrete time periods for which the benefits accrue and payments are made. The purchase generates a dated stream of utilities or benefits, $\{u_t\}_{t \in T_b}$, and a dated stream of payments or costs, $\{p_t\}_{t \in T_c}$. So, for instance, if a consumer buys a washing machine that gives utility over periods 1, 2, 3, and requires payments over periods 2, 3 (as in mortgage purchases), then $T_b = \{1, 2, 3\}$, $T_c = \{2, 3\}$. Suppose that the individual applies the discount factors δ_b , δ_c , respectively, to the streams of benefits and costs. Then, in the discounted utility model, the consumer should make the purchase if

$$\sum_{t \in T_b} \delta_b^t u_t - \mu \sum_{t \in T_c} \delta_c^t p_t > 0, \quad (20.12)$$

where μ is the marginal utility of money that converts a payment term into its utility equivalent. The *discounted utility decision criterion* given in (20.12) implies the following.

1. DU1: On account of discounting, the consumer prefers to pay later rather than earlier.
2. DU2: For any two arbitrary but different streams of benefits and costs *with identical present discounted values*, the purchase decision is identical. In other words, the characteristics of the two streams such as whether payments precede or succeed the stream of benefits are not relevant to the purchase decision.

Prelec and Loewenstein (1998) give the following two examples, based on experimental evidence, that violate DU1, DU2.

Example 20.19 (*Vacation*): Suppose that you are going to be away on vacation, six months from now. The cost of the vacation is \$1200. There are two methods of payment. In method 1, you pay six monthly payments of \$200 prior to the vacation. In method 2, you pay six payments of \$200 after returning from the vacation. In experiments, 60% of the subjects preferred method 1 (preponement of payment) despite an implicit interest penalty of about \$50 arising from paying earlier.

Example 20.20 (*Consumer durables*): Six months from now you will be purchasing a clothes washer/dryer that costs \$1200. There are two methods of paying. In method 1 you can pay in six equal monthly installments of \$200 starting now while in method 2, you pay in six equal monthly installments of \$200 with the first installment beginning in six months time. Now 84% of subjects prefer method 2 (postponement of payment).

In other examples, Prelec and Loewenstein find that the preference for prepaying does not apply only to luxury goods (e.g., vacations) but also to items covering miscellaneous living expenses. In another experiment, they find that a majority of subjects decline the offer of advance payment for work. Each of these examples show a form of debt aversion, which takes the form of aversion to consumption before paying for it, or getting advance payments for future work. One possible explanation for some of these results is that individuals prefer an increasing profile of consumption. In light of these anomalies, Prelec and Loewenstein propose an alternative theory that is based on the following main considerations.

- A1: (*Prospective accounting*) Consumption that has already been paid for can be enjoyed as if it were free in the current period. If payments are made prior to the enjoyment of benefits from a good, then, at the time of making the payments, the pain arising from the payments is mitigated by thoughts of future benefits.
- A2: (*Coupling*) While enjoying the benefits from a good, consumers could be thinking of the payments. Conversely, while making the payments, consumers could be thinking of the benefits. Prelec and Loewenstein term this as *coupling* between benefits and costs. Alternative methods of payment have different degrees of coupling. So, for instance, credit cards weaken coupling while cash payments strengthen it.
- A3: (*Prorating*) Essentially this implies that at any time, the remaining future benefits or costs are equally divided (prorated) over the remaining periods when the consumer constructs hedonic benefits and costs.

The theory can be formalized as follows.

First, we identify how the consumption experience (the benefit from consumption) of the consumer is modified by thoughts of payments. Define *hedonic benefits* or *net experienced utility* in period t as

$$u_t - \mu \hat{p}_t, \quad (20.13)$$

where u_t is the *experienced utility* at time t ; $\hat{p}_t$, to be formally defined below, is the imputed (not actual) cost in period t ; and μ is the marginal utility of money. The imputed psychological cost, $\mu\hat{p}_t$, reduces some of the benefits from consumption.

Next, we take into account how the payment experience (the cost of consumption) is influenced by thoughts of benefits received from the good. Define hedonic costs or *net experienced disutility* in period t as

$$\hat{u}_t - \mu p_t, \quad (20.14)$$

where $\hat{u}_t$ is the imputed (not actual) psychological benefits when one makes a payment of p_t . The imputed benefit offsets some of the cost of the good and if $\hat{u}_t - \mu p_t > 0$, it more than fully offsets the cost.

Second, we introduce a loss-aversion by a parameter $\eta \in [0, 1]$; as in prospect theory, losses are more salient than gains. Loss aversion applies to both experienced utility and experienced disutility, i.e., when $u_t - \mu\hat{p}_t < 0$ or $\hat{u}_t - \mu p_t < 0$. The “loss-aversion weights” are defined as follows.

$$\begin{cases} 1 - \eta & \text{if } u_t - \mu\hat{p}_t \geq 0 \text{ or } \hat{u}_t - \mu p_t \geq 0 \\ 1 + \eta & \text{if } u_t - \mu\hat{p}_t < 0 \text{ or } \hat{u}_t - \mu p_t < 0 \end{cases}$$

Define $T_b^+ \subset T_b$ for which $u_t - \mu\hat{p}_t \geq 0$ and $T_b^- \subset T_b$ for which $u_t - \mu\hat{p}_t < 0$. Similarly, define $T_c^+ \subset T_c$ for which $\hat{u}_t - \mu p_t \geq 0$ and $T_c^- \subset T_c$ for which $\hat{u}_t - \mu p_t < 0$.

Third, we use the following *purchase criterion* that captures the *red and black of mental accounts*. The individual buys the good if and only if

$$\begin{aligned} & \left(\sum_{t \in T_b^+} \delta_b^t (1 - \eta) [u_t - \mu\hat{p}_t] + \sum_{t \in T_b^-} \delta_b^t (1 + \eta) [u_t - \mu\hat{p}_t] \right) \\ & + \left(\sum_{t \in T_c^-} \delta_c^t (1 + \eta) [\hat{u}_t - \mu p_t] + \sum_{t \in T_c^+} \delta_c^t (1 - \eta) [\hat{u}_t - \mu p_t] \right) > 0. \end{aligned} \quad (20.15)$$

The first bracket gives the present discounted value of hedonic benefits while the second bracket is the present discounted value of hedonic costs. In the absence of loss aversion, i.e., $\eta = 0$ and the absence of hedonic affects, i.e., $\hat{u}_t = \hat{p}_t = 0$, (20.15) collapses to the standard discounted utility case of (20.12).

To operationalize the purchase criterion given in (20.15), we must define how the consumer imputes the values $\hat{u}_t, \hat{p}_t$. In principle, $\hat{u}_t$ and $\hat{p}_t$ can depend non-linearly on the entire stream of benefits and costs respectively. However, assuming a linear relation between imputed costs/benefits and the entire stream of costs/benefits, we get

$$\hat{p}_k = \sum_{t \in T_c} \omega_{tk}^c p_t; \quad k \in T_c, \quad (20.16)$$

where ω_{tk}^c is the fraction of period t price, p_t , that contributes to the imputed cost at time k , $\hat{p}_k$. If past prices do not influence current imputed costs, then $\omega_{tk}^c = 0$ for $t < k$.

Similarly, define

$$\hat{u}_k = \sum_{t \in T_b} \omega_{tk}^b u_t; \quad k \in T_c, \quad (20.17)$$

where ω_{tk}^b is the fraction of date t benefit that contributes towards the imputed date k benefits. Notice that variations in $\hat{p}_k$, $\hat{u}_k$ over time are caused by variations in the coefficients $\omega_{tk}^c, \omega_{tk}^b$ across time.

Definition 20.8 *The entire set of coefficients $\{\omega_{tk}^c, \omega_{tk}^b\}_{t,k}$ is called a consumer's mental accounting system.*

There are several alternative ways of constructing an individual's mental accounting system. Prelec and Loewenstein use *prospective accounting*, *coupling*, and *prorating over multiple events* (see A1–A3, above) to operationalize (20.16), (20.17) as follows.

$$\hat{p}_k = \alpha \left(\frac{u_k}{\sum_{t>k} u_t} \right) \sum_{t>k} p_t, \quad (20.18)$$

$$\hat{u}_k = \beta \left(\frac{p_k}{\sum_{t>k} p_t} \right) \sum_{t>k} u_t, \quad (20.19)$$

where $\alpha \geq 0, \beta \geq 0$ are the *coupling parameters*. α denotes the marginal impact of the importance of future payments in reducing net experienced utility or hedonic benefits at time t . β denotes the marginal impact of the importance of future benefits in buffering the pain of current payments or hedonic costs. So, for instance, if $\alpha = \beta = 0$ and $\eta = 0$, then (20.15) collapses to the standard discounted utility model in (20.12). In forming imputations $\hat{u}_k, \hat{p}_k$ in period k , the consumer ignores costs and benefits that arose in earlier periods (*prospective accounting*). The benefits and costs are *prorated* (which is reflected in the terms $u_k / \sum_{t>k} u_t, p_k / \sum_{t>k} p_t$).

Substituting (20.18), (20.19) in (20.13), (20.14) we get the hedonic benefits (or net experienced utility) and hedonic costs (or net experienced disutility) at time k as follows

$$\text{Hedonic benefits: } u_k - \mu \alpha \left(\frac{u_k}{\sum_{t>k} u_t} \right) \sum_{t>k} p_t. \quad (20.20)$$

$$\text{Hedonic costs: } \beta \left(\frac{p_k}{\sum_{t>k} p_t} \right) \sum_{t>k} u_t - \mu p_k. \quad (20.21)$$

Suppose that an individual prepays for an item, as in the vacation example. Then, given prospective accounting, hedonic benefits at date k , using (20.20), are simply given by actual benefits at date k , u_k (since $\sum_{t>k} p_t = 0$). However, if the individual buys an item on installments to be paid after the purchase, as in the case of consumer durables, then the thoughts of future payments mitigate the current benefits, as shown in (20.20).

Analogously, (20.21) captures the effect on hedonic costs when there are some future benefits to be derived from the purchase. In the special case when all payments are to be made after all benefits from the item have ceased to exist, then hedonic costs at date k are simply given by

Figure 20.1 Hedonic costs (light vertical lines) and hedonic benefits (bold shapes) for the two cases of prepayment and postpayment for vacations.

$-\mu p_k$ (since $\sum_{t>k} u_t = 0$). Hence, the “state” of the cost and the benefit accounts, *red or black*, influences hedonic costs and benefits; and, by implication, the purchase decision in (20.15).

Prepaying increases the current hedonic benefits by shrinking the term $\sum_{t>k} p_t$ (see (20.20)). However, the purchase decision in (20.15) clarifies the disadvantage; delayed payments bite less on account of the discount factor. This trade-off will sometimes make prepaying an optimal choice as in the vacation example. In other cases, it is optimal to pay later, as in the consumer durables example.

We illustrate this with the case of our vacation example. The consumer durables case is left as an exercise for the reader. The vacation example is represented in Figure 20.1. The vertical axis measures hedonic costs and benefits, as defined in (20.20), (20.21). The horizontal axis measures time. For the two alternative payment options, the bold shapes (the rectangle in panel A and the irregular shape in panel B) represent the temporal hedonic benefits. The lighter vertical lines represent the temporal hedonic costs at a particular date.

The vacation lasts over the time interval T_b . Suppose first that the vacation is prepaid in equal monthly installments of $\$p$ (panel A). Here, the benefit is received during the vacation period when all costs have been prepaid, so using (20.20), the hedonic benefits (or net experienced utility) per period equal the actual benefits during each time period in the vacation, u_t , $t \in T_b$. The experienced utility is shown by the area of the rectangle in panel A, after the vacation has been paid for by monthly installments. On the other hand, using (20.21), the hedonic costs (or net experienced disutility), shown by the vertical bars, falls over time because the outstanding payments $\sum_{t>k} p_t$ get reduced (while $\sum_{t>k} u_t, p_k$ are constant for all k). Thus, just before the vacation begins, the cost of the vacation is no longer aversive; the anticipation of future utility from the vacation coupled with prospective accounting swamps all costs.

Now consider panel B, where all payments are made after enjoying the vacation. As the vacation progresses, the remaining benefits of the vacation, $\sum_{t>k} u_t$, fall. Hence, using (20.20), the hedonic benefits fall as the vacation progresses. Towards the end of the vacation, the remaining benefits are minimal while the complete set of payments looms large so that the hedonic benefits

become negative. The vacation benefits have all been enjoyed in the past, so given the *prospective accounting* assumption, the hedonic costs stay the same in all periods following the vacation (or see (20.21)). It is quite possible that despite making adjustments for discounting, pre-paying for a vacation can be the optimal choice depending on the relative sizes of α , β and the streams of benefits and costs.

We now briefly outline some other predictions of the model.

1. **Mortgage payments and property values:** Generally speaking, hedonic benefits and hedonic costs can be thought of as two separate accounts. The accounts can be in the red or in the black. Individuals have a preference to keep the accounts in black (debt aversion). Hence, when the benefits from an item are declining, individuals would like to accelerate payments, otherwise the benefits account will go into red. This is obvious from (20.20); as $\sum_{t>k} u_t$ falls, one way to keep hedonic benefits high is to make a large current payment, p_k , in order to reduce the outstanding payments, $\sum_{t>k} p_t$. Therefore, one prediction of the model is that mortgage payments will increase if property values are anticipated to fall.
2. **Growing use of debit cards:** If individuals are debt-averse and prepayment increases the hedonic utility from consumption of the good, we should observe sellers taking advantage of this phenomenon. This potentially explains the growing use of debit cards (when they do not offer significant advantages over a credit card) because by paying upfront (as in the vacation example), individuals can ensure that their mental account does not go into red. Another possible example is the use of tokens in casinos. Whilst the act of buying a token gives hedonic pain, on account of parting with the money, the pain is cushioned by thoughts of future benefits as in (20.21). Furthermore, once the payment is in the past, the consumer gets a higher hedonic utility while actually playing in the casino (prospective accounting). This induces the individual to pay upfront for the casino tokens. A similar reasoning might apply to individuals who go on holiday to a foreign country and report that things are much cheaper abroad even when they are not. Once they have paid for the holiday and changed into the foreign currency, prospective accounting ensures that they can enjoy the holiday as if it were free.
3. **Popularity of fixed fee tariffs:** Perhaps the desire for prepayment also explains the popularity of fixed fee payment schemes such as unlimited Internet access, once an initial fee is paid. Telephone companies also engage in similar pricing schemes. Prelec and Loewenstein (1998) report that in one study, about 65% of consumers selected a flat rate telephone payment scheme when an alternative variable rate scheme would have saved them money. In contrast, only 10% of those who choose the variable rate payment option could have saved money by switching to the flat rate scheme. The mental accounts explanation would be that talking on the phone is less pleasurable under a variable rate scheme because the hedonic benefits of a currently enjoyable conversation are tempered by thoughts of future payment (see (20.20)). For a similar reason, a taxi ride is perhaps made less pleasant by the sight of the taxi meter ticking away. All these are examples of *payment decoupling* due to prospective accounting.
4. **Club Med vacations and gifts:** An increase in the coupling parameter α is bad news for the purchase decision because it reduces the hedonic benefits; see (20.20). Hence, it would seem to be in the interests of sellers to decouple benefits from costs. So, for instance, the Club Med vacation covers several activities (travel, meals, lodging and recreation) under a single fee so that the consumer feels that individual activities are uncoupled from the fee; see Thaler (1980). Another interesting application is to gift giving. Why do couples with joint accounts give gifts to one another? Perhaps the gift uncouples the payment from the

benefits for the receiver. The gift item might actually turn out to provide significant hedonic utility to the receiver who in the absence of the uncoupling might have agonized over its purchase.

20.6 Choice bracketing

In neoclassical economics, when faced with the problem of making a choice from a particular domain, individuals consider all available information and all available choices. *Choice bracketing* occurs when individuals group the available choices into sets, and view these sets in isolation from one another, or do not take into account the set of all possible choices. If not all choices are considered, or all available information is not used, then an individual is said to be engaged in *narrow choice bracketing*. By contrast, in neoclassical economics, individuals might be said to be engaged in *broad choice bracketing*.

In a dynamic setting, narrow choice bracketing occurs when individuals take actions in any time period by only considering the costs and benefits in that period, rather than optimally choosing the entire intertemporal profile of actions. A wide range of behaviors seems consistent with some form of choice bracketing. Our treatment in this section is based on Read et al. (1999). Consider the following examples under certainty.

Example 20.21 (*War strategy*): Consider an army general who is engaged in fighting a war that consists of a sequence of battles. In theory, one expects that the general is concerned about winning the war. However, if the general engages in narrow choice bracketing, he might give undue importance to winning particular battles, with the possibly unpleasant result of losing the war. So, for instance, in a battle that involves securing a particularly strategic position, such as high ground, a consideration of the battle alone (narrow choice bracketing) might dictate retreating because of the heavy losses involved. However, that could have a serious consequence for subsequent battles and for winning the war.

Example 20.22 (*Smoking*): Consider a smoker who brackets choices narrowly. Thus, the decision to smoke each cigarette is taken in terms of its current costs and benefits while ignoring the effect on future utilities. Because the future costs are underweighted in this decision, narrow choice bracketing is likely to promote smoking. However, under broad bracketing, the individual must consider that at the rate of a packet a day, such a strategy could lead her to smoke 7300 cigarettes a year. So, under broad bracketing, the individual might decide not to smoke. The choice of narrow or broad bracketing might also involve issues of emotions, temptation, and addiction, over which the individual could have limited self-control.

Example 20.23 (*New York cab drivers*): Camerer et. al. (1997) found that New York cab drivers have a particular earnings target for the day. This is a form of narrow bracketing because the cab drivers choose a very short horizon. On a busy day, therefore, they might quit earlier, generating a backward bending supply curve of labor. If they were to choose broad bracketing, say, in the form of maximizing earnings over a year, then they could presumably earn more; this appears to be the case for more experienced drivers. On the other hand, the gain from narrow bracketing might be an improvement in personal motivation (see below).

Although choice bracketing has been largely ignored in economics, models in economic theory often implicitly assume and invoke it. So, for instance, a consumer's risk aversion is often defined over her aggregate wealth. However, several kinds of insurance contracts deal with only very small

changes in wealth (such as an appliance breaking down). Individuals would have to be absurdly risk averse in some cases to buy such insurance. Hence, the presumption must be that individuals look at the cost and benefits of such actions in isolation, which is a form of narrow bracketing.

Under uncertainty, choice bracketing leads to other interesting effects as the following two examples show.

Example 20.24 (*Equity premium puzzle*): Suppose that individuals can invest either in bonds, or in equity. Consider two individuals who use prospect theory to evaluate risky choices: Mr. Anxious and Mr. Relaxed. The former checks portfolio returns far more regularly than the latter. Equity returns fluctuate more than bonds, and in any period, are as likely to go up as down. On account of loss aversion, observing equity returns will be stressful for both types of individuals, but particularly for Mr. Anxious who checks the portfolio more frequently. Hence, Mr. Anxious will hold stocks only if the return on equity is relatively higher. Within a temporal choice bracketing context, one description of Mr. Anxious is that he engages in narrow choice framing. Rather than being affected by the longer-run return on the equity, he is too sensitive to frequent fluctuations. If there are a large number of Mr. Anxious types in the population, then for equity to be held, arbitrage will ensure that there is a premium on equities, relative to the normal case of broad bracketing (Benartzi and Thaler, 1995).

Example 20.25 (*Risk aggregation*): Sometimes several gambles might be accepted if they are bracketed broadly, but not when they are bracketed narrowly. In a famous example, the Nobel laureate Paul Samuelson asked a colleague if he would accept the following gamble: win \$200 or lose \$100 with equal probability (Samuelson, 1963). The colleague replied that he would reject this bet but would accept 100 such bets.

In fact, if the colleague happens to be a prospect theory maximizer, he would prefer even two such bets to a single bet, as we now show. Suppose that the prizes (\$200 and \$100, respectively) reflect outcomes relative to the reference point. Consider the utility function in (20.1) with the empirically supported parameter values $\beta = 1$ and $\lambda = 2.25$ (see Part 1 of the book for details). Assuming linear probability weighting, the value function under prospect theory for a single bet is

$$V_1 = \frac{1}{2}(200) - \frac{1}{2}2.25(100) = -12.5 < 0. \quad (20.22)$$

When there are two bets, the following sequence of outcomes is equally possible: (200, 200), (200, -100), (-100, 200), (-100, -100). Suppose that if the individual accepts the two-period bet, he derives utility from the sum of undiscounted payoffs over the two periods. This is the sense in which he brackets broadly; narrow bracketing would take the form of treating the two separate bets as one-period bets; since the bets are identical, using (20.22) we know that $V_1 + V_1 < 0$. Given our assumptions, under broad bracketing, the four possible equally likely outcomes are 400, 100, 100, -200; the individual is in the domain of gains in the first three cases and in the domain of losses in the last case. The value function in this case is given by

$$V_2 = \frac{1}{4}(400) + \frac{2}{4}(100) - \frac{1}{4}2.25(200) = 37.5 > 0.$$

Thus, if the individual brackets broadly and aggregates the bets over the two periods, then he accepts ($V_2 > 0$). However, if he were to use narrow bracketing, and treat the two bets separately, then he rejects ($V_1 + V_1 < 0$).

Rabin and Weizsäcker (2009) apply narrow bracketing to explain the experimental findings in a problem in Tversky and Kahneman (1981). In this problem, individuals are given two sets of choices with two options within each set. Individuals are found to choose in a manner that is consistent with prospect theory: Choose the safe option in the domain of gains and the risky option in the domain of losses. However, when the two chosen options are combined, they are first order stochastically dominated by the combination of the two unchosen options. This behavior can be explained by narrow bracketing, which makes it acceptable for subjects to have missed out the stochastic dominance in the combined choices (broad bracketing).

The reason for why people engage in narrow bracketing is not well known. Read et al. (1999) conjecture the following possibilities. One possibility is that cognitive limitations preclude a consideration of the entire domain of choice. However, there is some experimental evidence that the heuristic of narrow bracketing arises even in the absence of cognitive limitations. Yet another possibility is that choice bracketing could be acquired by social norms and conventions. For example, we often divide the week into two unequal lengths: the working week and the weekend, and we label food as meals or snacks.

A particularly important justification for narrow bracketing is that it might reduce or overcome problems associated with self-control. Alcoholics under treatment are usually asked to take one day at a time (narrow bracketing) because the possibility of lifetime abstinence (broad bracketing) is too daunting. Narrow bracketing, in this case, improves motivation. Successful batsmen in the game of Test cricket, when asked about their batting strategy often say that they take one session of play at a time (narrow bracketing) rather than planning to bat out for the entire day. Or a tennis player may focus on winning one set/game at a time to keep motivation at a high level. Motivation might also explain the behavior of New York cab drivers mentioned above. By setting an attainable target over a short period of time, they are less likely to be daunted by the prospect of achieving a more ambitious target, say, a yearly income target.

Broad bracketing, under the typical assumptions in neoclassical economics, may be expected to achieve the global maximum. However, in the absence of these assumptions, narrow bracketing has certain advantages. First, broad bracketing might create relatively greater anxiety because targets and goals that it prescribes are likely to be more ambitious, so possibly more daunting as well. Second, and related to the first, narrow bracketing might be a better motivational device. Third, under broad bracketing, people need to take account of a larger set of factors that is more cognitively demanding, a factor that is important when relatively quick decisions need to be made, or when higher cognitive loads render the underlying problem too difficult/impossible to solve. Thus, in this case broad bracketing might lead to procrastination. Insofar as individuals make errors in computation and prediction, the consideration of a larger set of factors might also magnify errors. There are also other cognitive costs of engaging in broad bracketing, such as greater record keeping.

20.7 Coherent arbitrariness

Neoclassical economic theory rests on the foundation that choice reflects well-defined preferences. So, for instance, when consumers have preferences defined over consumption bundles, then, under certain conditions, the consumer has a downward sloping demand curve. Now suppose that we start with a downward sloping demand curve. Can we infer that consumers have well-defined initial preferences?

Ariely et al. (2003) consider this issue and advance the concept of *coherent arbitrariness*. They find that initial preferences of individuals might well be arbitrary. However, once arbitrary preferences get entrenched, then, economic agents behave in a coherent manner with respect to these preferences. So, for instance, a consumer's initial valuation for a product might differ noticeably from the fundamental value (*arbitrariness*). However, if the quality of the product is subsequently improved, consumers are willing to pay more, just as economic theory predicts (*coherence*).

The idea that preferences are not well defined initially, but become more clear as the decision process unfolds has also been suggested in other contexts. See, in particular, the idea of *constructed preferences* in Slovic (1995). In other contexts, it has been shown that preferences are quite malleable. For instance, in experiments on the elicitation of risk preferences conducted before and after the 2007 financial crash, the post-crash preferences are more risk averse (Gong et al., 2013).

So how do consumers *anchor* their initial preferences? The arbitrariness of the initial anchor can be illustrated by the following well-known experiment (see Section 19.6 in Chapter 19). Tversky and Kahneman (1974) found that the answers of subjects in experiments to the question of the number of African countries in the UN depended on the prior random outcome of a roulette wheel (arbitrary anchor). Similar results have been replicated in other contexts.⁵

The implication of these results is that consumers may not approach novel situations with well-defined, preexisting, preferences, nor with well-defined subjective probability distributions over outcomes. Hence, initial impressions and initial accidents of history are important anchors. So, for instance, the marketing decisions associated with the launch of a new product are often critical determinants of how much consumers are willing to pay for the product. Since marketing personnel are likely to be aware of these issues, there is a potential role for government regulation to ensure that accurate and transparent information is transmitted to consumers in the first instance.

To test the arbitrariness of anchors for initial preferences, Ariely et al. (2003) needed consumers, in this case MIT students, to value a product that they did not have any market experience of. They came up with the willingness to accept a payment (WTA) in return for the experience of listening to an unpleasant sound. Three groups of students were first asked to listen to a sample of unpleasant noise for 30 seconds. The first group was offered a payment of 10 cents (the low anchor group), the second group was offered a payment of 50 cents (the high anchor group), and the third group did not receive any anchor information. Thus, the initial payment was used as the (arbitrary) anchor. Then, they were asked if they would be willing to hear the same noise in return for a payment.

The WTA of the three groups of students was then elicited for increasing (10 sec, 30 sec, and 60 sec) and decreasing (60 sec, 30 sec, and 10 sec) durations of sounds; each sequence was repeated over three rounds. The results, for each sequence and for each of the three rounds, are shown in Figure 20.2. There are two main results. First, there is an almost linear relation between WTA and the duration of the sound (coherence). Second, the WTA was significantly higher in the high anchor group relative to the low anchor group and the no anchor group; indeed the high anchor group earned less money in the experiment, relative to the other two groups. There was no convergence of WTA among the high and low anchor groups. Repeated experience with the experiment did not override the anchoring effect.

One confounding factor in this experiment may arise if subjects infer that the anchors represent some risk to their hearing. Hence, the experiment was repeated with another group of

⁵ Green et. al. (1998) and Kahnemann and Knetsch (1993) find that a higher (lower) initial anchor elicits a higher (lower) willingness to pay for a public good. For other examples, see Section 19.6 in Chapter 19.

Figure 20.2 The WTA of the three groups of students for increasing and decreasing durations of sounds.

Source: Dan Ariely, George Loewenstein, and Drazen Prelec, "Coherent arbitrariness: stable demand curves without stable preference." *The Quarterly Journal of Economics* (2003) 118(1): 73–106, by permission of Oxford University Press.

students and the initial anchor used was the first three digits of the subject's own social security number. Also, in this experiment, the stakes were raised by a factor of 10. It turned out that subjects with smaller social security numbers required much lower payments, hence, it is anchoring that is at work. As in the previous experiment, subjects exhibited coherence by demanding higher payments for exposure to noise of a longer duration.

To test the results in a concrete economic environment, in yet another experiment, the subjects are initially exposed to an arbitrary anchor. Then their WTA was elicited in an auction. The idea is for subjects to listen to other bids and adjust their WTA in light of this market information. The high and the low anchors in this case were \$1 and 10 cents, respectively. The anchoring results survive. The mean WTA for the high (low) anchor group was 59 cents (8 cents). The WTA for the two anchor groups does not converge, although the variance of bids within each group reduces as the experiment is repeated.

Fudenberg et al. (2012) find, unusually, very weak anchoring effects for goods, and an absence of anchoring effects for lotteries. However, anchoring is one of the most robust findings in the heuristics literature (see Chapter 19). In general, the results survive with multiple anchors and non-monetary rewards. The role of anchors in determining subsequent choices can potentially explain several puzzles. For instance, why asset prices might have an arbitrary component that is unrelated to fundamentals? Anchoring might also explain the findings of Bewley (1998) that reducing payment to workers reduces morale but workers are less concerned about their wages relative to wages elsewhere; in this case, the anchor is the wage in one's own firm. This also potentially explains why inter-industry wage differentials can persist; see for example Thaler (1989).

20.8 Sunk costs and mental accounting

Neoclassical economics is based on a *marginalist principle*: Individuals are guided by the marginal costs and the marginal benefits of their actions. In particular, the fixed or sunk costs that might

have been incurred previously are irrelevant. However, experimental evidence indicates that sunk costs do have an important influence on the actual action taken.

Kahneman and Tversky (1984) report an experiment in which subjects in the experiments are told that they purchased a theater ticket for \$10 in advance (sunk cost) but subsequently lose it before the event. These subjects were less willing to buy another ticket (46%) as compared to a second set of subjects who were told that they had lost an equivalent sum of money (88%). Perhaps, consumers create a mental account on “theater outings” and losing the ticket is seen as an outflow from this account, while losing an equivalent amount of money leaves this account unaffected.

Suppose that you purchased a ticket for \$100 to see a basketball game, but there is a blizzard on the day of the game. Will you go to see the game? The cost of the ticket is a sunk cost and should not influence the decision to travel in a blizzard. However, individuals are more willing to travel in the blizzard if they already hold the ticket (Thaler, 1980). The explanation is that individuals have a mental account for the basketball game. It is debited for the \$100 when the ticket is purchased. If the game is missed, then the account must be closed in the red, which is aversive to the ticket holder, but not to a non-ticket holder. There is a cost of travelling to the game. However, Heath (1995) suggests that since these costs are not directly monetary, they are not included in the relevant mental account.

Sunk costs have real effects on decisions. However, the effect of sunk costs can wear off over time; this is known as *payment depreciation*. Thaler (1999) gives the following example. Suppose that you buy shoes that seem comfortable at the time of buying, but after wearing them for a day they feel uncomfortable. You try wearing them for the next few days but it gets worse. At this point, the shoes cannot be returned because of the wear and tear on them. If the shoes cannot be returned, then their purchase is a sunk cost. Thaler then makes the following plausible conjectures, which illustrate important mental accounting principles.

1. If the shoes are more expensive, you will try to wear them more often, despite the discomfort.
2. You will eventually stop wearing the shoes, but the more expensive are the shoes, the longer they will sit in the closet before being eventually thrown away.
3. Irrespective of how expensive the shoes, they are eventually thrown away.

The individual's behavior in 1 and 2 above is an example of the influence of *sunk costs*. The behavior in 3 is an example of *payment depreciation*, i.e., eventually people ignore sunk costs. See Arkes and Blumer (1985) for evidence on how the effect of sunk costs can persist, but the effect vanishes eventually. Gourville and Soman (1998) give evidence on payment depreciation in the context of payments for health club memberships. Thus, once the (depreciated) sunk costs fall below some lower limit, say, $\underline{c}$, the mental account is closed.

One could make use of the concepts of *acquisition utility* and *transaction utility* (see Section 20.9.1) to understand this example better. Suppose that the individual uses transaction utility to make the purchase decision, but then evaluates the subsequent experience in terms of acquisition utility. Since the shoe turns out to be smaller than expected, the ex-post valuation of the shoe, v , is lower. To consider an extreme case, suppose that ex-post, $v = 0$, so that the acquisition utility is $-p$ per period. The mental account corresponding to this purchase is, thus, in the red, equal to the dollar amount p . If losses depreciate continuously at the rate δ each period, then the mental account is closed when $pe^{-\delta t} = \underline{c}$, where t is the time period at which the equality is satisfied. It is clear that the size of t is increasing in the absolute magnitude of the loss, p . Hence, more expensive (but useless) shoes are kept in the closet longer before being thrown away.

Shafir and Thaler (2006) asked the following question to subscribers of a wine newsletter.⁶

Example 20.26 “Suppose you bought a case of a good 1982 Bordeaux in the futures market for \$20 a bottle. The wine now sells at auction for about \$75 a bottle. You have decided to drink a bottle. Which of the following best captures your feeling of the cost to you of drinking this bottle?” The respondents were given five answers to choose from: \$0, \$20, \$20 plus interest, \$75, and –\$55. The percentages of respondents choosing each answer was 30, 18, 7, 20 and 25.

This is a question on opportunity cost that lies at the very heart of any introductory course in economics. Based on an opportunity cost calculation, the correct answer is \$75, and the sunk cost of \$20 is irrelevant. However, more than half the respondents report that drinking the bottle either costs nothing or actually saves them money. There is a wide range of answers among these seasoned wine drinkers. When the experiment was posed in terms of giving the bottle away (rather than drinking it), then 30% gave the correct answer, \$75. The authors conclude that wine drinkers think of their initial purchase as an investment. People who choose the –\$55 option, for instance, think that the value of the investment turned out to be \$75, but they paid \$20, so they saved \$55. Thus, more than half the responders think that drinking the bottle either costs them nothing, or actually constitutes a saving.

Shafir and Thaler (2006) follow up this experiment with the following.

Example 20.27 “Suppose you buy a case of Bordeaux futures at \$400 a case. The wine will retail at about \$500 a case when it is shipped. You do not intend to start drinking this wine for a decade. At the time that you acquire this wine which statement more accurately captures your feelings?” (a) I feel like I just spent \$400, much as I would feel if I spent \$400 on a weekend getaway. (b) I feel like I made a \$400 investment which I will gradually consume after a period of years. (c) I feel like I just saved \$100, the difference between what the futures cost and what the wine will sell for when delivered.

Participants were asked to give a score from 1 (strongly agree) to 5 (strongly disagree) to each of the three options. The mean scores for the three choices were 3.31, 1.94, 2.88 (the lowest score indicates the strongest agreement). Hence, responders gave the maximum approval to option (b), the investment option, rather than the saving option (c).

Combining the results of the two experiments, the authors conclude the following. The wine connoisseurs think of the initial purchase as an investment. At a later date, the wine is drunk as if it were free. This is similar to the feature of *prospective accounting* in Prelec and Loewenstein (1998) that we consider in Section 20.5. This explains the title of the Shafir–Thaler paper: *Invest Now, Drink Later, Spend Never*. Furthermore, a large proportion of individuals (55%) start thinking in terms of the opportunity cost (\$75) if the question is posed in terms of the wine bottle having been broken accidentally. Indeed, breaking the bottle makes the replacement cost of the bottle more salient in a way that giving away the bottle does not.

Does the form of sunk costs matter? In particular, does it matter if sunk costs are expressed in terms of dollar value or in terms of time? The experimental evidence in Soman (2001) suggests that *sunk-time costs* have a smaller effect on actual actions relative to *sunk-dollar costs*. He gives three main distinguishing factors that are the source of the difference. First, time is perceived as

⁶ The wine newsletter in question, *Liquid Assets*, used to be published by the economist Orley Ashenfelter. The subscribers are extremely knowledgeable wine consumers who have substantial home cellars. In many cases, these are economists or business executives so they should, in principle, be able to fully appreciate the choices in the experiment.

a flow variable rather than a stock variable, which makes it difficult for an individual to make an inventory of the time expended on various activities. Second, in contrast to dollar costs, the disutility from expending time might not be directly proportional to the actual time spent. This disutility depends, for instance, on how enjoyable the activities undertaken during this time were, and how productively the time was spent. Finally, most people, particularly students, may have better training in accounting for money as compared to time. Navarro and Fantino (2009), however, find that sunk-time costs are also important, but that they can be moderated. There is also some evidence to suggest that individuals' willingness to pay is higher for risky options that involve time rather than money (Okada and Hoch, 2004).

Rajagopal and Rha (2009) ask if individuals have mental accounts for time, in a similar manner to the mental accounts that they have for money. They postulate two mental accounts for time: work and non-work. In experiments, they find that individuals face different degrees of anguish if they are delayed for work or non-work activities, suggesting that time is not fungible across these two mental accounts.

20.9 Some other mental accounting phenomena

In this section we consider an assortment of mental accounting phenomena.

20.9.1 Transaction utility and acquisition utility

Suppose that an individual has a valuation for an object, $v > 0$, and pays a price p to acquire it. Then, the net valuation of the object, or the *acquisition utility*, U_A , is

$$U_A(v, p) = v - p. \quad (20.23)$$

Acquisition utility corresponds to consumer surplus. A related concept is *transaction utility*, U_T , defined as follows (Thaler, 2008).⁷

$$U_T(\bar{p}, p) = \bar{p} - p, \quad (20.24)$$

where $\bar{p}$ is the reference price or the regular price that the consumer expects to pay. Thaler (2008) feels that the most important determinant of $\bar{p}$ is fairness, which depends on the costs of the seller. This is supported by the experimental evidence (Thaler, 2008, Table 1, p. 19). Transaction utility would dictate buying the good only if the actual price is below the reference price, i.e., $\bar{p} \geq p$. The total utility from the purchase is $U(v, \bar{p}, p) = U_A + U_T$.

Example 20.28 (Thaler, 1985, p. 189): *You are lying on the beach on a hot day. All you have to drink is ice water. For the last hour you have been thinking about how much you would enjoy a nice cold bottle of your favorite brand of beer. A companion gets up to go make a phone call and offers to bring back a beer from the only nearby place where beer is sold (a fancy resort hotel) [a small, run-down grocery store]. He says that the beer might be expensive and so asks how much you are willing to pay for the beer. He says that he will buy the beer if it costs as much or less than the price you state. But if it costs more than the price you state*

⁷ Thaler (2008) is a reprint of Thaler (1985).

he will not buy it. You trust your friend, and there is no possibility of bargaining with the (bartender) [store owner]. What price do you tell him?

The median willingness to pay for the beer from the resort and the grocery store was, respectively, \$2.65 and \$1.50 in 1984 prices. To rationalize this, suppose that the decision criterion of the consumer is to purchase the object if $U_T \geq 0$. Hence, if the consumer has a higher reference price, $\bar{p}$, for the resort relative to the grocery shop, then he would also be willing to pay a higher actual price, p . These results are quite striking because in each case, the object of consumption is an identical bottle of beer in an identical environment and there are no strategic considerations.

This would also appear to explain why we sometimes buy items at a sale that we do not find very useful subsequently. The reason is that transaction utility is salient at the time of a purchase. This rule, namely, over-purchase when the actual price is lower than the reference price can also be used to explain the puzzle in Example 20.13, where the individual buys a king size quilt when a queen size quilt would have been more appropriate.

20.9.2 *When to close an account?*

Individuals find it more difficult to close an account that is in the red. Consider a portfolio that has two assets. One of the assets has been going up in value, while the other has been going down in value. The gains and losses can either be *accrued* (so long as the stock is unsold), or they can be *realized* (if the stock is sold). Realized gains and losses seem more painful relative to accrued gains and losses (Thaler, 1999). If individuals have a mental account for returns on the stock and they find it aversive to close it in the red, then they are reluctant to sell losers. So if they have to raise some money they are more likely to sell winners. In contrast, the neoclassical prediction would be to sell losers because tax laws typically allow realized losses to be offset against other gains, allowing one to reduce the overall tax owed (Shefrin and Statman, 1985). Empirical evidence shows that people do indeed sell winners and hold on to loss making stock for too long—this is known as the disposition effect (Odean, 1998).

20.9.3 *Self-control and gift giving*

Let us take as given that individuals construct mental accounts that deal with distinct items of consumption. It is observed that people often set *low* budgets for some accounts. For instance, an individual who is worried about excessive wine consumption might cap his “wine mental account” at some upper limit, say, $\$a$. Suppose that a wine comes up on the market at a price $\$b > \$a$ for which the individual’s willingness to pay is $\$c > \$b$. In the absence of mental accounts, it is optimal to buy the wine. However, with a capped mental account, it is optimal not to buy. It is quite possible that a gift of the wine to this individual will be better appreciated relative to receiving an equivalent sum of money. This contrasts with the well-known result that, in the presence of convex indifference curves, equivalent sums of money must always be preferred to payments in kind.

Individuals might wish to cap expenditures on bads or sin goods, such as cigarettes and alcohol, because they realize that they may have self-control problems in the future. One form of expenditure capping for bads is an increased demand for smaller packets of the sin goods. The demand for such items, packaged in small amounts, can potentially create a premium above the price at which they are normally sold; this was found to be true for cigarette packets (Werthenbroch, 1998).

AN EXAMPLE: THE FOOD STAMP PROGRAM

Consider the Food Stamp Program in the US, which is the cornerstone of the *Federal food assistance programs*. The Food Stamp Program enables low-income families to buy nutritious food with coupons and Electronic Benefits Transfer (EBT) cards. Food stamp recipients spend their coupons to buy eligible food from authorized retail food stores. Neoclassical economic analysis predicts that government assistance in the form of equivalent cash benefits leads to higher utility for consumers, relative to in-kind assistance such as food coupons. We demonstrate the reverse to be true when the individual engages in mental accounting.

Suppose that a consumer derives utility from two goods only: food (Y) and all other goods lumped together as a composite good (X). The individual has a fixed, and low, amount of income, $I > 0$. The price per unit of X is normalized to unity, while the price of Y per unit is $p > 0$. The consumer's problem in the absence of any government intervention is to choose X, Y , to maximize a utility function $U(X, Y)$ that is increasing, concave, and twice continuously differentiable, subject to two constraints. The first constraint is the usual budget constraint that constrains expenditure to be no greater than income.

$$X + pY = I. \quad (20.25)$$

The second constraint is a mental accounting constraint. The individual has a system of mental accounts such that he evaluates expenditures on food arising from his own income in a separate account. The individual caps the expenditure on the food account *from his own income* at some number $\$c > 0$.

$$pY \leq c \Leftrightarrow Y \leq \frac{c}{p} \equiv y. \quad (20.26)$$

If the individual is given some *gift* of food, say, $\hat{y}$, then he is willing to consume up to an amount $\hat{y} + y$, but never buys more than y units from his own income. We assume, for simplicity of analysis, that the mental accounting constraint (20.26) is invariant with respect to changes in income or government policy. The individual's indifference curves in (food, non-food) space are very flat, hence, the individual buys too little food. We also make the mental accounting assumption that the individual treats all gifts of income as his own income.

In Figure 20.3, the vertical line at y indicates the maximum food that the individual is willing to buy with own income. The budget constraint in (20.25) is shown by the line AC . The intersection of the two constraints gives the convex choice set AB . Since the price of X is normalized to unity, the height of point A also gives I . The optimum is at B (an indifference curve is shown passing through it).

Direct Income Transfer Scheme: Suppose that the government provides assistance to the poor directly through an *income transfer scheme*. The individual's income, inclusive of the additional income, is now $\bar{I} : \bar{I} > I$. The new budget constraint under the *income transfer scheme* is given by

$$X + pY = \bar{I}, \quad (20.27)$$

and is shown by the line DH in Figure 20.3. Given our assumptions, the constraint (20.26) is unchanged. The intersection of the two constraints gives the convex choice set DF . The consumer's new optimum is at F .

Figure 20.3 The relative optimality of food stamps and direct cash benefits.

Food Stamp Program: Suppose now that the government undertakes a *food stamps program* and provides food stamps equal to F_s , expressed in units of Y , to the household, as shown in Figure 20.3. To ensure comparability of the two alternative government programs, we assume that the nominal transfer of income is the same in each case, i.e.,

$$pF_s = \bar{I} - I. \quad (20.28)$$

The budget constraint under the food stamp program is given by

$$X + p(Y - F_s) = I. \quad (20.29)$$

Given our assumptions, with the introduction of the food stamp program, the individual is willing to buy a maximum amount $F_s + y$ of food. Substituting (20.28) in (20.29) we get that $X + pY = \bar{I}$, which is identical to the budget constraint in the case of the direct income transfer scheme. Thus, under the food stamp program, the choice set of the individual is given by the convex choice set EGJ .

The optimum in the case of the food stamp program at point G , is on a higher indifference curve relative to the optimum for the income support program (at point F). Hence, under mental accounting, in-kind transfers may dominate cash transfer. Although our example is contrived to directly show the efficacy of the food stamp program under mental accounting, it highlights a more fundamental idea. If policymakers can understand the mental accounting system used by the poor, then policy intervention may lead to a Pareto improvement; the World Bank Development Report, 2015, highlights several such channels.

20.9.4 The house money effect

Thaler and Johnson (1990) extend the insights from static loss aversion in prospect theory to a dynamic context. Subjects in their experiments were given the following three problems. The percentage of subjects making each choice is given in square brackets.

Problem 1. You have just won \$30. Now choose between:

(a) A 50% chance to gain \$9 and a 50% chance to lose \$9. [70]

(b) No further gain or loss. [30]

Problem 2. You have just lost \$30. Now choose between:

(a) A 50% chance to gain \$9 and a 50% chance to lose \$9. [40]

(b) No further gain or loss. [60]

Problem 3. You have just lost \$30. Now choose between:

(a) A 33% chance to gain \$30 and a 67% chance to gain nothing. [60]

(b) A sure \$10. [40]

In Problem 1, subjects have made a prior gain. This induces more than two thirds of them to subsequently choose the risky option, a phenomenon known as the *house money effect*; gamblers refer to money they have won in a casino as *house money*. Furthermore, they are likely to put their winnings in a separate mental account from their own money (Thaler, 1999). Hence, a prior gain can induce risk seeking. Problems 2, 3 illustrate the ambivalent nature of a prior loss. Problem 2 shows the converse result from Problem 1; a prior loss can induce more conservative behavior. However, Problem 3 shows that a prior loss can also stimulate risk seeking. The difference between Problems 2 and 3 is that option (a) in Problem 3 gives a chance to break even, while this is not the case in Problem 2.

The house money effect, namely, that current attitudes to risk are conditioned by previous gains and losses has several applications. Barberis and Huang (2001) apply this idea to the following puzzle in finance. At the level of an individual stock, returns over time have a high mean, are highly volatile, and lagged returns have some predictive ability to forecast future returns. However, the cross-sectional evidence is that stocks whose price relative to fundamentals is low have higher than average returns.

Barberis and Huang postulate that the utility of individuals is influenced not only by the final levels of consumption, but also by the gains and losses in the value of individual stocks. Furthermore, the evaluation of current gains and losses depends on previous gains and losses. Thus, for instance, if a stock, say stock A, has been performing well in the recent past, investors become less concerned about future losses on the stock. In other words, previous gains offset (in a psychic sense) future losses. An implication is that investors view the stock as less risky. Conversely, if a stock, say stock B, has been making losses in the recent past or not doing too well, then it is perceived as more risky. This, in turn, induces perceived changes such that possible future losses from the stock become relatively more salient. For the individual to be willing to hold stock B, its returns must increase in equilibrium. Hence, stocks fluctuate in value, below-par performance being followed by above-par performance.

Furthermore, the more the return fluctuates, the greater the psychic costs on the loss averse individual, so the greater must be the average expected return on the asset for it to be held in the portfolio. When investors in Barberis and Huang (2001) derive utility from changes in the value of individual stocks, they engage in a form of *narrow bracketing*. An alternative, which is considered by the authors, is for investors to focus on the changes in the aggregate value of their portfolios as, for instance, would be recommended under *broad bracketing*. However, empirical evidence in this case is more supportive of the narrow bracketing approach. Information on the gains and losses of individual stocks is more readily available relative to aggregate information on various portfolios.

Rockenbach (2004) reports on experimental evidence whereby investors keep separate mental accounts for risky and riskless assets. Investors exhibit features of loss aversion when they react to changes in the value of assets in the risky portfolio. However, the presence of separate mental

accounts hinders the exploitation of arbitrage opportunities across the different accounts, especially if money is not fungible across the accounts. This multi-layered portfolio approach supports the behavioral finance theory of Shefrin and Statman (2000).

20.9.5 *The diversification heuristic*

The *diversification heuristic* exemplifies the human tendency to choose too much variety when presented with a larger set of alternatives, *each of which can be simultaneously chosen*. The situation may be quite different when only one alternative can be chosen, in which case a greater number of choices may result in a choice impasse. The term diversification heuristic was used by Read and Loewenstein (1995) and Benartzi and Thaler (2001) credit Simonson (1990) with the first demonstration of this heuristic. Some diversification is always optimal and lack of diversification is most likely to be suboptimal. However, in the presence of a sufficient degree of complexity in the choices, the observed extent and nature of diversification is often quite naive and unlikely to be the outcome of a neoclassical optimization exercise.

In an extreme form of the diversification heuristic, when faced with many different options, subjects may choose each option equally. Consider the following quote from Benartzi and Thaler (2001, p. 79): “Writing in about the fourth century, a Rabbi Issac bar Aha gave the following asset allocation advice: ‘A man should always place his money, a third into land, a third into merchandise, and keep a third at hand.’ There is anecdotal evidence that this rule is still in use.”

The growth in defined pension contribution plans raises the issue of the financial sophistication of individual decision makers to optimally allocate funds in their portfolios. Benartzi and Thaler (2001) ask employees to make a choice among alternative retirement funds. They find that individuals prefer to diversify by using simple heuristics. One of the retirement funds offered one bond option and one stock option. On average, half the portfolio was allocated to the stock. But if another stock was added to the possible portfolio, then the average allocation towards each stock was a third. This motivates the authors to propose the idea of a $\frac{1}{n}$ heuristic: When individuals have n funds to choose from, they divide their portfolio equally among the alternatives. While some diversification is generally good, here the extent of diversification is naive.

Picking from funds that contain predominantly stocks, an individual who uses the $\frac{1}{n}$ heuristic will load his portfolio towards stocks. Likewise, picking from a fund that contains predominantly bonds, the portfolio will be loaded towards bonds. Benartzi and Thaler (2001) confirm this by comparing two different actual pension plans. In one plan, the TWA plan, the choices comprise of five core stocks and one core bond. The average portfolio chosen in this case has 75% stocks. Another pension plan, the University of California plan, comprises of four core bonds and one core stock. Here, the average portfolio has 34% stocks, well below the national average of 57% stocks in retirement portfolios.

Other supporting evidence from the US shows that individuals invest excessively in the stocks of their own companies (Poterba, 2003; Mitchell and Utkus, 2004). In a related problem, individuals invest too much in home stocks that they are more familiar with, forgoing the diversification benefits from investing in foreign stock (French and Poterba, 1991; Cooper and Kaplanis, 1994; Lewis, 1999; Solnik and Zuo, 2011). However, there is some evidence that investors are improving the extent of their diversification (French, 2008).

Read and Loewenstein (1995) focus on the behavior of trick-or-treaters on Halloween night as they visited different houses.⁸ In the first treatment, the sequential choice condition, the children

⁸ This is one of four different experiments that supports the diversification heuristic in their paper.

were offered a choice between two candies, Three Musketeers and Milky Way, in two consecutive houses. In the second treatment they were told at the first house they visited to “choose whichever two candy bars you like” from a large pile of both types of candies. In the first treatment, 52% of the children picked up two pieces of their favorite candy at the two houses and 48% picked different candies. In the second treatment, they showed a strong desire to diversify and all children picked each candy of a different type.

20.9.6 *The mental accounting of goals*

Individuals often set a variety of goals for themselves. Goals can be very explicit (all or nothing goals). For instance, losing x kilos of weight over t time periods. Or goals might be less well-specified (graded goals). For instance, a simple target of reducing weight over time. Other examples of goals include writing term papers, completing referee reports, cleaning one's room, quitting an addiction such as smoking, and resuming physical activity after surgery.

Evidence shows that setting goals improves performance (Locke and Latham, 1990; Orbell and Sheeran, 2000). Two important factors that are conducive to an improvement in performance are whether the goal is well-specified (as opposed to vaguely specified goals such as “do your best”) and “the level of difficulty” of the goal. The evidence on the positive effects of goals is considered in Part 1 of the book.

However, goals that are too difficult may be less helpful for the individual; for a theoretical analysis of goals, see Part 1 of the book. Soman and Cheema (2004) ask if such goals are counterproductive. In particular, they consider cases where individuals miss their goal, and the effect of a failure to achieve the goal on subsequent behavior. They look at two well-specified goals: a saving's goal and a task completion goal that imposes a deadline. Soman and Cheema point out the following main drawbacks of goals.

First, on account of mental accounting, individuals might code outcomes as gains or losses. Missing a goal is coded as a loss, so it reduces utility much more sharply. This is particularly true of the all-or-nothing goals where, ex-post, one cannot rationalize missing a goal. However, for graded goals, one can rationalize one's behavior better, and possibly reduce the set of outcomes in the domain of losses. Second, missing an all-or-nothing goal generates strong negative emotions. The individual then engages in *emotional repair*. This takes the form of diverting attention to those activities that generate a feeling of well-being and positive emotion. Emotional repair could take the form of a pleasurable, but eventually harmful activity or a redirection of goals that diverts from the original goal. Third, following a period in which one suppresses an activity in order to achieve a goal (e.g., smoking), one's craving for it can reach a level that is higher relative to the level without suppression. This is termed as the *rebound effect*.

In conjunction, these effects might make goals counterproductive in some cases. The experimental results in Soman and Cheema support their assertion.

20.9.7 *The behavioral economics of retirement savings*

Thaler and Benartzi (2007) outline the behavioral economics approach to retirement savings; we return to these issues with a complementary discussion in Part 8. We summarize their main findings as follows.

1. Enrollment defaults: In actual practice, the tax rules in most countries provide significant inducements to contribute to pension plans. These rules include tax deductible contribu-

tions and tax deferred accumulations of pension savings. However, the take-up of pension plans is often suboptimal, possibly due to procrastination and inertia in joining these plans. There is significantly more participation in retirement savings plans when the default option automatically enrolls, but individuals can choose to opt-out if they desire (Choi et al., 2002, 2004); this is the opt-out approach. However, in the converse case of the opt-in approach, participation is much lower.

Why do defaults influence choices? One potential explanation is that initial preferences, particularly for new or unknown options, need to be constructed (Slovic, 1995; discussion in Section 20.7). However, constructing preferences is cognitively costly, while accepting a default option is costless, hence, more likely to be accepted. This channel is probably even more important in the face of procrastination arising from present-biased preferences.

2. Complexity of the pension plan: There is a negative correlation between the number of investment options offered in the savings plan and the participation rates. Furthermore, a simplification of pension plans in terms of a pre-selected contribution rate and asset allocation reduces procrastination and improves the take-up of pension plans (Choi et al., 2009; Beshears et al., 2013a).
3. Initial contribution rates: Initial contribution rates in many savings plans are found to be too low. The typical default savings rate is 2–3% and the investment choice is normally a conservative one (e.g., money market account). Savers often use mental heuristics to decide on contribution rates as multiples of 5 or save at the minimum rate required to get employers to match at the upper allowable limit.
4. Portfolio allocation: Many pension plan participants use the $\frac{1}{n}$ decision heuristic, i.e., given a choice between n investments, choose to allocate the portfolio equally among the options; see Section 20.9.5, above. Experts in finance need not be exempt from the diversification heuristic. Thaler and Benartzi (2007) report the following quote from Harry Markowitz. “I should have computed the historic covariances of the asset classes and drawn an efficiency frontier. Instead, . . . I split my contributions fifty-fifty between bonds and equities.” Depending on the fraction of risky/riskless assets in the portfolio, the $\frac{1}{n}$ decision heuristic can expose the plan participant to a non-optimal level of risk. If the diversification heuristic is important, then it would seem that adding options to the 401(k) plans will have little effect when the number of options is already large. Two additional features of portfolio allocation are of interest.

First, individuals invest a disproportionate fraction in the stock of their own company (Mitchell and Utkus, 2004). Thaler and Benartzi (2007) report that 33% of individuals who own company stock do not realize that it is more risky, relative to a diversified portfolio. It is possible that company stock is a unique asset that is neither viewed as equity nor as bonds (Benartzi and Thaler, 2001). Portfolios in retirement plans that do not have company stock are normally split evenly between bonds and stocks. But in the presence of company stock, pension portfolios invest 43% in company assets and the remaining amount is split evenly between stocks and bonds. Hence, those with company stock in their pension portfolios end up investing a disproportionate amount of their pension savings, about 71%, in equities. Second, in evaluating the attractiveness of assets, individuals overly extrapolate past performance of a stock for the foreseeable future (Benartzi, 2001). Third, the availability of faster information on the Internet and other newer communication media means that the variability of stock prices will be even more salient. The latter will possibly create even greater myopic loss aversion.

5. Intervention by plan providers: There is little evidence to indicate that education improves saving rates among workers. However, elements of plan design might play a beneficial role. An example is the “Save more tomorrow” (SMT) plan (Benartzi and Thaler, 2004). Suppose workers were asked to increase their plan contributions now, conditional on the current wage. Given loss aversion, this might be viewed as a loss in current consumption, so it is less likely to be successful in increasing savings. Hence, a more sensible strategy is to have workers agree to deduct a fraction of a future wage increase as additional saving contributions, up to a certain limit (sometimes known as *automatic escalation*). If the reference income level of workers is the initial wage level, then additional contributions out of potential future income do not induce loss aversion. Evidence indicates that the SMT plan has led to an increase in savings (Benartzi and Thaler, 2013).

CHAPTER 21

Bounded Rationality in Financial Markets

21.1 Introduction

Financial markets have traditionally been held up as an ideal example of efficiently functioning markets. These markets are often used in introductory courses in economics to demonstrate why it is not restrictive to focus exclusively on fully rational economic agents. By way of extra realism, it is typically added that economics does not rule out irrationality; however, it is argued, this can be safely ignored. Two arguments are typically given to justify this conclusion on a-priori grounds. First, individual errors will cancel out in the aggregate. Second, irrational market participants (or *noise traders*, a term due to Black, 1986), if any, will be driven out of the market by rational market participants (sometimes known as *arbitrageurs*).

In stark contrast to the natural sciences, fundamentally important assumptions are often justified in economics on grounds of plausibility, rather than an appeal to rigorous evidence. In the case of financial markets, the theory of efficient financial markets has not been very successful in accounting for the evidence. Furthermore, a great deal of progress has been made in the theoretical models in behavioral finance to better explain the economic implications of noise traders. The term *investor sentiment* that describes the activities of noise traders is now routinely used, even in the popular press.

The *efficient markets hypothesis* (EMH) is the cornerstone of classical finance. The EMH stresses that, at any instant in time, the price of a security equals its fundamental value, i.e., the present discounted values of all future income flows (e.g., dividends) associated with the security. In Section 21.2.1, we outline the concept of *short-selling* or *shorting* of an asset, a mechanism that lies at the heart of EMH and effective arbitrage. While this concept will be quite familiar to those who have taken a basic course in finance, for others it is important to grasp its importance.

Section 21.2.2 gives a statement of the EMH, and considers six different implications of EMH that have been subjected to empirical testing. These include, for instance, the *weak form* of EMH (stale information should not affect current prices); *semi-strong form* of EMH (publicly available information should not affect current prices); *strong form* of EMH (insider trading should be ineffective); prices of substitute securities should not differ; and prices should not react to no-news.

In Section 21.2.3, we outline the theoretical objections to the EMH; formal models of these objections are given in subsequent sections of this chapter. On account of various judgment heuristics, individual investors may exhibit *investor sentiment* that can lead to systematic departures of prices from fundamental values. In the face of persistent investor sentiment, arbitrageurs

might not be able to hold on to their rational, but loss making, positions for too long, hence they might have to exit the market. Furthermore, professional arbitrage does not solve the problem either, for a variety of reasons that we discuss in more detail, below.

The recent literature has focused on two misperceptions in decisions under risk. First, overconfident individuals assign higher probabilities to their stocks doing well. Second, they overweight small probabilities (see Part 1). These misperceptions have led to interesting insights in the emerging literature on the *psychology of tail events* (Barberis, 2013). For instance, the market will price skewness in the returns to assets, and the two misperceptions also potentially explain the equity premium puzzle.

In Section 21.2.4, we consider the empirical evidence for EMH. Stock prices are far too volatile relative to the predictions of EMH (Shiller, 1981). The weak form of EMH is contradicted in many empirical studies (De Bondt and Thaler, 1985). Stale information can predict future prices; past winners over a long horizon give low subsequent returns and past losers give higher subsequent returns. Stocks with high *market to book value ratios* (MBVR) in the past do worse in the future (Lakonishok et al., 1994). There is also a well-documented *momentum effect*; stocks that have done well in the recent past continue to do well while those that have recently done badly continue to do so (Jegadeesh and Titman, 1993). The semi-strong form of the EMH is contradicted by evidence of a *post-earnings-news drift* in which prices continue to move in the direction of initial public news (Bernard and Thomas, 1989; Michaely et al., 1995).

Prices of strictly substitute securities are found to differ systematically. There is particularly clean evidence on this effect from *Siamese-twin companies* that have merged in the past, but continue to operate and trade in different markets, e.g., Royal Dutch Petroleum, and Shell Transport and Trading, PLC. A security in such a company is a claim to the total income of the merged companies in the ratio in which they originally merged their assets. However, the observed market ratios of the security prices of these companies differ systematically from the ratio predicted by theory (Froot and Dabora, 1999). Security prices also react to no-news and many stock market crashes occur without any apparent change in fundamental values (Cutler et al., 1991). The price of freshly inducted stocks in the S&P 500 index jumps upwards without any new information about the fundamental values (Shleifer, 1986; Wurgler and Zuravskaya, 2002).

Defenders of the EMH often cite the difficulty of beating the stock market as proof that financial markets are efficient. However, this is simply a confusion between necessary and sufficient conditions (Barberis and Thaler, 2003). The EMH implies that there are no arbitrage opportunities; however, the absence of arbitrage opportunities does not logically imply that EMH holds. Several interesting findings have emerged about the performance of individual investors in stock markets (Barber and Odean, 2013). On average, individual investors do indeed earn below average market returns on longer-term investments, and have poor stock selection ability, while their success at shorter horizons is better. Furthermore, there is evidence that many institutional investors, and the most skilled individual investors, can earn abnormal returns that are correlated across time. There is substantial heterogeneity in the performance of individual investors that is correlated with age, overconfidence, and gender.

In Section 21.3, we describe a seminal model of noise trader risk in which there are two assets, a riskless asset and a risky asset (De Long et al., 1990a). The only source of uncertainty is the noisy beliefs of the noise traders about the future price of the risky asset, which otherwise is subjected to no underlying fundamental uncertainty. The presence of noise trader risk creates uncertainty about the future price of the risky asset. Hence, it affects the current demand of the risky asset. Risk averse arbitrageurs are deterred by the presence of future uncertainty, so they reduce their demand for the risky asset. However, due to investor sentiment, the noise traders

might be currently bullish and demand higher amounts of the risky asset. If the future price turns out to be high due to the future bullishness of noise traders, then the profits of noise traders who had overinvested in the risky asset are higher. Under appropriate conditions, that we outline, noise traders may earn higher average profits than arbitrageurs.

Modern financial markets are characterized by a separation between brains and capital. Small and dispersed investors typically lack detailed knowledge of the working of financial markets, and often use the services of professional investors. Professional investors invest the capital of others, and charge a fee in return for their services. Since professional investors are trained and supposedly knowledgeable, can we be sure that the heuristics and biases of individual investors that impede market efficiency, no longer operate? While the traditional biases might not operate, new biases are introduced, which once again preclude market efficiency. We consider this question in several places in Part 7 (see, for instance, Sections 19.18 and 21.7).

In Section 21.4 we consider a formal model of *professional arbitrage* (Shleifer and Vishny, 1997). Since small investors do not have the expertise to evaluate professional arbitrageurs, they resort to a simple heuristic. Namely, invest more in a professional arbitrageur whose past market returns are high; this is known as *performance based arbitrage*. However, in any period, a negative shock to investor sentiment reduces current prices and the returns of professional arbitrageurs. Small investors who rely on performance based arbitrage then withdraw funds from professional arbitrageurs precisely when current prices are low and so the potential returns on investing are high. This hampers the ability of professional arbitrageurs to push prices in the direction of fundamental values.

An important assumption underlying the EMH is that the flow of any relevant information is instantaneous. However, a great deal of evidence shows that information flows in financial markets may be gradual, so that stock prices adjust slowly (Hong et al., 2000). In Section 21.5, we outline a formal model that combines gradual flow of information with heterogeneity among investors (Hong and Stein, 1999, 2007). We show that there can be intense trading even when prices equal fundamental values because investors may hold incorrect models of the real world. Information that may correct their models flows gradually. We also show that *momentum* and *trading volume* are closely related.

In Section 21.6, we consider the twin phenomena of stock market *underreaction* and *overreaction*. Stock market underreaction takes place when good news about a stock is not immediately incorporated into its price so that we expect its return to be higher next period. Overreaction takes place if following a sequence of good news, lower returns are expected in the future, indicating that the market initially overreacted. We use a formal model in which investors hold on to two incorrect models of the world, a mean reverting model and a trending model, and based on stock market news, update their beliefs about the models (Barberis et al., 1998). Within such a framework, we derive appropriate restrictions on the parameters that ensure the model can match the data on underreaction and overreaction.

Section 21.7 considers the subject of *behavioral corporate finance*. Classical corporate finance studies the interaction between managers and shareholders of a firm and decisions such as the source of finance, investment decisions, and design of managerial compensation. Behavioral corporate finance enriches the domain of this enquiry by considering the possibility that managers and shareholders might not be fully rational in the sense of classical finance. There are two main difficulties in this area. First, unlike the EMH in behavioral finance, there is no clear benchmark to test. Second, corporations are naturally reluctant to part with internal data that would allow for more stringent tests of theory. Despite these hurdles, impressive progress has already been made.

Section 21.7.1 considers a range of biases exhibited by managers of firms. Many managerial decisions are of an infrequent nature (e.g., capital restructuring, mergers) that offer limited learning opportunities. These decisions are often taken under extreme uncertainty, so not only is it unclear what the optimal decision is, methods for evaluating the quality of these decisions are also vague, and subject to alternative interpretations. On account of these reasons, when outcomes are bad, managers can blame luck, but when the outcomes are good they can ascribe them to their ability levels; this is known as *attribution-bias* (Langer and Roth, 1975; Bettman and Weitz, 1983; Bertrand and Mullainathan, 2001).

Managers and CEOs are also known to exhibit a great deal of *overconfidence*, and evidence indicates that more overconfident managers, purely because they might have been lucky, rise to the top (Goel and Thakor, 2008). Due to overconfidence, managers might overvalue their firms, therefore, relying on borrowing rather than raising equity for investments (Malmendier and Tate, 2005). Overconfident managers are also more likely to merge because they are overconfident of their abilities in turning around the target firm (Roll, 1986; Malmendier and Tate, 2008; Gervais et al., 2011).

Sections 21.7.2 and 21.7.3 consider two kinds of polar possibilities. In Section 21.7.2, we consider the possibility that managers are rational, but investors are potentially irrational and draw the implications for merger activity (Shleifer and Vishny, 2003). We consider the short- and long-run impacts of acquiring a firm through three different methods: cash, stock, and outright purchase of capital. We also consider empirical evidence on three main objectives of mergers (Baker and Wurgler, 2012). These objectives are: *maximizing fundamental values*; *catering* to increase stock prices above fundamental values; and *market timing*, i.e., taking advantage of temporary stock mispricing to issue new shares or repurchase old shares. In Section 21.7.3, we consider the other polar extreme of irrational managers and rational investors. Irrationality of managers takes the form of managerial overconfidence (Gervais et al., 2011). In this context, we also clarify the role of risk aversion, manager's ability, and alternative incentive schemes.

Finally, in Section 21.7.4, we consider *behavioral corporate signaling*. Classical corporate finance explains the existence of dividends, IPO underpricing, capital restructuring, and debt as costly signals to investors of the quality of the firm (Ross, 1977; Myers and Majluf, 1984; Harris and Raviv, 1985). However, empirical evidence shows that the main reason for issuing dividends is to take advantage of temporary mispricing of securities. Indeed, survey evidence rejects the main implications of the classical signaling model in corporate finance (Brav et al., 2005). When surveyed, managers reject the idea that dividends are costly signals of the competence of firms that might reduce the value of the firm. We consider the possibility that benevolent managers may signal the underlying earnings of the firm through dividends (Baker and Wurgler, 2011). Yet these signals do not reduce the value of the firm, nor do they signal the strength of the firm.

21.2 The efficient markets hypothesis

21.2.1 *An introduction to short selling*

We shall need the standard concept of a *short position* or *shorting* to understand some of the material in this chapter. Suppose that there are two time periods, $t = 1, 2$ and that there is a single security priced at P_1 in period 1. Ignore issues of time discounting. Suppose that investor A believes that the second period price, P_2 , will be lower than P_1 . It makes sense for investor A to sell the security in period 1 and buy it back in period 2. For physical goods, one generally needs

to have possession of the goods before one can sell them. This is not the case for financial instruments such as securities. It is possible that another investor, say, investor B, actually possesses the security. Investor A can then ask a broker to lend him n units of the security for one period. The broker borrows n units of the security from investor B and lends it to investor A for one period.

Investor A sells the security in period 1 and receives an amount of money equal to nP_1 . In the next period, period 2, investor A purchases n units of the security at a price P_2 and returns the security to investor B, through the broker. The broker, who performs the financial intermediation, much as banks do, receives a brokerage fee for the service. The profit of investor A equals $n(P_1 - P_2) \geq 0$. Thus investor A can make a profit if beliefs turn out to be correct, but can also make a loss if they do not. In particular, this strategy of shorting is successful only if the actual price falls; thus, shorting is typically a response to expectations of a price fall in the future. If any dividends or interest payments accrue to the security during the period that it is in the possession of investor A, then these must be passed on to investor B, via the broker. There are also regulations on which types of securities can be shorted and when.¹ Indeed, these issues were part of the regulatory response to the 2007–2008 financial crises.

In the examples below, we use the following structure. Consider only two time periods, 1 and 2, and assume that at the end of period 2, investors simply sell all shares and spend the money on consumption. Consider an investor who has a choice between buying securities either in Ford or in General Motors. Since these companies sell similar products, we should expect that they are exposed to the same *fundamental risk* (say, involving the car industry as a whole). *Idiosyncratic risk*, on the other hand, is risk that is specific to each company such as a problem that might arise with brake disks or software in one of the companies; e.g., the problem with the so-called “defeat software” in VW cars in 2015 is an example of idiosyncratic risk. We assume that ex-ante, each company carries the same idiosyncratic risk. Suppose that the fundamental value of a security in each time period for each of the two companies is \$30. Since the risk and return on securities issued by both firms is similar, they are *close substitutes*.

Example 21.29 (*Efficiency in financial markets*): Let us work through an example to see how the arbitrage argument advanced by Friedman (1953) and Fama (1965), works to produce the efficient markets hypothesis. For whatever reason, say, on account of irrational investors, suppose that Ford shares drop to \$20 in period 1. Arbitrageurs jump on this opportunity to take a short position in GM shares. Consider an arbitrageur who borrows 6 GM shares in period 1. He sells them for $30 \times 6 = \$180$ in period 1 and buys $\frac{180}{20} = 9$ Ford shares with the money. The buying of Ford shares in this manner will continue until excess demand puts sufficient upward pressure on the price of Ford shares for them to equal the fundamental value of 30. Suppose that, as expected, on account of the activity of arbitrageurs, Ford shares revert to their fundamental value of 30 in period 2. Then the arbitrageur sells the 9 Ford shares for $30 \times 9 = \$270$ in period 2. Using this money he buys 6 GM shares for $30 \times 6 = \$180$ in period 2, which are returned back to the broker. The total profits of the investor equal $270 - 180 = \$90$. The efficient markets hypothesis holds because each security now equals its fundamental value; the presence of substitute securities, shorting activity, and the arbitrage activities of rational arbitrageurs are all critical to this result.

Example 21.30 (*Substitute securities, shorting and protection from fundamental risk*): The main advantage of taking a short position in a substitute security (GM in this case) is that it protects the investor from fundamental risk. To see this, suppose that in the second period, on

¹ These and other insitutional details can be picked up from any basic text on finance.

account of fundamental risk, the fundamental value of both securities unexpectedly drops to 20. In this case, in period 2, the arbitrageur sells the 9 Ford shares for $20 \times 9 = \$180$. Using this money he buys 6 GM shares for $20 \times 6 = \$120$ in period 2, which are returned back to the broker. The total profits of the investor then equal $180 - 120 = \$60$. So, while fundamental risk reduces the price at which the Ford shares can be sold (fall in revenue from \$270 to \$180) it also reduces the cost of purchasing the GM shares (fall in cost from \$180 to \$120) that have to be returned back to the broker in period 2. Hence, the act of shorting, reduces the exposure of the investor to fundamental risk. However, legal constraints might prevent many investors, particularly mutual fund and pension managers from taking a short position. This exposes them to fundamental risk, hence, they might undertake insufficient arbitrage to ensure that price equals the fundamental value of the security.

Example 21.31 (Exposure to idiosyncratic risk remains): Taking a short position does not, however, protect the investor from idiosyncratic risk. Continue to assume the setup of Examples 21.29, 21.30. However, now suppose that in period 2, on account of idiosyncratic risk (say, recall of Ford cars because there was a problem with faulty brakes), the price of a Ford security drops to \$20 in period 2. The arbitrageur then sells the 9 Ford shares for $20 \times 9 = \$180$ in period 2. Using this money he buys 6 GM shares for $30 \times 6 = \$180$ in period 2, which are returned back to the broker. The total profits to the investor then equal $180 - 180 = \$0$. Worse, if the Ford securities drop to a price below \$20, the investor makes a loss.

21.2.2 Statement and implications of EMH

The efficient markets hypothesis (EMH) has been a cornerstone in neoclassical finance. We give a brief outline of its definition and assumptions.

Definition 21.9 EMH implies that the value of a security at any point in time equals its fundamental value, i.e., the present discounted value of all future dividends and earnings. All publicly available information is immediately incorporated into security prices. Otherwise prices would not be the same as fundamental values at some instant in time.

The EMH rests on the following main assumptions.

- A1: Rationality:** By and large, investors are assumed to be rational. In finance, rational investors are called *arbitrageurs*. Rationality has two requirements in this case.
 - (i) In response to new information, investors update their priors in a Bayesian manner.
 - (ii) When faced with a risky situation, investors have beliefs over outcomes and use subjective expected utility to evaluate the risky situation.
- A2: Irrationality, if any, cancels out in the aggregate:** Any irrationality, if it exists at all, is random and so, in the aggregate, it is expected to cancel out.
- A3: Irrational investors eventually exit the market:** If irrational traders bet on a price that is different from the fundamentals, then arbitrageurs will step in and make money off them. Since, irrational traders cannot continue to lose money forever, they must eventually exit the market.

How does one test the EMH? The implication of EMH is that prices should respond instantly to news that alters fundamental values. Thus, instantaneously, price should equal the new fundamental value. EMH implies the following six testable implications, T1–T6.

- T1: Stale information should *not* affect current prices of securities. It must already have been incorporated into security prices on account of the activity of the arbitrageurs. Thus, past prices and returns should not affect current stock prices. This is known as the *weak form of EMH*.
- T2: Any publicly available information should *not* affect current prices of securities. Such information is expected to be instantaneously incorporated into security prices. This is known as the *semi-strong form of EMH*.
- T3: Investors should *not* be able to earn more than the average market profits by using information that might not be available to others (absence of *insider trading*). The expectation is that such information would be quickly picked up by other investors, wiping out any potentially abnormal profits. This is known as the *strong form of EMH*.
- T4: Security prices must *not* first underreact to news about fundamental values, but then overreact to it before finally reverting to the new fundamental value, possibly over several periods.
- T5: There should be *no* consistent differences in the prices of strictly substitute securities.
- T6: Security prices should *not* react to *no-news*, i.e., news that is unrelated to fundamental values.

21.2.3 *Evaluating the theoretical case for EMH*

We first catalog, informally, some theoretical objections to the EMH that are treated more formally in subsequent sections.

1. *Availability of substitute securities*: Substitute securities are not always available.² The existence of such securities is essential to the argument for EMH because they allow investors to take a short position and, hence, protect themselves from fundamental risk (Examples 21.29, 21.30). The absence of substitute securities and fears of inability to insure against fundamental risk might dissuade arbitrageurs from undertaking the right level of economic activity that is required to ensure that prices of assets equal fundamental values.
2. *Investor sentiment and judgment heuristics*: The EMH assumes that investors use Bayes' rule to update their priors. Our discussion of judgment heuristics in Chapter 19 suggests that investors often do not use Bayes' rule correctly (e.g., base rates are underweighted). People are known to assign confidence intervals to their estimates that are too narrow and 90% of those surveyed report that they have above-average levels of intelligence and emotional ability.³ At the same time, individuals can be too cautious and underestimate the likelihood of the sample. This is known as *conservatism* (see Chapter 19).

In other contexts, individuals rely on *representativeness* and exhibit the law of small numbers. People use the *availability heuristic*, relying on their memory for the available information. However, all memories are not equally retrievable or salient. For instance, more recent events and more unusual events might be more salient and more retrievable, which can result in individual actions being biased. Any departure from Bayesian rationality, typically on account of judgment heuristics, is termed as *investor sentiment*. Other names for such investors include *unsophisticated investors* (Kyle, 1985) and *noise traders* (Black, 1986).

² See, Figlewski (1979), Roll (1988), Campbell and Kyle (1993). For a review see Shleifer (2000), Barberis and Thaler (2003).

³ See Weinstein (1980) for an early study and Barberis and Thaler (2003) for references to the subsequent literature.

In example 21.29, suppose that the decrease in the original price of Ford securities in period 1 from \$30 to \$20 is caused by investor sentiment, say, noise traders. Arbitrageurs (or rational traders) then face an additional risk when they “short” GM securities. Namely, that investor sentiment may get worse in period 2. This problem may become even more serious due to the presence of *positive feedback traders*, i.e., traders who base their decision to buy an asset only if it performed well last period (De Long et al., 1990b). Following the lead of noise traders, such investors may be even more reluctant to buy Ford securities in period 2, increasing the downward pressure on Ford securities. Thus, mispricing of Ford securities in the first period, caused by investor sentiment, may persist in period 2.

In this case, Ford shares do not revert to their fundamental value of 30 in period 2. Suppose that on account of noise traders and positive feedback traders, the period 2 price of Ford securities turns out to be 15. In the two-period setup of Example 21.29, the arbitrageur sells the 9 Ford shares for $15 \times 9 = \$135$ in period 2. The investor then needs to purchase the 6 GM shares which cost $30 \times 6 = \$180$ in order to return them back to the broker. The total profits of the investor equal $135 - 180 = -\$45 < 0$. This is the risk created on account of noise traders and positive feedback traders, which might well limit arbitrage.

Indeed, if arbitrageurs can see through the behavior of noise traders then they might take actions that bet on mispricing getting worse. It might also be the case that noise traders take a long time to lose money and to exit the market. The result could be that arbitrageurs liquidate their positions before noise traders can exit the market because they cannot hold on to their positions for too long (Figlewski, 1979). This takes away the normal countervailing effect of arbitrageurs to bring price back in line with fundamental values; Section 21.3 below formalizes these issues. This simple example also demonstrates the dangers of holding on to entrenched positions, based on purely ex-ante plausibility, such as the following arguments given to undergraduate students in economics. (1) If there are any irrational agents, then rational agents will make money off them and drive them out of the market. (2) Any irrationality in the market cancels out in the aggregate. The work on judgment heuristics (Chapter 19) rejects this assumption. It shows that laypersons and experts have persistent and *systematic biases*. Hence, the probability that such errors point in the same direction, rather than canceling out, is much greater, with serious implications for financial stability.

Noise traders is not just a theoretical construct. Consider the evidence from the market price of shares in closed-end funds. The manager of a closed-end fund raises a fixed initial amount of money towards a fund. Additional money can neither be added to, nor withdrawn from the fund, although shares in the fund trade actively in the stock market. EMH predicts that the market price of a security in the fund should equal the net asset value (NAV) of the fund. However, systematic differences between the market price and NAV were found by Lee et al. (1991). To get some idea of these differences, consider the updated figures from Thaler (2015) drawn from closed-end funds: Shares in Gabelli Utility Trust sold at a premium of 18.2% over the NAV, while shares in Firsthand Technology Val sold at a discount of 37.4%.

Lee et al. (1991) also provide evidence to explain the following four *closed-end fund puzzles* that cannot be accounted for by classical models in finance. At the time of starting the fund, security prices trade at a sizable premium of about 7% due to start-up costs and underwriting costs. Within six months, the fund trades at a discount of 10%. There is

substantial variation in the premia and discounts over time. However, when there is a merger or liquidation or conversion of the fund to an open-end fund (to which money can be added and withdrawn), the market price converges to the NAV. Why do these systematic patterns of returns persist if all market participants are rational?

It turns out that the closed-end puzzles can be explained by the existence of noise traders. The basic idea is that individual investors are more likely to invest in the shares of small firms (which includes closed-end funds), relative to larger institutional investors. Thus, insofar as investor sentiment is more likely to be exhibited by small investors rather than institutional investors, the time variation of investor sentiment is likely to be reflected in the relative stock performance of small and large companies. Lee et al. (1991) were able to show that they could correlate well the premium/discount in the security prices of closed-end funds with the difference between the performance of small and large companies. For more empirical evidence on noise traders and a detailed discussion of the closed-end fund puzzles, see Shleifer (2000).

In addition to incompatibility with Bayes' rule and choosing on the basis of representativeness, or anchoring, several other forms of investor sentiment have been documented. Hindsight bias can lead to underestimation of financial volatility (Biais and Weber, 2009). In order to be induced to hold stocks, sellers must offer too high a premium on equities relative to bonds; this is known as the equity premium puzzle (Benartzi and Thaler, 1995). Investors also hold on to losing stocks for far too long and sell winning stock too early relative to the predictions of standard theory; this is known as the *disposition effect* (Odean, 1998). Both these phenomena can be explained using prospect theory (see Part 1 of the book). Benartzi and Thaler (1995) also demonstrate the importance of *framing effects* on investor choice. In particular, the decision of investors to buy stock depends on whether news about the performance is presented as *high, long-term, returns* or a *more finely presented series of fluctuating short-term stock returns*.

The following quote from Shleifer (2000, p. 10) illustrates a set of other judgment heuristics and biases that run contrary to the assumption of EMH, further undermining the theoretical case for EMH:

... it is difficult to sustain the case that people in general, and investors in particular, are fully rational. At the superficial level, many investors react to irrelevant information ... Investors follow the advice of financial gurus, fail to diversify, actively trade stocks and churn their portfolios, sell winning stocks and hold on to losing stocks thereby increasing their tax liabilities, buy and sell actively and expensively managed mutual funds, follow stock price patterns and other popular models. In short, investors hardly pursue the passive strategies expected of uninformed market participants by the efficient market theory.

Heuristics also explain why there is far too much trading and churning of assets. Thaler (1999) reports that 700 million shares are traded on the NYSE. For 2005, Hong and Stein (2007) give a figure of \$51 trillion in trading volume for the 50 members of the World Federation of Exchanges. This is too large a volume to be plausibly explained by classical theories in finance. Barber and Odean (2000) show empirically that there is far too much trading relative to a rational benchmark. Indeed, in their sample, and after taking account of trading costs, investors would have done better by trading less. Furthermore, in one possible manifestation of overconfidence, investors who traded the most, earn the lowest average returns.

The phenomenon of too much trading by market participants is different from the puzzle of limited stock market participation. Given the relatively high mean rates of returns, why are so many potential investors unwilling to invest? Barberis et al. (2006) argue that the answer lies in narrow framing of options in which individuals segregate stock market returns from other sources of income. Once this is assumed, then they invoke the tendency of individuals to reject small gambles, even those that are actuarially favorable (Tversky and Kahneman, 1992). Thus, a combination of first order risk aversion and narrow framing provides one possible rationalization of the puzzle of stock market participation.

Expected utility theory underpins EMH. In the general case under risk, the formula—prices of stocks equal the present discounted value of future dividends—relies on a first order linear stochastic difference equation that exploits the arbitrage relation between the returns on safe and risky assets (Blanchard and Fischer, 1989, ch. 5). We have seen in Part I of the book that, contrary to expected utility theory, the bulk of the empirical evidence supports *non-linear probability weighting*. In particular, individuals overweight small probability events and underweight high probability events. Furthermore, individuals may often think that an event is more probable than it actually is, e.g., the probability of an air-crash. In stock markets, overconfidence is a particularly salient factor that might cause *overassignment of probabilities*.

These two misperceptions (non-linear probability weighting and overassignment) have several implications that are studied under the emerging topic of the *psychology of tail events*. An important implication is that the market will price skewness in asset returns (Barberis and Huang, 2008). Suppose that the return on an asset is positively skewed. Then there is a small probability that the investor will earn very high returns. On account of the two misperceptions mentioned above, the demand for such assets is higher than it should ideally be, pushing up the prices and reducing the average returns. Empirical evidence is supportive of this prediction (Boyer et al., 2010). These ideas can also be used to explain the equity premium puzzle (De Giorgi and Legg, 2012): The two misperceptions lead investors to overestimate and overweight the small probability of a stock market crash, hence, they demand a premium for holding stocks relative to bonds.

In Part I of the book we documented two kinds of behaviors for very low probabilities; the first, overweighting of small and underweighting of large probabilities has been mentioned above. A second kind of behavior arises when we approach even lower probabilities; these extremely low probabilities are either underweighted or simply ignored (e.g., we do not scurry around to get insurance against an asteroid hitting us). This explains why individuals are reluctant to purchase insurance for low probability natural hazards and a host of other behaviors (see Part I for details). Taleb (2007) draws attention to this kind of behavior in his book, *The Black Swan*, where individuals assign very low probabilities to tail events. In this case, the misperceptions are the exact opposite of the two misperceptions reported above.

How do we know which of the two sets of misperceptions (overweighting or underweighting of very small probabilities) applies? A plausible suggestion is that the availability heuristic may help distinguish between the two cases (Barberis, 2013). Events that are rare and unusual do not bring to mind similar instances. Thus, individuals might have underweighted the probability of the stock market crash of 2008 because they could not recall how events similar to 2005 and 2006 led to a crash in the past.

3. *Professional arbitrageurs*: In actual practice, there are a large number of small and dispersed investors. Professional arbitrageurs typically make the bulk of their investments in financial markets on behalf of these small investors; we may term this as the *separation of brains and capital* (Shleifer and Vishny, 1997). Several features of the operation of professional arbitrageurs are relevant for the success of EMH. These mainly arise from the inability of dispersed and small investors to fully comprehend the operations of financial markets; thus, they rely on indirect signals of the ability of professional arbitrageurs. Among the indirect signals used by small investors are the following. (1) The end of year reports on the performance of professional arbitrageurs. (2) How well one professional manager does relative to another? (3) The performance of professional arbitrageurs relative to some publicly observed target, such as the S&P 500 Index.

Each of these features creates serious distortions. Feature (1) often forces professional arbitrageurs to liquidate their positions in a loss making asset too quickly, even when holding on to such a position would have been beneficial in the longer run. This makes it difficult to counter the activity of noise traders.

Feature (2) induces professional arbitrageurs to invest in similar assets so that each can avoid looking worse than each other; this is a form of *herding behavior* (Scharfstein and Stein, 1990). Feature (3) induces professional arbitrageurs to choose portfolios whose returns are closely aligned to the S&P 500 Index. There is some evidence that these distortions reduce the performance of professional arbitrageurs below that of passive investment strategies (Ippolito, 1989; Lakonishok et al., 1992).

To these factors, one could add transaction costs of arbitrage which might prevent market efficiency. Transaction costs include the cost of finding information about which shares are mispriced relative to their fundamental values, as well as the brokerage fees for taking a short position (D'Avolio, 2002).

21.2.4 *The empirical evidence on efficiency of financial markets*

The early evidence in the 1960s till about the mid 1970s repeatedly confirmed the EMH (Fama, 1965, 1970; Jensen, 1978). It focused mostly on T1 and T2 above, i.e., the weak and the semi-strong forms of the EMH. Fama (1965) found that stock prices approximately follow a random walk. Fama et al. (1969) suggested the use of *event studies* to test for the EMH and these became very popular. The basic idea was to focus on a particular event. For instance, the announcement of earnings or dividends, news of a takeover or divestiture, news about the issue of new shares or repurchases of existing shares, and other news about changes in management or of management strategy. Researchers then checked to see if there was an effect on security prices, subsequent to these events, as information became stale. The expectation was that the effect of the news would be incorporated immediately, or even prior to the announcement of news. The results were predominantly supportive of the EMH; see Fama (1970) for a review.

Since the late 1970s there have been serious challenges to the EMH. The theoretical and empirical objections have not only focused on T1 and T2 above, but also on T3–T6. Unfortunately for the EMH, and despite econometric and data caveats, all of the implications in T1 to T6 were not only rejected, but the theoretical case for them was found to be on shaky ground (Shleifer, 2000; Barberis and Thaler, 2003). We have considered some elements of the theoretical case in Section 21.2.3 above and more details are considered later, but in this section we focus on the empirical evidence.

Figure 21.1 A plot of price and dividends against time.

Source: Shiller (2003) with permission from the American Economics Association.

The empirical evidence against EMH has been extensively documented.⁴ Shiller (1981) provided an early empirical challenge to the EMH. He found *excess volatility* in stock prices that could not be explained by fundamental values. Denote by P_t , the price of a stock at time t , by I_t the information set at time t , and by $E[D | I_t]$ the conditional expected present value of subsequent dividends. Then the EMH states that $P_t = E[D | I_t]$, or $P_t = D + u_t$, where u_t is a mean zero random variable. Thus,

$$D = P_t - u_t. \quad (21.1)$$

Under EMH, all information is incorporated in prices, thus, u_t and P_t are uncorrelated. Denoting by $V(x)$, the variance of x , (21.1) implies that:

$$V(D) = V(P_t) + V(u_t). \quad (21.2)$$

Since variances are non-negative, it follows that an implication of EMH is

$$V(P_t) \leq V(D). \quad (21.3)$$

A plot of P_t and D against time is shown in Figure 21.1; these variables are labeled respectively as “Real Stock Price (S&P 500)” and “PDV, Constant Discount Rate.” D was proxied by the present value of actual dividends paid in the following year. From Figure 21.1, it is evident that $V(P_t) >$

⁴ There are several good surveys; see, for instance, Shleifer (2000), Barberis and Thaler (2003), Subrahmanyam (2008), and Barber and Odean (2013). There are two textbook treatments that use a behavioral economics perspective to cover a wide terrain in behavioral finance; see Akerlof and Shiller (2008) and Shiller (2015).

Figure 21.2 Cumulative average residuals for W and L portfolios of 35 stocks.

Source: De Bondt, W. F. M. and Thaler, R. (1985). "Does the stock market overreact?" *The Journal of Finance* 40: 793–805. © American Finance Association. With permission from John Wiley & Sons.

$V(D)$, contradicting EMH. In other words, there is excessive stock price volatility relative to the predictions of the theory. This should not come as a surprise to behavioral economists. Stock market decisions are often likely to be based on investor sentiment and behavioral features that create another source of price volatility; these factors are not taken into account under classical finance. These results were challenged by Marsh and Merton (1986), mainly in terms of the proxies used for D and P_t as well as issues of time-invariant interest rates. However Shiller's basic result was borne out by several papers that strove to address the Marsh and Merton (1986) critique (Barberis and Thaler, 2003).

The weak form of EMH is contradicted by several studies. De Bondt and Thaler (1985) look at the performance of winners (W) and losers (L), over the past three years, on the New York Stock Exchange over the time period 1926–1982. They then compute the returns on W and L stocks for the following five years, controlling for the relative risks of the two stocks. They find that W stocks and L stocks give, respectively, low and high subsequent returns. They explain their results by positing that the stock prices have overreacted in the past. The returns on W (respectively, L) stocks overshot (respectively, undershot) their fundamental values. The result is that the market gradually corrects for the mispricing. This directly contradicts weak form EMH because past performance is able to predict future returns. Figure 21.2 plots the "cumulative average residuals" for Winner and Loser portfolios of 35 stocks over five years (60 months); for any asset, the residual is an estimate of the difference between the return on the asset and the market portfolio.

Similar arguments can be used to explain why companies with high *market to book value ratios* (MBVR) in the past do worse in the future (De Bondt and Thaler, 1987; Fama and French, 1992; Lakonishok et al., 1994). Stocks of such companies are also sometimes called *glamour stocks*. A high MBVR in the past could indicate overreaction, which is gradually corrected in the future by a drop in stock prices. This contradicts weak-form EMH because stale information on MBVR helps to predict future returns.

One response in classical finance has been to interpret the MBVR as a measure of fundamental risk of a company. Hence, a high MBVR is associated with higher risk and lower subsequent returns (Fama and French, 1993, 1996a). However, not everyone is persuaded by the interpretation of MBVR as a measure of fundamental risk (Lakonishok et al., 1994; Mackinlay 1995; Daniel and Titman, 1997).⁵

Another violation of the weak form of EMH is the *momentum effect* (Jegadeesh and Titman, 1993). They classify portfolios into deciles based on performance in the previous six months. The main finding is that portfolios in the top deciles in the previous six months give about 10% higher returns relative to those in the bottom deciles for the next six months.⁶ They consider a trading strategy that buys past winners and sells past losers. This strategy earns a compounded excess annual return of 12.01% on average.

The semi-strong form of the EMH is contradicted by several pieces of evidence. EMH requires public news to be immediately reflected in stock prices. However, there is evidence of a *post-earnings-news drift*; prices move in the same direction as the initial public news (up if the news is good and down if it is bad) for a significant amount of time. This post-public-news drift is well documented for a range of public news such as earnings news (Bernard and Thomas, 1989, 1990; La Porta et al., 1997), share repurchase news (Ikenberry et al., 1995), stock issue news (Loughran and Ritter, 1995; Spiess and Affleck-Graves, 1995), and new dividend issues (Michaley et al., 1995).

Another piece of evidence comes from the *January effect*. Using data over the period 1904–1974, Rozeff and Kinney (1976) find that the average stock market returns during the month of January were 3.48%, compared with an average monthly return of 0.42% during the remaining 11 months of the year, which is eight times higher. The January effect is found in many other studies (De Bondt and Thaler, 1985). Rozeff and Kinney used an equally weighted index of New York Stock Exchange prices, hence, their results could have been caused by the overweighting of small firms. This was confirmed by Reinganum (1983). The January effect cannot be fully explained by risk considerations and issues of tax liability. Since the company size and the time of the year are both public information, this evidence contradicts the semi-strong form of EMH.

EMH requires prices of strictly substitute securities to show no consistent differences (see T5 above). This is rejected by the evidence (Lamont and Thaler, 2003). This evidence is immune to the Fama (1970) critique mentioned above. Froot and Dabora (1999) examine the share prices of large *Siamese twin* companies. These are companies that (i) have merged at some point in the past, but operate in geographically separate areas, and (ii) pool their cashflows, but each twin retains its own stock. So if companies A and B are Siamese twins who have merged on an $x : y$ basis ($x + y = 1$), then shares in company A are a claim to $x\%$ of the total cashflows of the merged company. If, as EMH suggests, prices of shares equal fundamental values, then the ratio of share prices of companies A and B should also be in the proportion $x : y$.

Froot and Dabora (1999) examine three pairs of Siamese Twins. (1) Royal Dutch Petroleum and Shell Transport and Trading, PLC. (2) Unilever NV and Unilever PLC. (3) SmithKline Beecham. Rosenthal and Young (1990) had already shown that there is a significant departure of the relative

⁵ A more satisfactory objection is that the book value might not adequately capture the fundamental value of the firm. For instance, firms that have excellent future growth prospects have high book to market values; in contrast those that are perceived to face agency problems have low book to market values. For attempts to construct a better measure of MBVR, but in the context of merger decisions of firms, see Ang and Cheng (2006) and Dong et al. (2006).

⁶ Grinblatt and Moskowitz (2004) use tax factors to explain a part of the momentum effect. However, tax factors cannot explain the momentum effect in its entirety.

Figure 21.3 Log deviations of prices from the predicted 1.5 : 1 ratio for Royal Dutch and Shell Transport.

Source: Reprinted from *Journal of Financial Economics* 53(2): 189–216. Kenneth A. Froot and Emil M. Debora. (1999). "How are stock prices affected by the location of trade?" Copyright © 1999, with permission from Elsevier.

share prices of Royal Dutch-Shell and Unilever NV and Unilever PLC from the predicted ratio under EMH. Froot and Dabora report two main findings:

(a) Traded price is rarely in the proportion $x : y$, contradicting the EMH. Consider, for instance, Royal Dutch and Shell Transport, which merged in 1970 on a 60:40 or 1.5:1 basis. So a share in Royal Dutch is a claim to 60% of the cash flow of the merged companies. The percent deviations of the ratio of prices from the predicted 1.5:1 basis are significant and shown in Figure 21.3. Similar disparities are reported for all three pairs of companies in Froot and Dabora.

(b) The price of the stock of each twin is highly correlated with the market index shares where the twin predominantly trades. For instance, when the US stock market performs relative to the UK market, then share prices of Royal Dutch, predominantly traded on the US stock market, rise relative to Shell, which is predominantly traded in the UK market. The same effect is obtained when the US dollar appreciates against the British pound.

A corollary of T5 is that controlling for the degree of differences in assets, their returns should be similar. However, the well-known equity premium puzzle (see Part 1 of the book), is a counterexample. Stocks are riskier than bonds, however, the 7% a year premium on stocks over bonds, averaged over a sufficiently long period, is too large to be explained, even accounting for the level of risk (Mehra and Prescott, 1985; Benartzi and Thaler, 1995).

Finally, we turn to the last implication of EMH that security prices should *not* react to no-news (see T6 above). The stock market crash of 1987, in which the Dow Jones fell by 22.6%, did not follow any apparently relevant news. Cutler et al. (1991) find that no major news accompanied the 50 largest one-day stock price movements since World War II. A corollary of T6 is that prices of stocks should not be affected by factors that are unrelated to fundamentals; for the evidence from Treasury bills see Duffee (1996), Krishnamurthy (2002), and Greenwood and Vayanos (2010).

Evidence relevant for T6 also comes from the inclusion of new stocks into the S&P 500 index. From time to time, some of the existing stocks in the index are withdrawn because, say, companies merge or are taken over. New stocks are then used to replace the withdrawn stocks with the objective of maintaining the representativeness of the index. The EMH predicts no change in the price of the stock that has been newly inducted into the index. The reason is that the induction, per se,

does not convey any new information about the company that was not available earlier. However, the evidence is that there is substantially increased trading in the freshly inducted stocks, contradicting T6; see, for instance, Harris and Gurel (1986), Shleifer (1986), Wurgler and Zuravskaya (2002).

Another piece of evidence comes from the literature on bubbles/sunspots in asset prices (Shiller, 2003). Speculative bubbles could cause departures of the price of an asset from fundamental values. However, as this departure worsens, the situation becomes unsustainable. Investors start expecting a reversion of prices towards the fundamental value. When the bubble bursts, there is a large change in the price of the asset without any apparent news. Similarly, stock prices often react to an announcement of an increase, or an initiation of dividends when such events convey no new news about fundamentals. The traditional explanations have sometimes relied on “dividends as a signaling device.” However, see Benartzi et al. (1997) who do not find any evidence that a dividend increase signals future changes in earnings.

For most investors, it is very hard to beat the stock market. For instance, Malkiel (1990) points out that, on average, mutual and pension fund managers are not able to beat passive investment strategies. This would, on the face of it, seem to rescue the EMH (Rubinstein, 2001). However, as Barberis and Thaler (2003) point out, on closer examination, this just turns out to be a confusion between necessary and sufficient conditions. The EMH implies that

“Prices equal fundamental values $\Rightarrow$ no arbitrage opportunities.”

However, the absence of arbitrage opportunities is only a necessary, but not sufficient condition for stock prices to equal fundamental values. Hence,

“No arbitrage opportunities $\nRightarrow$ prices equal fundamental values.”

Thus, the lack of success of actual fund managers in beating the stock market cannot be taken as evidence that prices equal fundamental values, or that the EMH holds.

The rejection of EMH has not gone unchallenged; see for instance Fama (1970). News that is favorable for returns might also be associated with changes in the risk from holding the security. So we need a model that incorporates both risk and return (the capital asset pricing model is one such model). Suppose that for some security, the level of return and exposure to risk go up following some news about the security. Furthermore, suppose we observe that prices are below fundamental values, yet sufficient arbitrage activity does not take place. The Fama (1970) critique would imply that we do not see enough arbitrage precisely because the security is more risky now and the higher return justifies the greater risk. So there is no need for further arbitrage to put downward pressure on the return.

Every empirical finding that is contrary to the EMH could then be challenged on this technical ground. However, this possibility was already checked for in the results of stock market underreaction and overreaction by De Bondt and Thaler (1985), reported above. They measured risk using the then dominant model in finance, the capital asset pricing model (CAPM), under which the only risk relevant for the pricing of an asset is the covariance of the stock returns with the market portfolio; the correlation between the two is called “beta.” They found the beta value for winners to be 1.37 and the beta value for losers to be 1.03. Thus, losers were actually less risky than winners, which goes in the reverse direction to Fama’s critique. Beginning with a series of papers in the early 1990s, written by Fama and French, the response in classical finance has been to debunk the CAPM model (Fama and French, 1996a,b). Fama and French went on to construct

three factor and five factor models with additional explanatory variables that were proposed to give a better measure of risk, but it is not clear if these models are supported by the empirical evidence (Fama and French, 2015).

It is worthwhile to review some of the evidence of the success, or lack of it, of individual investors in beating the stock market. In general, the evidence suggests that, on average, individual investors earn below market rates of pre-tax return on investments, whether one takes account of transaction costs or not. However, for very short run investments, say, a week, the performance of individual investors is better, at least based on US data. This evidence is nicely summarized in Barber and Odean (2013) that we draw on here.

Based on the trading records of 10,000 investors, Odean (1999) gave evidence documenting below-average returns of individual investors in the absence of transaction costs of trade. Barber and Odean (2000) replicate these results in the presence of transaction costs from the trading records of 78,000 investors. Their main findings are as follows. First, transaction costs are the main reason for the underperformance of individual investors relative to the market. Second, those investors who traded more are, on average, more likely to realize lower returns. For instance, the difference in annual rates of return between the 20% of investors who trade the most and the 20% who trade the least, is 7 percentage points.

These results have been widely replicated in other countries. For holding periods ranging from a day to six months, Barber, Lee, et al. (2009) examine trading data from Taiwan over 1995–1999. Individual investors buy stocks that subsequently perform poorly and sell stocks that subsequently perform strongly. The behavior of institutional investors is the opposite, suggesting poor stock picking skills on the part of individual investors. Grinblatt and Keloharju (2000) show, for Finnish data, that individual investors earn low returns. Furthermore, they have poor stock selection abilities. They are net buyers of stocks that have weak future performance, while institutional investors are net buyers of stocks that do well subsequently. Poor stock selection ability of individual investors is also found for US data (Hvidkjaer, 2008; Barber, Odean, and Zhu, 2009).

For investments over a short horizon, say, one week, the evidence from the US suggests that individual investors perform quite well (Barber, Odean, and Zhu, 2009; Kaniel et al., 2012; Kelly and Tetlock, 2013). However, these results are not supported by Taiwanese data (Andrade et al., 2008; Barber, Lee, et al., 2009). For Finland, empirical evidence suggests that investors make losses on limit orders⁷ but gains on market orders (Linnainma, 2010), but the opposite result is found for Taiwan (Barber, Lee, et al., 2009).

There is substantial heterogeneity in investors' skills. There is some evidence that there might be a positive correlation between cognitive skills and investor performance (Korniotis and Kumar, 2013; Grinblatt et al., 2012) and a negative correlation between age and investor performance (Korniotis and Kumar, 2009). A strong gender effect has been noted by Barber and Odean (2001) who report two main findings. First men trade more than women. Second, those who trade more earn lower profits. Gender effects on the extent of trading are found for Germany, although these are weakened once we take account of risk aversion (Dorn and Huberman, 2005).

Men are often found to be more overconfident than women in empirical studies. This is one possible reason why men trade more and so realize lower returns (Glaser and Weber, 2007; Grinblatt and Keloharju, 2009). Evidence from US data indicates a strong correlation between self-reported measures of competence and the extent of trading (Graham et al., 2009).

⁷ A limit order is an order placed with a brokerage firm to buy or sell a fixed number of shares at a specified price or better.

Excessive trading may also be the result of *sensation seeking*. The idea is that individuals view trading activity as a form of entertainment, or sensation seeking. Thus, there might be a degree of substitutability between various sensation seeking activities so that when individuals have access to alternative sensation seeking activities (e.g., raised stakes in state lotteries or the introduction of a new legal lottery), they engage in less stock market trading (Dorn and Sengmueller, 2009; Gao and Lin, 2014).

Coval et. al. (2005) show that market inefficiencies can be exploited by skillful individual investors to earn abnormal profits, which exceed the profits arising from other strategies based upon size, value, or momentum. Furthermore, there is persistence in profits, across time, among skillful investors. Similar results of persistence in intertemporal returns among the most skillful investors are found for Taiwanese data by Barber et al. (2014). However, the percentage of these skillful investors is very low. As one might expect, evidence shows that the special skills required to earn above-average returns in the stock market are more likely to reside with institutional investors (Grinblatt and Titman, 1989; Daniel et al., 1997).

21.3 Noise trader risk

Any departure from Bayesian rationality on account of, say, judgment heuristics that are inconsistent with classical statistics is termed as *investor sentiment*. Investors who exhibit investor sentiment are sometimes called *unsophisticated investors*, or *noise traders*. In this section, we consider the seminal model of noise trader risk due to De Long et al. (1990a).

Noise, in this context, may be defined as any information that is irrelevant to the fundamental value of a security. Rational traders, or *arbitrageurs* in neoclassical theory, are assumed to ignore such noise. In contrast, noise traders view noise as useful information. Black (1986, p. 531) describes noise traders, thus: “People who trade on noise are willing to trade even though from an objective point of view, they would be better off not trading. Perhaps they think the noise they are trading on is information. Or perhaps they just like to trade.” The presence of noise traders provides a powerful theoretical case against EMH, which, for the reasons we have documented above, serves to limit arbitrage activities.

On account of the noise traders, arbitrageurs face two kinds of risk.

1. Arbitrageurs incur a *noise trader risk* by participating in arbitrage activity. For instance, mispricing caused by the noise traders might get worse in the future, or arbitrageurs might not be able to hold on to a loss making position for the length of time that it takes for noise traders to lose enough money to exit the market. Thus, prices might deviate from fundamental values for extended periods of time, even in the absence of any fundamental risk. Classical finance does not deny the existence of noise traders. However, and purely on grounds of theoretical implausibility rather than concrete evidence, it is argued that noise traders have no more than a fleeting impact on financial markets. Furthermore it is believed that rational arbitrageurs would trade against noise traders who would then lose money and exit the market (Friedman, 1953; Fama, 1965). However, this rules out the possibility that noise traders may hold on to irrational beliefs for a sufficient length of time and arbitrageurs might have to liquidate their loss making positions before noise traders can exit.
2. Arbitrageurs may undertake insufficient arbitrage for assets with high *fundamental risk*, provided they are sufficiently risk averse. By contrast, investor sentiment may be sufficiently

strong for noise traders to engage in active trading despite the high fundamental risk and risk aversion. This takes away the normal countervailing effect of arbitrageurs in bringing prices in line with fundamental values.

We now introduce noise traders into a simple model in finance (De Long et al., 1990a). The two main results, each contradicting the supposition in classical finance, are as follows. First, the returns of noise traders may exceed the returns of arbitrageurs for a length of time, precisely because of noise trader risk. Second, several anomalies in the financial economics literature can be reconciled by the model, e.g., excessive volatility of stock prices, and long-run under-pricing of stocks. The main assumptions of the model are as follows.

1. (*Basic economic structure*) Consider an overlapping generations model of two-period lived individuals.⁸ There is no population growth. In the first period of their lives, individuals are “young” and in the second period they are “old.” For pedagogical simplicity, the young do not consume, so only the old consume (this is not critical to the results). Individuals are born with an endowment of $y > 0$ units of a single consumption good, which is also the numeraire good whose price in any period, is normalized to 1. There are no bequests and no production decisions to be made, only financial decisions, which we now turn to.
2. (*Financial assets*) The only economic decision taken by a young person is to allocate the endowment, y , between a risky asset and a riskless asset. Both assets earn a one-period return $r > 0$ per unit (in terms of the consumption good). The main difference between the two assets is that the riskless asset is in perfectly elastic supply, while there is only one unit of the risky asset in the aggregate. One unit of the riskless asset can always be converted into one unit of the consumption good (and back), hence, the price of the riskless asset equals 1 every period. On the other hand, because the risky asset is in a fixed supply of 1 unit, its price in period t is denoted by P_t in units of the consumption good.
3. (*Types of investors*) There are two types of young people in any period. (a) *Noise traders* hold noisy beliefs about the returns on the risky asset that have no basis in the fundamentals. (b) *Rational arbitrageurs* hold correct beliefs about the returns on the risky asset based only on the fundamentals, although they take account of the presence of noise traders. Variables pertaining to these two types of traders are superscripted, respectively, by $i = n, a$ (n for noise traders and a for arbitrageurs). There is no fundamental risk in the economy because each of the two assets has an identical return of $r > 0$ per period. The one, and only, source of risk is the noisy beliefs held by noise traders (described below).
The proportion of noise traders and arbitrageurs in the population is, respectively, $\mu \in [0, 1]$ and $1 - \mu \in [0, 1]$. Within each type of investor, the population is completely homogeneous. The size of the total population is normalized to $N = 1$.
4. (*Sequence of moves*) In any time period t , each type of young individual, $i = n, a$, receives an endowment, $y > 0$, and decides to hold $\lambda_t^i \geq 0$ units of the risky asset, which cost P_t per unit, and $y - \lambda_t^i P_t$ units of the riskless asset. The old in any period t hold the 1 unit of the risky asset. Since $N = 1$, the total demand for the risky asset by the young is given by

$$\mu \lambda_t^n + (1 - \mu) \lambda_t^a.$$

⁸ Readers can consult any standard macroeconomics book for the overlapping generations model; see, for instance, Blanchard and Fischer (1989, ch. 3).

There is a fixed supply of one unit of the risky asset, hence, the market clearing condition that determines the price of the risky asset, P_t , in period t , is given by

$$\mu\lambda_t^n + (1 - \mu)\lambda_t^a = 1. \quad (21.4)$$

5. (*Nature of noisy beliefs*) In any time period t , noise traders misperceive the expected price of the risky asset in period $t + 1$ by a misperception term ρ_t that is normally distributed with mean ρ^* and variance η^2 , i.e.,

$$\rho_t \sim N(\rho^*, \eta^2), \forall t. \quad (21.5)$$

Hence, $\rho_t > 0$ implies overestimation (or overconfidence), while $\rho_t < 0$ implies underestimation (or conservatism) of expected returns on the risky asset. This is the only source of risk in the model. ρ_t is realized at the end of period t , hence, its realized value is known at the beginning of period $t + 1$. Arbitrageurs continue to think that the return on the risky asset is r , based on the fundamental values. In making their decisions on how much to invest at time t , arbitrageurs know that the price at time $t + 1$ will be influenced by the demand of noise traders at time $t + 1$. At time t , $\rho_{t+1} \sim N(\rho^*, \eta^2)$, so the investors do not know the realization of ρ_{t+1} . But they do know that this creates an uncertain price for the risky asset at time $t + 1$, P_{t+1} (expressed in terms of the consumption good).

6. (*Wealth and its moments when old*) A young arbitrageur at time t purchases λ_t^a units of the risky asset, which cost $\lambda_t^a P_t$ in units of the period t consumption good. When old, each unit of the risky asset gives a return of r and is sold at a price P_{t+1} . All assets must be sold when old because there are no bequests and individuals only derive direct utility from consumption. The remaining amount, $y - \lambda_t^a P_t$, is spent on the riskless asset. The riskless asset earns a return of r when old and can be sold at a price of 1 (expressed in units of the consumption good). Hence, the total wealth, expressed in units of the consumption good of the arbitrageur, when old, net of the cost, y , is given by

$$w_{t+1}^a = (y - \lambda_t^a P_t)(r + 1) + \lambda_t^a(r + P_{t+1}) - y, \quad (21.6)$$

or,

$$w_{t+1}^a = ry + \lambda_t^a [r + P_{t+1} - P_t(1 + r)]. \quad (21.7)$$

For a random variable at time $t + 1$, x_{t+1} , we use the notation $\bar{x}_{t+1} = E[x_{t+1} | I_t]$, $\sigma_{x_{t+1}}^2 = \text{Var}[x_{t+1} | I_t]$, respectively, to denote the mathematical expectation and the variance of x_{t+1} , conditional on the information set, I_t . In (21.7), the only random variable on the RHS is P_{t+1} . This randomness, from the perspective of time t , is caused by the misperception of period $t + 1$ noise traders as reflected in the term $\rho_{t+1} \sim N(\rho^*, \eta^2)$. Thus, the expected wealth of arbitrageurs is

$$\bar{w}_{t+1}^a = ry + \lambda_t^a [r + \bar{P}_{t+1} - P_t(1 + r)], \quad (21.8)$$

and the variance of their wealth is

$$\sigma_{w_{t+1}^a}^2 = (\lambda_t^a)^2 \sigma_{P_{t+1}}^2, \quad (21.9)$$

where $\bar{P}_{t+1} = E[P_{t+1} | I_t]$ and

$$\sigma_{\bar{P}_{t+1}}^2 \equiv E[(P_{t+1} - \bar{P}_{t+1})^2 | I_t], \quad (21.10)$$

is the variance of the period $t + 1$ price, conditional on the period t information set.

Now consider the second group of investors at time t , the young noise traders. They operate in a similar manner to the arbitrageurs, except that they misperceive the price P_{t+1} by an amount $\rho_t \geq 0$, due to investor sentiment. Recall that ρ_t is known at the end of period t , so it is already contained in the information set of noise traders at time t . Hence, analogous to (21.6), noise traders (mis)perceive their wealth to be

$$w_{t+1}^n = (y - \lambda_t^n P_t)(1 + r) + \lambda_t^n(r + \rho_t + P_{t+1}) - y. \quad (21.11)$$

Note that in (21.11), the actual realization of the random term ρ_t is also denoted by ρ_t in order to conserve on notation. Proceeding as above, noise traders compute their expected wealth to be

$$\bar{w}_{t+1}^n = ry + \lambda_t^n [r + \rho_t + \bar{P}_{t+1} - P_t(1 + r)], \quad (21.12)$$

and their computed variance of wealth is analogous to (21.9), $\sigma_{w_{t+1}^n}^2 = (\lambda_t^n)^2 \sigma_{P_{t+1}}^2$, because ρ_t is known at the end of period t .

7. (Preferences) Noise traders and arbitrageurs have identical *constant absolute risk aversion* (CARA) preferences. Since there is no consumption when young, the utility of any individual depends only on their wealth when they are old. This utility is given by

$$U(w_{t+1}) = -\exp(-2\gamma w_{t+1}),$$

where $2\gamma > 0$ is the coefficient of absolute risk aversion, i.e., $-U''/U'$.

We now use a well-known result in statistics. If x is normally distributed with mean $\bar{x}$ and variance σ_x^2 , then

$$E[-\exp(-\gamma x)] = -\exp\left(-\gamma\left(\bar{x} - \frac{\gamma}{2}\sigma_x^2\right)\right), \gamma > 0.$$

It turns out that w_{t+1} is normally distributed; this arises because the misperception term ρ_{t+1} that influences P_{t+1} in (21.11) is normally distributed. Thus, we can compute the expected utility of an individual with random wealth w_{t+1} and the CARA utility function explicitly as follows.

$$EU(w_{t+1}) = E[-\exp(-2\gamma w_{t+1})] = -\exp\left(-2\gamma\left(\bar{w}_{t+1} - \frac{1}{2}2\gamma\sigma_{w_{t+1}}^2\right)\right). \quad (21.13)$$

Notice that the expectation operator is eliminated from the RHS; we assume that $EU > 0$, otherwise demand for the risky asset collapses. Maximizing $EU(w_{t+1})$ is formally equivalent to maximizing $\bar{w}_{t+1} - \gamma\sigma_{w_{t+1}}^2$. Using (21.8), (21.9), an arbitrageur, $i = a$, maximizes the following objective.

$$\max_{\langle \lambda_t^a \in [0,1] \rangle} EU(\bar{w}_{t+1}^a) \Leftrightarrow \max_{\langle \lambda_t^a \in [0,1] \rangle} \left[ry + \lambda_t^a [r + \bar{P}_{t+1} - P_t(1+r)] - \gamma (\lambda_t^a)^2 \sigma_{P_{t+1}}^2 \right]. \quad (21.14)$$

On account of (21.5), the noise trader misperceives the return on the risky asset. Using (21.12), (21.9) we can derive an expression analogous to (21.14) for the noise trader.

$$\max_{\langle \lambda_t^n \in [0,1] \rangle} EU(\bar{w}_{t+1}^n) \Leftrightarrow \max_{\langle \lambda_t^n \in [0,1] \rangle} \left[ry + \lambda_t^n [r + \bar{P}_{t+1} - P_t(1+r) + \rho_t] - \gamma (\lambda_t^n)^2 \sigma_{P_{t+1}}^2 \right]. \quad (21.15)$$

This completes the description of the model. The optimization problems in (21.14), (21.15) are unconstrained concave optimization problems. From the first order conditions, we can find λ_t^a, λ_t^n .

$$\lambda_t^a = \frac{r + \bar{P}_{t+1} - P_t(1+r)}{2\gamma \sigma_{P_{t+1}}^2}. \quad (21.16)$$

$$\lambda_t^n = \frac{r + \bar{P}_{t+1} - P_t(1+r)}{2\gamma \sigma_{P_{t+1}}^2} + \frac{\rho_t}{2\gamma \sigma_{P_{t+1}}^2}. \quad (21.17)$$

The optimal holding of the risky asset can be positive or negative, i.e., $\lambda_t^i \geq 0$. In particular, $\lambda_t^i < 0$ implies that the investor engages in short selling (or shorting) of the asset. From (21.16), (21.17), the following three comparative static effects are obvious.

1. Each type of investor invests more in the risky asset if its expected return, $r + \bar{P}_{t+1}$, is high.
2. Each type of investor invests less in the risky asset if the conditional variance of the next period price of the risky asset, $\sigma_{P_{t+1}}^2$, is high. Risk averse investors dislike fluctuations in the capital gains of the assets they hold. Higher risk aversion (higher γ) magnifies this effect.
3. Noise traders invest more in the risky asset, the greater the realization of the noise term, ρ_t , i.e., the greater is their degree of bullishness.

To find the price of the risky asset in period t , P_t , substitute the demands for the risky asset in (21.16), (21.17) into the market clearing condition (21.4) to get,

$$P_t = \frac{1}{1+r} \left[r + \bar{P}_{t+1} - 2\gamma \sigma_{P_{t+1}}^2 + \mu \rho_t \right]. \quad (21.18)$$

The model is difficult to solve because of the presence of the expectation term, $\bar{P}_{t+1}$, on the right hand side. However, by restricting attention to steady states we can make progress. In the steady state, the conditional expectations of future prices and their conditional variances are time invariant,

$$\bar{P}_{t+1} = \bar{P}_{t+j}, \text{ and } \sigma_{P_{t+1}}^2 = \sigma_{P_{t+j}}^2; j = 2, 3, \dots \quad (21.19)$$

Rewrite (21.18) at $t+1$

$$P_{t+1} = \frac{1}{1+r} \left[r + \bar{P}_{t+2} - 2\gamma \sigma_{P_{t+2}}^2 + \mu \rho_{t+1} \right]. \quad (21.20)$$

Hence, the conditional variance of the one-period-ahead price in the steady state is

$$\sigma_{\bar{P}_{t+1}}^2 = \left(\frac{\mu}{1+r} \right)^2 \eta^2. \quad (21.21)$$

Take expectations on both sides of (21.20), and using (21.5), (21.19), we get $\bar{P}_{t+1} = \frac{1}{1+r} [r + \bar{P}_{t+1} - 2\gamma\sigma_{\bar{P}_{t+1}}^2 + \mu\rho^*]$. Solving out for $\bar{P}_{t+1}$, we get

$$\bar{P}_{t+1} = \frac{1}{r} [r - 2\gamma\sigma_{\bar{P}_{t+1}}^2 + \mu\rho^*]. \quad (21.22)$$

Substituting (21.21), (21.22) into (21.18) we get the steady state solution to the price of the risky asset in period t ,

$$P_t = 1 + \frac{\mu(\rho_t - \rho^*)}{1+r} + \frac{\mu\rho^*}{r} - \frac{2\gamma}{r} \left(\frac{\mu}{1+r} \right)^2 \eta^2. \quad (21.23)$$

We can infer the following insights from (21.23).

1. If the noise traders behaved like the arbitrageurs (i.e., $\rho_t = 0$, $\rho^* = 0$ and $\eta^2 = 0$), then (21.23) implies that the price of the risky asset equals its fundamental value, i.e., $P_t = 1$. In this case, the risky and the riskless assets become perfect substitutes, so the market values them identically.
2. There is no fundamental risk in the model. However, variations in the degree of misperception of the noise traders, as captured by the size of $\rho_t - \rho^*$ (second term in (21.23)), determines the variation in the price of the risky asset in the steady state. If young noise traders at time t are bullish (high ρ_t), then the price of the risky asset is higher. The mechanism works like a self-fulfilling prophesy. From (21.17), noise traders invest more in the risky asset if they believe that the future price of the risky asset will be higher, and this is directly determined by the realization of ρ_t ; this increased demand, in turn, pushes up the actual price of the risky asset. Conversely, if they are bearish (low ρ_t), then the price of the risky asset is lower. As the second term in (21.23) shows, the impact of the degree of bullishness and bearishness of the noise traders is increasing in the fraction of noise traders, μ .
3. In deciding how much of the risky asset to hold, the young in period t take into consideration, the return $r + P_{t+1}$. The period $t + 1$ price, P_{t+1} , is expected to be higher if the average bullishness of period $t + 1$ noise traders, ρ^* , is high. In this case, the young in period t are willing to pay a higher price, P_t , for the risky asset (third term in (21.23)) because they can sell their risky asset in period $t + 1$ at a higher price.
4. Noise traders might become more or less bullish in period $t + 1$ (recall that $\rho_{t+1} \sim N(\rho^*, \eta^2)$, $\forall t$). This creates uncertainty in the minds of investors in period t about the price of the risky asset, P_{t+1} , and its returns, $r + P_{t+1}$. The fourth term in (21.23) takes account of this risk; the size of this term is directly proportional to the degree of risk aversion of the trader, as captured by the size of γ . Risk averse investors are compensated by a reduction in the current price of the risky asset that is directly proportional to the variance, η^2 , of the misperception term.

We now analyze the difference in the expected relative returns of the noise traders and the arbitrageurs, Δ^e . From (21.8), (21.12), and noting that the actual return on the risky asset is r and

not $r + \rho_t$, the “actual” difference in expected wealth levels of the noise traders and the arbitrageurs is given by

$$\Delta^e = (\lambda_t^n - \lambda_t^a) [r + \bar{P}_{t+1} - P_t(1 + r)]. \quad (21.24)$$

Using (21.16), (21.17), we get

$$\lambda_t^n - \lambda_t^a = \frac{\rho_t (1 + r)^2}{2\gamma\mu^2\eta^2}. \quad (21.25)$$

From (21.25), noise traders invest relatively more in the risky asset if they are optimistic ($\rho_t > 0$). Using (21.22), (21.23), the expected excess return from holding the risky asset relative to the safe asset is given by

$$r + \bar{P}_{t+1} - P_t(1 + r) = \frac{2\gamma\mu^2\eta^2}{(1 + r)^2} - \mu\rho_t. \quad (21.26)$$

In the absence of any noise trader misperception ($\rho_t = 0$, $\eta^2 = 0$), the RHS of (21.26) is zero, so there is no excess return on the risk asset. From (21.24), when expected excess return from holding the risky asset is positive, then by holding relatively more of the risky asset ($\lambda_t^n > \lambda_t^a$), noise traders ensure that their returns are higher, i.e., $\Delta^e > 0$.

Substitute (21.25), (21.26) in (21.24) to get

$$\Delta^e = \rho_t - \frac{\rho_t^2 (1 + r)^2}{2\gamma\mu\eta^2}. \quad (21.27)$$

It is quite possible that noise traders have higher expected returns than arbitrageurs, i.e., $\Delta^e > 0$.⁹ It is clear that a necessary condition for this to happen is that $\rho_t > 0$. When $\rho_t > 0$, noise traders are bullish, so they invest relatively more than arbitrageurs in the risky asset ($\lambda_t^n > \lambda_t^a$). But for the risk undertaken by noise traders to pay off, the risky asset should earn excess returns relative to its fundamentals (the riskless asset always earns its fundamental return). This, in turn, requires that the RHS of (21.26) be positive.

The extent of excess return on the risky asset depends on the variance of ρ_{t+1} , which is given by η^2 . The reason is that if there is considerable uncertainty about the beliefs of noise traders at time $t + 1$, then risk averse arbitrageurs at time t wish to curtail their investment in the risk asset. Noise traders are also risk averse, but their bullishness ($\rho_t > 0$) counteracts their risk aversion to invest in the risky asset. On net, it is possible that the price of the risky asset at time t , P_t (see (21.23)), is reduced. Higher risk aversion of the arbitrageurs (higher γ) magnifies this effect, hence, increasing the excess return on the risky asset.

Thus, paradoxically, in an environment of considerable uncertainty and strong investor sentiment in a direction that is contrary to the fundamentals, noise traders may outperform rational arbitrageurs. It is important, in this argument, that noise traders be bullish, but not too bullish. For if they are too bullish, they end up increasing P_t (see second term in (21.23)) and depressing the return on the risky asset. It is for this reason that for a high enough ρ_t , $\Delta^e < 0$. Conversely when noise traders are bearish, $\rho_t < 0$, they can make a considerable loss. The reason is that on

⁹ Hirshleifer et al. (2003) also give a similar theoretical result.

account of noise trader risk, the risky asset always earns a premium in the presence of risk averse investors. If $\rho_t < 0$, noise traders invest less in the risky asset as compared to the arbitrageurs and miss out on the premium, hence, their returns are relatively lower.

As a final comment, taking expectations on both sides of (21.27), and noting that $E\rho_t^2 = \rho^{*2} + \eta^2$ we get

$$E\Delta^e = \rho^* - \frac{\rho^{*2}(1+r)^2 + \eta^2(1+r)^2}{2\gamma\mu\eta^2}. \quad (21.28)$$

From (21.28), a necessary condition for the average return of noise traders to be relatively higher is that mean misperception is positive, i.e., $\rho^* > 0$. The first term captures the positive effect of bullishness of the beliefs of noise traders in enhancing their profits relative to the arbitrageurs. However, more bullish noise traders buy more of the risky asset, driving up the price P_t , which reduces the return on the risky asset and their relative profits (second term). The fact that under these conditions, the average expected returns of noise traders could be relatively higher, predisposes them to outlast the rational arbitrageurs; exactly the opposite conclusion to that advocated in all principles of economics courses.

21.4 The limits to arbitrage

The vast bulk of arbitrage activity in financial markets is not undertaken by dispersed small investors. Rather, it is undertaken by a relatively small number of professional mutual and pension funds managers who manage portfolios on behalf of millions of dispersed investors. We now consider the implications of this *separation between brains and capital for financial markets* in a simple three-period, partial equilibrium model (Shleifer and Vishny, 1997). Figure 21.4 gives a concise bird's eye view of the model that we now explain in greater detail.

1. (*Basic structure*) There are three time periods, $t = 1, 2, 3$. There is a single perfectly divisible asset whose supply is normalized to 1 unit, and whose fundamental value in any time period

Figure 21.4 A basic description of the structure of the three-period model under professional arbitrage.

is $V > 0$. The price of the asset at time t is p_t . In time period $t = 3$, the price of the stock always equals its fundamental value, i.e., $p_3 = V$. Hence, there is no fundamental risk in the economy.

2. (*Types of investors*) There are three kinds of investors who create a demand for the single asset. (1) Noise traders. (2) Arbitrageurs, whose objective is to maximize period 3 profits, or revenues, because there are no costs. (3) Small investors.

The arbitrageurs do not invest their own funds; one may think of them as professional managers of mutual and pension funds who invest the funds of small investors. Noise traders are of the *pessimistic type*. In each of the first two periods, they think that the value of the single asset is $V - S_t$, $t = 1, 2$. The arbitrageurs know and observe S_1 , but they are uncertain about S_2 , which has the interpretation of a shock to noise trader sentiment in period 2. With probability q , S_2 takes a value $S > S_1$, i.e., the pessimistic misperceptions become worse. With the complementary probability $1 - q$, $S_2 = 0$, i.e., all misperception disappears.

Arbitrageurs and small investors are risk neutral and fully rational (although, small investors rely on the arbitrageurs to invest their funds, perhaps because they do not understand the structure of the problem).

3. (*Direct demands for the asset*) We take a reduced-form approach and directly specify demands for noise traders and the arbitrageurs. The direct monetary, or nominal, demand of noise traders in the first two time periods is

$$D_t^n = V - S_t, t = 1, 2. \quad (21.29)$$

Thus, the real demand of noise traders (in units of the asset) equals

$$\frac{D_t^n}{p_t} = \frac{V - S_t}{p_t}, t = 1, 2. \quad (21.30)$$

Arbitrageurs depend solely on the resources gathered from small investors in order to demand the asset. Denote the cumulative funds at the disposal of the arbitrageurs in time period $t = 1, 2$ by F_t . We assume that $F_1 < S_1$ is exogenously given, while F_2 is endogenous and depends on the decisions made by arbitrageurs in period 1. The endogenously determined nominal demand of arbitrageurs for the asset in period 1, D_1^a , must satisfy

$$D_1^a \leq F_1. \quad (21.31)$$

If $D_1^a = F_1$, then arbitrageurs are said to be *fully invested*. However, arbitrageurs could be worried that the pessimism of noise traders might get worse in period 2. In this case, if they are carrying the asset into period 2, they might have to sell it at a lower price. And so, they might be better-off hedging their portfolio and carrying ahead some “cash” into the second period. The cash can then be used in period 2 to buy the asset whose price at $t = 3$ is known with certainty ($p_3 = V$). Thus, if $D_1^a < F_1$, we say that investors are *not fully invested*. In terms of units of the asset, the real demand for the asset by the arbitrageurs in period 1 is, thus, given by

$$\frac{D_1^a}{p_1}. \quad (21.32)$$

Using (21.30), (21.32) we can set the total demand for the asset $\frac{V-S_1}{p_1} + \frac{D_1^a}{p_1}$ equal to the total supply of 1 unit. This determines the price, p_1 , in the first period, i.e.,

$$\frac{D_1^n}{p_1} + \frac{D_1^a}{p_1} = 1 \Leftrightarrow p_1 = V - S_1 + D_1^a. \quad (21.33)$$

In period 2, there are two possibilities depending on the realization of S_2 .

(a) With probability $1 - q$, $S_2 = 0$, so all noise trader misperceptions disappear. Recall that noise trader misperceptions are only of the pessimistic type, and serve only to lower demand and, thus, the price of the asset. Thus, when $S_2 = 0$, the second period price, p_2 , is the highest possible and the returns to the arbitrageurs from selling the asset are the highest possible. Hence, they liquidate their positions at a gain and hold cash between periods 2 and 3. Thus, second period resources, F_2 , of the arbitrageurs do not contribute anything towards second period demand of the asset, and only the noise traders demand the asset in period 2, thus,

$$1 = \frac{D_2^n}{p_2} = \frac{V}{p_2} \\ \Rightarrow p_2 = V.$$

(b) With probability q , $S_2 = S > S_1$, so the noise traders' pessimistic misperceptions deepen further. From (21.30), the demand by noise traders for the asset falls, so p_2 is low (in the absence of any demand by arbitrageurs, $p_2 = V - S < V$). By assumption $p_3 = V$, so the return to arbitrageurs from investing an extra unit of money in the asset exceeds that from holding cash. We make the assumption that in any period, the total resources available to the arbitrageurs to invest in the risky asset are restricted by the following condition.

$$F_1 < S_1; F_2 < S_2. \quad (21.34)$$

Condition (21.34) ensures that the arbitrageurs never have enough resources to completely negate the mispricing created by noise traders in any of the periods. So in the presence of noise traders' misperceptions, it is always the case that $p_1 \leq V$ (see (21.31), (21.33)) and $p_2 \leq V$ (see (21.35), below). So long as $p_2 \leq V$, the arbitrageurs will put all their second period resources, F_2 , into buying the asset. Thus, equating demand to the one unit supply gives the second period price of the asset as follows:¹⁰

$$1 = \frac{D_2^n}{p_2} + \frac{F_2}{p_2} \Leftrightarrow p_2 = V - S + F_2. \quad (21.35)$$

The condition $F_2 < S_2$ ensures that $p_2 \leq V$.

4. (*Performance based arbitrage*) Small investors ask the arbitrageurs to invest their funds because they do not have the necessary expertise or specialized knowledge to understand the working of financial markets. Furthermore, the arbitrageurs are informed about the

¹⁰ We allow short selling of assets. It is possible that some part of the asset is held by individual investors between periods 1 and 2 and these investors choose not to sell the asset in period 2. However, short selling does not require physical ownership of the asset. Thus, the total availability of the asset is one unit in period 2.

fundamental value of the asset, while the small investors are not. In the absence of any specialized knowledge of either the stock market or the fundamental value of the stock, small investors infer the quality of the arbitrageur simply by the past performance of the arbitrageur.¹¹ This is referred to as *performance based arbitrage* (PBA).

PBA can lead to perverse effects. Suppose, for instance, that noise traders' misperception worsens at $t = 2$, i.e., $S_2 = S$ increases. From (21.35), p_2 falls. Hence, the (gross) return on the period 1 investment made by arbitrageurs, $\frac{p_2}{p_1}$, falls; the net return, r , is $r = \frac{p_2 - p_1}{p_1} = \frac{p_2}{p_1} - 1$, so the gross return $r_g = 1 + r = \frac{p_2}{p_1}$. Observing a fall in the return offered by the arbitrageur between periods 1 and 2, PBA implies that in period 2 small investors withdraw funds from the arbitrageur, reducing the resources, F_2 , available to arbitrageurs to buy the asset. This, paradoxically, happens at a time when the gross return on the asset between periods 2 and 3, $\frac{p_3}{p_2}$, is the highest (because p_3 is fixed and p_2 takes the lowest possible value).

PBA is implemented as follows. The gross return r_g generated by the arbitrageur with borrowed funds from the small investors, between periods 1 and 2, on one dollar, is defined as

$$r_g = \frac{D_1^a}{F_1} \times \frac{p_2}{p_1} + \frac{F_1 - D_1^a}{F_1} \times 1. \quad (21.36)$$

Equation (21.36) is easy to understand. A fraction $\frac{D_1^a}{F_1}$ of the first period resources are invested by the arbitrageur in the asset, on which there is a gross return equal to $\frac{p_2}{p_1}$. The remaining fraction $\frac{F_1 - D_1^a}{F_1}$ is carried into period 2 as cash on which there is no net return. The supply of resources available to the arbitrageur at time $t = 2$, F_2 , is assumed to be given by the following functional relation, $F_2 = \phi(F_1 r_g)$; $\phi' > 1$, $\phi'' \leq 0$. For our purposes, a simple linear form will do, so let $\phi(x) = ax + (1 - a)$ where $a > 1$, so

$$F_2 = aF_1 r_g + (1 - a); a > 1. \quad (21.37)$$

Thus, a greater return between periods 1 and 2, r_g , leads to an increase in funds at the disposal of the arbitrageurs, F_2 , in period 2. These features capture PBA in the model. Substituting r_g from (21.36) in (21.37) we get

$$F_2 = a \left(D_1^a \times \frac{p_2}{p_1} + F_1 - D_1^a \right) + (1 - a). \quad (21.38)$$

5. (*Optimization problem of arbitrageurs*) The objective of the arbitrageurs at time $t = 1$ is to maximize the expected profits at $t = 3$. With no fixed costs of operation of the arbitrageurs, this is equivalent to maximizing period 3 expected revenues. Now consider the two possible events in period 2.

(a) With probability $1 - q$, $S_2 = 0$, $p_2 = V$ and arbitrageurs liquidate their position in the asset and only hold cash between periods 2 and 3. Hence, the expected funds at the disposal of investors at $t = 3$, $F_3|_{S_2=0}$, can be found by substituting $p_2 = V$ in (21.38) to get,

¹¹ See Shleifer and Vishny (1997) for why the use of signaling devices to generate a separating equilibrium, which is revealing of the arbitrageur's quality, is not plausible.

$$F_3 |_{S_2=0} = a \left(D_1^a \times \frac{V}{p_1} + F_1 - D_1^a \right) + (1-a). \quad (21.39)$$

(b) With the complementary probability, q , $S_2 = S > S_1$, and noise trader misperceptions deepen. Second period price p_2 drops to its lowest level and with a fixed $p_3 = V$, the return on holding a unit of the asset between periods 2 and 3 is the highest. Hence, the arbitrageurs put all their second period resources, F_2 , into buying the asset. With nominal funds, F_2 , arbitrageurs buy $\frac{F_2}{p_2}$ units of the asset at $t = 2$. At $t = 3$, each of these units sells for a guaranteed price of $p_3 = V$; this gives a total revenue of $\frac{V}{p_2} F_2$. Using (21.38) to substitute for F_2 (and noting that $p_2 \neq V$), the expected third period revenues, in this case, are,

$$F_3 |_{S_2=S} = \frac{V}{p_2} \left(a \left(D_1^a \times \frac{p_2}{p_1} + F_1 - D_1^a \right) + (1-a) \right). \quad (21.40)$$

Using (21.39), (21.40), the unconditional expected third period revenue of the arbitrageurs is $R = (1-q)F_3 |_{S_2=0} + qF_3 |_{S_2=S}$, or

$$R = (1-q) \left(a \left(D_1^a \times \frac{V}{p_1} + F_1 - D_1^a \right) + (1-a) \right) + q \frac{V}{p_2} \left(a \left(D_1^a \times \frac{p_2}{p_1} + F_1 - D_1^a \right) + (1-a) \right). \quad (21.41)$$

The optimization problem of the arbitrageur is to maximize (21.41) with respect to D_1^a subject to the constraint that¹²

$$D_1^a \leq F_1. \quad (21.42)$$

Since $D_1^a \leq F_1$ and from (21.34) $F_1 < S_1$, thus, from (21.33), $p_1 < V$. With probability $1-q$, $S_2 = 0$, $p_2 = V$. Thus, in this case, $\frac{V}{p_1} - 1 > 0$. With probability q , the misperceptions worsen to $S_2 = S > S_1$ and p_2 drops to its lowest level.

Differentiating (21.41) with respect to D_1^a , we get

$$\frac{\partial R}{\partial D_1^a} = a(1-q) \left(\frac{V}{p_1} - 1 \right) + aq \left(\frac{p_2}{p_1} - 1 \right) \frac{V}{p_2}. \quad (21.43)$$

An increase in the first period demand for the asset by the arbitrageurs, D_1^a , creates two opposing effects on third period revenues. These are captured, respectively, by the first and second terms on the RHS in (21.43). The first term captures the state of the world where noise trader misperception clears up ($S_2 = 0$), in which case the arbitrageurs sell off their asset holdings and make a profit; this is the positive marginal impact of increasing D_1^a . The second term captures the complementary state of the world in which misperceptions worsen ($S_2 = S$), and $\frac{p_2}{p_1} < 1$. In this state, due to PBA, small investors withdraw some of their funds from the arbitrageurs. The second term captures the opportunity cost of these lost funds precisely when the return on these funds is very high; this is the negative marginal impact of increasing D_1^a .

The RHS of (21.43) depends on D_1^a through p_1 . For a corner solution, $D_1^a = F_1$, we require that $\frac{\partial R}{\partial D_1^a} > 0$, thus,

¹² We allow $D_1^a < 0$ through the usual process of shorting an asset.

$$(1 - q) \left(\frac{V}{p_1} - 1 \right) + q \left(\frac{p_2}{p_1} - 1 \right) \frac{V}{p_2} > 0 \Leftrightarrow D_1^a = F_1. \quad (21.44)$$

For the case $D_1^a < F_1$, we need $\frac{\partial R}{\partial D_1^a} = 0$, thus,

$$(1 - q) \left(\frac{V}{p_1} - 1 \right) + q \left(\frac{p_2}{p_1} - 1 \right) \frac{V}{p_2} = 0 \Leftrightarrow D_1^a < F_1. \quad (21.45)$$

A necessary condition for (21.45) to hold is that the second term is negative, i.e., $p_2 < p_1$ so $\frac{p_2}{p_1} - 1 < 0$.

What factors are important for the arbitrageur to choose to be *partially invested* ($D_1^a < F_1$) rather than *fully invested* ($D_1^a = F_1$)? Comparing (21.44), (21.45), and assuming that $\frac{p_2}{p_1} - 1 < 0$, the necessary conditions are the following.

1. High probability of worsening misperceptions in period 2, i.e., high q .
2. Small misperception shock, S_1 , in period 1. From (21.33), this increases p_1 relative to V , so $\frac{V}{p_1}$ is low.
3. S should be relatively high so that p_2 is low; this ensures that $\frac{p_2}{p_1}$ is not too high.

At the other extreme, the arbitrageurs are fully invested ($D_1^a = F_1$); they bet on a price recovery in period 2, following the slump in period 1. This is the case that we predominantly want to focus on below. Substituting $D_1^a = F_1$ in (21.38) we get that

$$F_2 = a \left(F_1 \frac{p_2}{p_1} \right) + 1 - a. \quad (21.46)$$

We can summarize these results in a proposition and leave the proof for the reader.

Proposition 21.8 (Shleifer and Vishny, 1997): (a) There exists a value q^* such that if $q < q^*$, then $D_1^a = F_1$, and if $q > q^*$, then $D_1^a < F_1$.
 (b) When the arbitrageurs are fully invested, $D_1^a = F_1$, then $\frac{dp_1}{dS_1} < 0$, $\frac{dp_2}{dS} < 0$, and $\frac{dp_1}{dS} = 0$.
 However, when not fully invested, $D_1^a < F_1$, then $\frac{dp_1}{dS_1} < 0$, $\frac{dp_2}{dS} < 0$, and $\frac{dp_1}{dS} < 0$.

In Proposition 21.8(b), the main difference between the two cases is the sign of $\frac{dp_1}{dS}$. When not fully invested, an expectation of greater noise trader misperception in period 2 reduces the period 2 price and reduces the return from holding the asset between periods 1 and 2. This reduces period 1 demand of the asset on the part of arbitrageurs, hence reducing the period 1 price, $\frac{dp_1}{dS} < 0$.

From (21.35), we know that $p_2 = V - S_2 + F_2$, hence,

$$p_2 = V - S_2 + a \left(F_1 \frac{p_2}{p_1} \right) + 1 - a \equiv f(p_2); f' > 0, f'' = 0. \quad (21.47)$$

In (21.47), a fixed point of the relation $p_2 = f(p_2)$ is given by $p_2^* = f(p_2^*)$. Stability requires that $f'(p_2^*) = a \frac{F_1}{p_1} < 1$. We illustrate the situation in Figure 21.5, for two cases: $f' < 1$ (curve I) and $f' > 1$ (curve II). There are two fixed points corresponding to each of these curves, p_2^* and p_2^{**} ; p_2^* is stable while p_2^{**} is unstable.

Figure 21.5 Stability analysis in the Shleifer and Vishny (1997) model.

Source: Shleifer, A. and Vishny, R. W. (1992). "Liquidation values and debt capacity: a market equilibrium approach." *The Journal of Finance* 47: 1343–66. © American Finance Association. With permission from John Wiley & Sons.

At the unstable equilibrium, $f'(p_2^{**}) > 1$. Even the slightest decrease in price to any $p_2 < p_2^{**}$ will push the second period price down all the way to $V - S_2$ (which is assumed to be strictly positive in the diagram). The intuition is that in this case, second period prices are too low, thus, the returns on investment between periods 1 and 2 are so low that small investors start withdrawing their resources from the arbitrageurs (this is due to PBA). As this happens, second period price falls further, another round of withdrawals takes place and so on, until the arbitrageurs are left with no funds to invest. Unlike the neoclassical assumptions, there is a complete failure of arbitrage. The only demand for the asset in this case comes from noise traders who demand $V - S_2$.

At the stable equilibrium, $p_2^* > V - S_2$, the arbitrageur does not run out of resources because the second period price is high enough, and gross returns on investment are adequate for small investors who rely on PBA to invest at least some resources with the arbitrageurs.

Implicitly differentiate both sides of (21.47) with respect to S_2 to get,

$$\frac{\partial p_2}{\partial S_2} = \frac{-1}{1 - f'} = \frac{-1}{1 - a \frac{F_1}{p_1}}.$$

At the stable equilibrium, $p_2 = p_2^*$, we know that $f'(p_2) = a \frac{F_1}{p_1} < 1$, hence, $\frac{\partial p_2}{\partial S_2} < -1$. Thus, following a worsening of noise trader misperceptions (increase in S_2), prices fall more than one to one. This occurs because PBA ensures that small investors reduce the flow of funds to arbitrageurs, which leads to a further collapse of demand for the asset. From (21.47), we know that in the absence of any demand for the asset by the arbitrageurs, $p_2 = V - S_2$, so p_2 should fall one to one with a worsening of noise trader misperceptions.

The claim of classical finance theory has been that the role of irrational noise traders can be neglected in the presence of rational arbitrageurs because the arbitrageurs will take trading positions that nullify irrational activity. In other words, classical finance assumes that $\frac{\partial p_2}{\partial S_2} = 0$. However, we have just shown that the presence of these rational arbitrageurs coupled with the

plausible assumption of PBA actually makes matters worse because prices move in the wrong direction by even more (i.e., more than one to one). The reason is that as prices fall, gross return on the investment falls between periods 1 and 2, so small investors start withdrawing their money. When this run on the financial resources of the arbitrageurs takes place, they start to liquidate their positions in the asset.¹³ But as they do so, demand for the asset collapses further and its price falls even more. Hence in extreme situations, the arbitrageurs can be ineffective in bringing prices back to their fundamental values.¹⁴

One implication of these results is that newly formed hedge funds are less likely to succeed in the marketplace relative to older, established ones. The reason is that PBA would bite more for the younger funds (higher value of a), because small investors are unsure of their quality. Hence, as noise trader misperceptions worsen, and gross rates of returns on assets decline, the run on younger funds would be far greater relative to that on established funds. Thus, paradoxically, newer and younger funds lose money exactly at the time when expected returns on assets are very high, but average returns in the past are lower.

The financial events involving the Long Term Capital Management (LTCM) fund in 1998 are also indicative of the mechanism outlined in this section. Russia defaulted on its ruble denominated debt in 1998. This eventually created events in the West that look similar to a large S_2 shock in the model (Shleifer, 2000). The result was that arbitrageurs such as LTCM lost funds precisely when the expected returns on these funds were very high. In the event, LTCM was bailed out by the US Federal Reserve Bank for a temporary reprieve, but many other arbitrageurs were less fortunate.

21.5 Gradual flow of information

We have noted above, the very large trading volume in stock markets that poses a puzzle for EMH. One possible explanation of too large a trading volume is the presence of heterogeneity among investors about their prior beliefs. Despite receiving identical public information, different investors may interpret it differently due to underlying heterogeneity in beliefs about fundamentals, or the relevant economic model (Harris and Raviv, 1993; Kandel and Pearson, 1995). This potentially triggers far too much trade among investors even when the underlying fundamentals do not warrant it. This difference in beliefs can induce investors to trade far more than that warranted by the economic fundamentals.

Bubbles and stock market booms are often preceded by excessive trading volumes that appear unlikely to be driven by economic fundamentals. Examples include the internet bubble during 1997–2000 and the stock market boom of the late 1920s; for fascinating accounts, see Ofek and Richardson (2003), Galbraith (1997), and Kindleberger and Aliber (2005). A leading explanation is that during these periods, there is disagreement among the beliefs of market participants about the nature of future price movements.

An illuminating example of these disparate beliefs is given by Huberman and Regev (2001). They look at the effect of news announcements about a biotechnology firm, *EntreMed*, on its stock prices. News that *EntreMed* had undertaken pathbreaking research into cancer treatment

¹³ Arbitrageurs would liquidate even more quickly if they were risk averse rather than risk neutral, as is assumed here. Hence, the conclusions are even more stark under risk aversion.

¹⁴ The result that in the presence of limited capital, arbitrageurs might liquidate their positions prematurely is also a feature of several other models; see, for instance, Shleifer and Vishny (1992).

appeared in the journal *Nature* in November 1997. The news also appeared in the newspaper *the Times* on page A28 (not a particularly salient page), as well as in other media. This resulted in an increase in the price of EntreMed stocks. However, five months later, on May 3, 1998, *The Times* carried out a front page story (a very salient page) on topical cancer research innovations in which EntreMed's contributions were noted prominently. However, this news was not new. Contrary to the predictions of EMH, the stock price of EntreMed rose from \$12/share to \$52/share within a day.

Hong and Stein (1999, 2007) suggest the following interpretation of this event. There are two kinds of investors, *specialists*, who read specialist scientific journals (such as *Nature*) and *generalists*, who avoid a serious scientific read, but keep a lookout for salient bits of news (such as the front page of *The Times*). The original news in *Nature*, read by the specialists, but not by the generalists, lead to a difference in beliefs about the future prices of EntreMed stocks. The attempts by the specialists to buy the EntreMed stock triggered the initial jump in the stock prices. An important aspect of the behavior of generalists is that they do not draw inferences from the buying activities of the specialists. They do not imagine that perhaps the specialists have some important bit of news that could be relevant for future stock prices. The generalists only wake up to the news when it is presented to them in a very salient form in a non-specialist publication, which, in this case, happened five months later.

If it is true that generalists only respond to very salient information, then the framing of information must play an important role in their decisions. An important corollary is that inattentive investors must respond less when they are distracted. DellaVigna and Pollet (2009) exploit this corollary to show that announcements of earnings on Friday generate less trading activity relative to announcements on other days. One plausible explanation is that *inattentive investors* get distracted by weekend activities, so they do not act sufficiently on the announcement when they next have an opportunity, on the following Monday.

Barber and Odean (2008) show that *attention grabbing stocks* that have experienced abnormal trading/returns or news coverage recently, trade more. Coverage of an earnings announcement in the local newspaper also boosts trading of the associated stock (Engelberg and Parsons, 2011). Overnight buy-sell recommendations in the TV show *Mad Money* also lead to greater trading when the viewership on the show is higher (Engleberg et al., 2011). For the Shanghai stock exchange, Seasholes and Wu (2007) find that there is greater trading in a stock if it hits an upper price limit (an attention grabbing event). In a similar vein, Hirshleifer et al. (2009) find that the immediate stock price and volume response to a firm's earnings surprise is weaker, and post-earnings announcement drift is stronger, when a greater number of earnings announcements by other firms are made on the same day.

Hong and Stein (1999) propose a model of gradual information transmission while Hong et al. (2000) provide the relevant empirical evidence. Hong and Stein (2007) give a simple stylized model that conveys the essentials of their ideas, which we now outline below. The main feature of the model is that biased investors are of two types; each type believes in its incorrect economic model of the world. The purpose of this simple model is to illustrate the following points.

1. Investor heterogeneity has an important impact on temporal prices and returns.
2. Momentum and trading volume are closely related.
3. Even when price equals fundamental value, there can be aggressive trading.

Consider a three-period model, with time $t = 1, 2, 3$. There is a single stock that pays a dividend equal to D at time $t = 3$. The interest rate is normalized to zero and there is no risk premium for holding the stock. The realized dividends at time $t = 3$ obey the "true" economic model,

$$D = s_1 + s_2, \quad (21.48)$$

where s_1, s_2 are two distinct, uncorrelated, public signals whose realization is known only at time $t = 2$. At time $t = 1$, the signals are just known to have zero means and respective variances σ_1^2, σ_2^2 .

There are two kinds of investors, each with an incorrect and incompatible model of the real world.

1. A fraction $\lambda \in [0, 1]$ of investors believes that the model describing dividends is $D = s_1$.
2. The remaining fraction, $1 - \lambda$, of investors believes that the model is $D = s_2$.

Furthermore, at time $t = 2$, the fraction λ only observes s_1 (but not s_2), while the fraction $1 - \lambda$ only observes s_2 (but not s_1). Often, in the short run, individuals observe what they are looking for and miss what they are not looking for because of limited attention and confirmation-bias. At time $t = 3$, everyone observes both signals as well as the true model given in (21.48). The model, thus, incorporates both gradual information transmission, and limited attention. In period 3, everyone learns the true model and observes the actual realizations of the signals, s_1, s_2 .

At time t , the price of the stock is given by P_t . Each investor is willing to pay a price for the stock that equals the expected dividend. The aggregate price P_t is simply a weighted average of the prices expected by the two kinds of investors. Thus, letting E denote the expectation operator with respect to the information set at time $t = 1$,

$$P_1 = \lambda E[s_1] + (1 - \lambda)E[s_2] = 0. \quad (21.49)$$

At time $t = 2$, s_1 is observed by a fraction λ and s_2 by a fraction $1 - \lambda$ of investors, hence,

$$P_2 = \lambda s_1 + (1 - \lambda)s_2. \quad (21.50)$$

At time $t = 3$, s_1, s_2 is observed by all investors and the price of the stock is simply equal to the dividend, hence,

$$P_3 = D = s_1 + s_2. \quad (21.51)$$

Using (21.49), (21.50), the monetary return, R_2 , from holding the stock between periods 1 and 2 is

$$R_2 = P_2 - P_1 = \lambda s_1 + (1 - \lambda)s_2. \quad (21.52)$$

Using (21.50), (21.51), the monetary return, R_3 , between periods 2 and 3 is

$$R_3 = P_3 - P_2 = (1 - \lambda)s_1 + \lambda s_2. \quad (21.53)$$

At $t = 1$, $E[R_2] = E[R_3] = 0$ because $E[s_1] = E[s_2] = 0$. Hence, the perceived covariance at $t = 1$ between the returns R_2 and R_3 is given by

$$\text{Cov}(R_2, R_3) = E[R_2 R_3]. \quad (21.54)$$

Substituting R_2, R_3 from (21.52), (21.53) into (21.54) we get

$$\text{Cov}(R_2, R_3) = E[\lambda(1-\lambda)(s_1^2 + s_2^2)] = \lambda(1-\lambda)(\sigma_1^2 + \sigma_2^2). \quad (21.55)$$

We now give the following reasonable definition of momentum; momentum is higher if there is a higher correlation in returns.¹⁵

Definition 21.10 (*Momentum*): Momentum is defined by $\text{Cov}(R_2, R_3) = \lambda(1-\lambda)(\sigma_1^2 + \sigma_2^2)$.

It is reasonable to assume that, at time $t = 2$, investors engage in greater trading if the difference between the investor's own expectation of the period 3 price and the actual price in period 2 is higher; in this case the perceived expected returns are higher.

At time $t = 2$, a fraction λ of the investors expect that $P_3 = s_1$ (these investors observe s_1 at $t = 2$). The current price is, however, P_2 . If $P_2 \neq s_1$, then these investors see a trading opportunity. If $P_2 > s_1$, then such investors believe that $P_2 > P_3$, so they engage in short selling the asset.¹⁶ If $P_2 < s_1$, then they take a long position. Furthermore, the greater is $|P_2 - s_1|$, the greater is the perceived trading opportunity, thus, the greater is the volume of trade engaged in by these traders.

Analogously, a fraction $1 - \lambda$ of the investors expects that $P_3 = s_2$ (these investors observe s_2 at $t = 2$). They see a trading opportunity if $P_2 \neq s_2$. Averaged across the two types of investors, the trading volume is proportional to

$$V = \lambda |P_2 - s_1| + (1 - \lambda) |P_2 - s_2|. \quad (21.56)$$

Substituting P_2 from (21.50) into (21.56) we get

$$\begin{aligned} V &= \lambda |(1-\lambda)(s_2 - s_1)| + (1-\lambda) |\lambda(s_1 - s_2)|. \\ \Rightarrow V &= \lambda(1-\lambda) |s_1 - s_2|. \end{aligned} \quad (21.57)$$

Definition 21.11 (*Trading volume*): The trading volume is defined by $V = \lambda(1-\lambda) |s_1 - s_2|$.

We can now use this simple framework to derive our results.

1. Heterogeneity in beliefs is crucial to generate momentum in stock prices. From (21.55), momentum is maximized at the unique value $\lambda = 0.5$. Suppose, for example, that $\lambda = 1$. In this case, all investors mistakenly believe that the economic model for dividends is given by $D = s_1$. So the realization of s_2 at date $t = 2$ is ignored by all investors and does not affect P_2 , thus, $P_2 = s_1$. P_3 continues to be given by $P_3 = s_1 + s_2$. Since $P_1 = 0$, thus,

¹⁵ Other explanations for momentum have also been given. For instance, Daniel et al. (1998, 2001) give an explanation based on the distinction between private and public information. Investors are overconfident about private information (relative to public information) that they have worked to generate. Our section on behavioral corporate finance below develops this point. Overconfidence arising from private information can drive prices above fundamental values. Public information has an asymmetric effect. Confirmatory public news strengthens private information, however, contrary public news is slow to shake off wrongly held private beliefs (see attribution-bias in the behavioral corporate finance section below). *Ceteris paribus*, public news may gradually, over time, drive prices back towards fundamentals.

¹⁶ For a theoretical model of gradual flow of information in the presence of short sales constraints, see Palfrey and Wang (2012). An important result of this model is speculative overpricing and asymmetric reaction to good news and bad news.

- $R_2 = s_1$ and $R_3 = s_2$. Since s_1, s_2 are uncorrelated, so are R_2, R_3 and there is no momentum in stock prices. Analogously it is easy to check that when $\lambda = 0$, there is no momentum either. Hence, heterogeneity in beliefs is crucial to generate momentum in stock prices.
2. From (21.57), trading volume is (uniquely) maximized when $\lambda = 0.5$. Thus, trading volume is highest when momentum is highest. A testable prediction is that momentum should be highest for stocks whose trading volume is high; this is borne out by the empirical evidence (Lee and Swaminathan, 2000).
 3. Consider now the case where price equals fundamental value. So suppose that the realizations of s_1, s_2 at date $t = 2$ are such that $s_1 = -s_2$. From (21.48), (21.49), (21.51) we know that in this case $P_1 = P_3 = D = 0$. Hence, the prices at times $t = 1, 3$ are equal to the fundamental value of the stock. However, from (21.57), the trading volume is given by $V = 2\lambda(1 - \lambda)|-s_2| > 0$. Furthermore, V is increasing in the size of $|-s_2|$. In the special case of no heterogeneity, i.e., $\lambda = 0$ or $\lambda = 1$, $V = 0$. Thus, on account of investor heterogeneity (when $\lambda \neq 0$ or $\lambda \neq 1$), there can be large trading volumes, despite the fact that prices equal fundamental values ($P_1 = P_3 = D = 0$).

21.6 Stock market underreaction and overreaction

Suppose that there is a single investor who invests in a security that has a return r_t in period t . In every period, the investor hears some news, x_t , about the company that sells the security. The news can take two possible forms, good (G) and bad (B). Empirical evidence suggests that over short horizons (1–12 months) stock markets *underreact* to news. However, in the long run (3–5 years), stock markets *overreact* to consistent news pointing in the same direction. Thus, an important phenomenon in stock markets is *underreaction* in the short run and *overreaction* in the long run.¹⁷ In this section, we explain underreaction and overreaction by using the representativeness heuristic and conservatism-bias (Barberis et al., 1998). First we need to define the terms underreaction and overreaction formally, using the definitions in Barberis et al. (1998).

Definition 21.12 (*Underreaction*): Stock market underreaction takes place if following good news at time t , the next period return, r_{t+1} , is higher than that following bad news.

$$E[r_{t+1} | x_t = G] > E[r_{t+1} | x_t = B]. \quad (21.58)$$

In classical finance, and as reflected in the EMH, good or bad news is immediately reflected in stock market prices; there are no implications for prices or returns in the next period. Indeed, if the market anticipates such news, its effect is supposed to be already incorporated in the rates of return prior to period t . In contrast, from (21.58), stock markets do not react fully to the good news in period t . This mistake is reflected in a higher expectation of the next period return. This has implications for the EMH in that expectations are correlated with elements of the information set. In other words, stale information can help predict future returns. Thus, if investors are sophisticated, and are aware of (21.58), they can beat the market.

Definition 21.13 (*Overreaction*): Stock market overreaction takes place if following a sequence of good news, the expected future return is relatively lower as compared to that following a sequence of bad news. In other words,

¹⁷ There is extensive empirical evidence, see, for instance, De Bondt and Thaler (1985), Bernard and Thomas (1989), Cutler et al. (1991), Chopra et al. (1992), Fama and French (1992), Jegadeesh and Titman (1993), Lakonishok et al. (1994), La Porta (1996), and Chan et al. (1997).

$\varepsilon_t = -x$	$1 - p_L$	p_L

Table 21.2 States and transition probabilities in the trending model (T).

	$\varepsilon_{t+1} = x$	$\varepsilon_{t+1} = -x$
$\varepsilon_t = x$	p_H	$1 - p_H$
$\varepsilon_t = -x$	$1 - p_H$	p_H

$$E[r_{t+1} | x_t = G, x_{t-1} = G, \dots, x_{t-j} = G] < E[r_{t+1} | x_t = B, x_{t-1} = B, \dots, x_{t-j} = B]. \quad (21.59)$$

For a given sequence of good news the market overreacts, so to take account of this, future returns are expected to fall. In this case, high past returns help to predict a lower future return, which again runs counter to the EMH.

To explain (21.58), (21.59), we use the following formal setup. There is a single risk-neutral representative investor whose discount rate is θ . A single security pays out all its earnings as dividends. The *true model* of earnings is a random walk, so the dividends at time t , D_t , are given by

$$D_t = D_{t-1} + \varepsilon_t; \quad \varepsilon_t = \pm x, \quad (21.60)$$

where ε_t is a random term. In any time period, ε_t takes on two possible values, $x > 0$ and $-x$ with equal probability.

The investor mistakenly believes that the true model is either (1) *mean reverting* (M), or (2) *trending* (T). In particular, the correct model, the random walk model, is not even considered to be a possibility by the investor.¹⁸ The investor wishes to figure out which of the two incorrect models best fits the sample. In all other respects, the investor obeys the classical laws of probability. Models M and T are both Markov processes that we now describe; see Tables 21.1 and 21.2. We assume that the transition probabilities p_L, p_H obey the restriction,

$$0 \leq p_L < 0.5 < p_H \leq 1. \quad (21.61)$$

In model M there is a relatively greater likelihood of the outcomes reversing from one period to the next (x followed by $-x$ or vice versa). This is the sense in which it is mean reverting. In model T , on the other hand, there is a relatively greater likelihood of the same outcome in two

¹⁸ In the model in Hong et al. (2007), the true model is multivariate, but investors use a univariate model. Economic agents keep track of errors they make in successive periods. Learning allows them to change from one incorrect model to another incorrect model.

Table 21.3 Markov transition probabilities for the two states of the world.

	$s_{t+1} = M$	$s_{t+1} = T$
$s_t = M$	$1 - \lambda_1$	λ_1
$s_t = T$	λ_2	$1 - \lambda_2$

consecutive periods (x followed by x or $-x$ followed by $-x$). In this sense, model T is a trending model.

The investor knows p_L, p_H and believes that the world potentially switches between the two models in any two contiguous time periods. In particular, investors believe that there is a Markov transition *between the two models* in any two consecutive periods. Denote by $s_t = M, T$ to be the state of the world at time t . Then, the state changes according to the transition matrix shown in Table 21.3.

$\lambda_1 \in [0, 1]$ is the transition probability of switching from model M to model T , while λ_2 is the transition probability of switching from model T to model M in two successive periods. We make the following assumptions on λ_1, λ_2 .

$$\lambda_1 + \lambda_2 < 1 \text{ and } \lambda_1 < \lambda_2. \quad (21.62)$$

The assumptions in (21.62) impose two restrictions. (1) Each of λ_1, λ_2 is individually small. So the investor believes that the probability of a model change is small. (2) The probability of switching from model M to T is lower than the probability of switching in the reverse direction; thus model M is the more persistent model.

In order to value the security, the investor must evaluate the expected returns from holding it. This requires the investor to guess which of the two (incorrect) models generates the earnings. In period t , denote by π_t^M , the belief that the data is generated by model M ; with the complementary probability, $1 - \pi_t^M$, the data is believed to be generated by model T .

The investor observes the earnings shock ε_{t+1} and wishes to calculate the posterior probability, $\pi_{t+1}^M = P(s_{t+1} = M \mid \varepsilon_{t+1}, \varepsilon_t, \pi_t^M)$, that model M generated the earnings in period $t + 1$. Using Bayes' rule,

$$\pi_{t+1}^M = \frac{P(\varepsilon_{t+1} \mid \varepsilon_t, s_{t+1} = M, \pi_t^M) P(s_{t+1} = M)}{P(\varepsilon_{t+1} \mid \varepsilon_t, s_{t+1} = M, \pi_t^M) P(s_{t+1} = M) + P(\varepsilon_{t+1} \mid \varepsilon_t, s_{t+1} = T, \pi_t^M) P(s_{t+1} = T)}, \quad (21.63)$$

where

$$P(s_{t+1} = M) = (1 - \lambda_1) \pi_t^M + \lambda_2 (1 - \pi_t^M) \quad (21.64)$$

$$P(s_{t+1} = T) = \lambda_1 \pi_t^M + (1 - \lambda_2) (1 - \pi_t^M) \quad (21.65)$$

Equation (21.64) is derived as follows. In period t , the investor assigns respective probabilities π_t^M and $1 - \pi_t^M$ that the data is generated by models M and T . If the period t model is M , then there is a probability $1 - \lambda_1$ that one transits to model M in the next period (first term in (21.64)). If the period t model is T , then there is a probability λ_2 that one transits to model M in the next

period (second term in (21.64)). Adding the two terms gives the total probability of transiting to model M in period $t + 1$. (21.65) can be explained in a similar manner.

For any values of $\varepsilon_t = \pm x$, $\varepsilon_{t+1} = \pm x$, we can calculate the RHS of (21.63). Suppose, for instance, that $\varepsilon_t = \varepsilon_{t+1} = x$, i.e., we have two successive x outcomes. Using Tables 21.1 and 21.2, we get that

$$P(\varepsilon_{t+1} = x \mid \varepsilon_t = x, s_{t+1} = M, \pi_t^M) = p_L \text{ and } P(\varepsilon_{t+1} = x \mid \varepsilon_t = x, s_{t+1} = T, \pi_t^M) = p_H \quad (21.66)$$

Substituting (21.64), (21.65), (21.66) in (21.63) we get

$$\pi_{t+1}^M = \frac{p_L [(1 - \lambda_1) \pi_t^M + \lambda_2 (1 - \pi_t^M)]}{p_L [(1 - \lambda_1) \pi_t^M + \lambda_2 (1 - \pi_t^M)] + p_H [\lambda_1 \pi_t^M + (1 - \lambda_2) (1 - \pi_t^M)]}. \quad (21.67)$$

Now suppose that we get two different outcomes in two consecutive periods, say, $\varepsilon_t = -x$, $\varepsilon_{t+1} = x$. Then proceeding as above, the analog of (21.67) is

$$\pi_{t+1}^M = \frac{(1 - p_L) [(1 - \lambda_1) \pi_t^M + \lambda_2 (1 - \pi_t^M)]}{(1 - p_L) [(1 - \lambda_1) \pi_t^M + \lambda_2 (1 - \pi_t^M)] + (1 - p_H) [\lambda_1 \pi_t^M + (1 - \lambda_2) (1 - \pi_t^M)]}. \quad (21.68)$$

Equations (21.67) and (21.68) enable us to derive the following important result.

Proposition 21.9 *Following two consecutive signals of the same sign, i.e., $\varepsilon_t = \varepsilon_{t+1} = x$ or $\varepsilon_t = \varepsilon_{t+1} = -x$ we get that*

$$\pi_{t+1}^M < \pi_t^M. \quad (21.69)$$

However, following two consecutive signals of the opposite sign, i.e., $\varepsilon_t = -x$, $\varepsilon_{t+1} = x$ or $\varepsilon_t = x$, $\varepsilon_{t+1} = -x$, we get that

$$\pi_{t+1}^M > \pi_t^M. \quad (21.70)$$

Proof: We sketch a brief heuristic proof. Using (21.67), when we get two successive x outcomes, define

$$\underline{\Delta}(\pi) = (\pi_t^M - \pi_{t+1}^M) \big|_{\pi_t^M = \pi} = \pi - \frac{p_L [(1 - \lambda_1) \pi + \lambda_2 (1 - \pi)]}{p_L [(1 - \lambda_1) \pi + \lambda_2 (1 - \pi)] + p_H [\lambda_1 \pi + (1 - \lambda_2) (1 - \pi)]}.$$

Using (21.68), when we get two consecutive signals of the opposite sign, define

$$\overline{\Delta}(\pi) = (\pi_{t+1}^M - \pi_t^M) \big|_{\pi_t^M = \pi} = \frac{(1 - p_L) [(1 - \lambda_1) \pi + \lambda_2 (1 - \pi)]}{(1 - p_L) [(1 - \lambda_1) \pi + \lambda_2 (1 - \pi)] + (1 - p_H) [\lambda_1 \pi + (1 - \lambda_2) (1 - \pi)]} - \pi.$$

Let q_t be the probability at time t that the signal came from model M . One can now verify that the shapes of $\underline{\Delta}(\pi)$, $\overline{\Delta}(\pi)$ shown in Figure 21.6 are consistent with the expressions above.

Figure 21.6 Figure corresponding to the proof of Proposition 21.9.

It can be checked that $\underline{\Delta}(\pi), \bar{\Delta}(\pi)$ are both concave in π and when $\pi \in [q_1, q_2]$, $\underline{\Delta}(\pi) \geq 0, \bar{\Delta}(\pi) \geq 0$. We can show that starting at any value of π outside the interval $[q_1, q_2]$ the investor's beliefs will come to lie in this interval. Suppose that the prior belief $\pi < q_1$. If there are two consecutive shocks of the same sign, then $\underline{\Delta}(\pi) < 0$ in this region, thus $\pi_{t+1}^M > \pi_t^M$ and beliefs are revised upwards towards the interval $[q_1, q_2]$. If, on the other hand, there are two consecutive shocks of opposite signs, then $\bar{\Delta}(\pi) > 0$ in this region, so $\pi_{t+1}^M > \pi_t^M$. Thus, beliefs are again revised upwards towards the interval $[q_1, q_2]$. One can derive a similar result in the case $q_2 < \pi$. Thus, provided that the investor is given sufficient time to update beliefs, there is no loss in generality in concentrating exclusively in the interval $[q_1, q_2]$ because starting with any prior beliefs outside this interval, with probability one, beliefs come to lie in this interval. In the interval $[q_1, q_2]$, if consecutive shocks have the same sign, then $\underline{\Delta}(\pi) > 0 \Rightarrow \pi_t^M > \pi_{t+1}^M$, as in (21.69). If, however, shocks have opposite signs, then $\bar{\Delta}(\pi) > 0 \Rightarrow \pi_{t+1}^M > \pi_t^M$ which verifies the claim in (21.70). ■

Proposition 21.9 shows that individuals revise their beliefs about the model M downwards if they observe two successive outcomes that are identical. Conversely if there are two successive outcomes that are of the opposite sign, then they revise their beliefs about model M upwards (and about model T downwards). This is an example of the representativeness heuristic. People are too quick to alter their beliefs based on a small sample.

Consider the following simulation exercise. Let $\pi_0^M = 0.5$, $\varepsilon_0 = x$, $p_L = 1/3$, $p_H = 3/4$, $\lambda_1 = 0.1$, $\lambda_2 = 0.3$. Then over the next 20 time periods, using the results derived so far, the evolution of beliefs that the model is mean reverting, π_t^M , is given in Table 21.4 for a sequence of realizations of ε_t , $t = 1, \dots, 20$.

Consider the time periods 1 to 4. During this period, the shocks alternate in sign. To the investor, this is suggestive of model M , despite the fact that the underlying model is a random walk. Hence, the investor's beliefs in model M go up very rapidly (from 0.5 to 0.94). On the other hand, during time periods 10 to 14, there are five successive and identical outcomes, which to the investor, is suggestive of model T . Hence, the beliefs of the investor that the model is M go down very rapidly (from 0.94 to 0.36). Table 21.4 also illustrates both the results in Proposition 21.9.

The price of the security is determined as follows. There is a single representative investor. The price, P_t , of the security in period t is the present discounted value of expected future dividends, $D_t, E_t D_{t+1}, \dots$

Table 21.4 Simulations for the Barberis et al. (1998) model.

t	ε_t	π_t^M	t	ε_t	π_t^M
0	x	.50	11	x	.74
1	$-x$	.80	12	x	.56
2	x	.90	13	x	.44
3	$-x$	.93	14	x	.36
4	x	.94	15	$-x$	.74
5	x	.74	16	x	.89
6	$-x$	.89	17	x	.69
7	$-x$	.69	18	$-x$	.87
8	x	.87	19	x	.92
9	$-x$	.92	20	x	.72
10	x	.94			

$$P_t = \left[\frac{D_t}{1+\theta} + \frac{E_t D_{t+1}}{(1+\theta)^2} + \dots \right]. \quad (21.71)$$

Using the true model, (21.60), i.e., $D_t = D_{t-1} + \varepsilon_t$; $\varepsilon_t = \pm x$, we know that

$$\begin{aligned} D_{t+1} &= D_t + \varepsilon_{t+1}, \text{ so } E_t D_{t+1} = D_t, \\ D_{t+2} &= D_{t+1} + \varepsilon_{t+2} = D_t + \varepsilon_{t+1} + \varepsilon_{t+2}, \text{ so } E_t D_{t+2} = D_t. \end{aligned}$$

In general, $E_t D_{t+j} = D_t, j = 1, 2, 3, \dots$. Thus (21.71) implies

$$\begin{aligned} P_t &= \frac{D_t}{1+\theta} \left[1 + \frac{1}{(1+\theta)} + \frac{1}{(1+\theta)^2} + \dots \right]. \\ \Rightarrow P_t &= \frac{D_t}{1+\theta} \left(\frac{1}{1 - \frac{1}{(1+\theta)}} \right) = \frac{D_t}{\theta}. \end{aligned} \quad (21.72)$$

Thus, if the investor knew the correct model of the economy, then the price of the security is given in (21.72). However, for an investor who mistakenly thinks that the dividends are generated by either a mean reverting or a trending model, Barberis et al. (1998, Proposition 1, p. 324) show that the price is given instead by

$$P_t = \frac{D_t}{\theta} + \varepsilon_t (c_1 - c_2 \pi_t^M), \quad (21.73)$$

where c_1, c_2 are constants that depend on the parameters of the model. Comparing (21.72), (21.73), misperception of the true model adds a bias-term, $\varepsilon_t (c_1 - c_2 \pi_t^M)$, to the correct price. For suitable values of c_1, c_2 one can generate underreaction in the short run and overreaction in the longer run. We briefly provide some intuition for the restrictions on the values of c_1, c_2 ; for details, see Barberis et al. (1998).

In the short run, following good news, there is, on average, insufficient adjustment; see (21.58). Thus, the price does not, on average, adjust sufficiently upwards (short-run underreaction). When

investors know the true model and there is no underreaction, $P_t = \frac{D_t}{\theta}$. However, in the presence of short-run underreaction and model misperception, P_t is given by (21.73). This short-run underreaction implies that $\varepsilon_t(c_1 - c_2\pi_{avg}^M) < 0$ (where π_{avg}^M is the average value of π) or equivalently,

$$c_1 < c_2\pi_{avg}^M. \quad (21.74)$$

Analogously, for P_t to exhibit long-run overreaction following a sequence of good news we know that the expected future price is lower. We know (see Table 21.4) that following a sequence of good news, the belief in model M, π_t^M , is quite low; let this low value be π_{low}^M . Then, for overreaction, we need P_t to exceed its fundamental value $\frac{D_t}{\theta}$, or equivalently

$$c_1 - c_2\pi_{low}^M > 0. \quad (21.75)$$

From (21.74), (21.75) we get the necessary restrictions on c_1, c_2 ,

$$c_2\pi_{low}^M < c_1 < c_2\pi_{avg}^M. \quad (21.76)$$

Condition (21.76) is sufficient to generate both underreaction and overreaction.

There are, however, other explanations of overreaction. Hong et al. (2007) formulate a model in which demands and prices of securities are determined by the interaction between financial advisors and investors. Consider an event that captures technical innovation. Advisors are of two types, tech-savvies (who understand new technology) and old-fogies (who do not understand the new technology, thus, they make downward biased recommendations). In order to signal their type, tech-savvies inflate their forecasts about the new technology, creating a bubble (or overreaction) in the new technology.¹⁹

21.7 Behavioral corporate finance

The subject of *corporate finance* has traditionally examined the interaction between managers of firms and investors in the firm. Implications are then drawn about the various actions taken by the firm, such as the source of finance, e.g., equity versus bonds, merger and acquisition decisions, capital restructuring, and the level of output. Classical finance assumes that both managers and investors are fully rational. Recent developments in *behavioral corporate finance* typically relax one of these two assumptions at a time. In this section we look at one representative model from each of these emerging literatures.²⁰

There are two main reasons for the rapid development and success of behavioral finance (as distinct from behavioral corporate finance). First, there is a generally agreed upon theoretical benchmark, the efficient markets hypothesis, which is refutable. Second, there is a good availability of data that makes it possible to refute the benchmark. However, both these aspects are

¹⁹ Many investors who are *sophisticated* might be informed about the types of the financial advisors. However, the results survive, provided that there is some critical minimum fraction of investors, which is *naïve*.

²⁰ For surveys of behavioral corporate finance, see Baker and Wurgler (2012) and the collection of papers in Baker and Nofsinger (2010).

missing in corporate finance, with the result that developments in this area have been relatively slower, but not insignificant.

21.7.1 *An introduction to managerial biases*

It is likely that the top levels of management in firms (henceforth, CEOs) exhibit several behavioral biases. Further, CEOs might be entrenched in the firm and hard to get rid of, e.g., the market cannot short sell a biased CEO. At the same time, there is a lack of good panel datasets on events that take place within a firm that could enable one to examine the several competing explanations in corporate finance. But why are CEOs likely to make mistakes or have biases that might be difficult to correct? There are several reasons that apply, in particular, to top level management, rather than the lower echelons of the hierarchy (Lazear, 2004).

First, many managerial decisions are of an infrequent nature that do not allow sufficient learning. The decisions are often so complex that the optimal solution is unclear, e.g., decisions to engage in specialized investments, large investments, merger decisions, acquisition decisions, and capital restructuring. Second, there might be no widely acceptable method of evaluating the efficiency of several corporate decisions, e.g., the appropriate evaluation of the long-run effects of mergers. Third, CEOs might be able to protect themselves against market competition. Unlike the standard assumption in the economics of contracts, the board of directors might not always act in a manner that maximizes the shareholder value. Top executives might be able to influence the board, determine their own pay, and be able to extract rents (Bebchuk et al., 2002).

A related question is why do biased CEOs make it to the top? Do not the firms' internal selection processes mitigate against such appointments? Not necessarily. Overconfident managers, for instance, are likely to take more risks and are more likely to leapfrog other managers in a tournament setting when relative performances are compared (Goel and Thakor, 2008). Furthermore, it is conceivable that more confident managers might have other traits that are correlated with the perception of being a good manager. These might include, for instance, the traits of being inspiring, charming, and possessing a positive outlook.

Another reason why the performance of CEOs might be hard to evaluate is because of *attribution-bias*. Outcomes often depend both on the CEO's skills as well as on purely random luck/external factors. However, boards of directors or shareholders might underestimate the effect of luck/external factors. The problem is exacerbated by a *self-serving bias* on the part of the CEOs. When companies do badly, annual reports are likely to pin the blame on external factors that are beyond the control of the CEOs. Conversely, the good performance of companies is attributed to internal factors (Bettman and Weitz, 1983). Bertrand and Mullainathan (2001) find that as oil prices increase, the compensation of executives in oil companies increases. However, oil prices are determined by events that the executives of oil companies have little control over, such as the world demand as well as the strategic policies of the OPEC countries.

Thus, there are good grounds to suspect that top managers can be biased, but is this borne out by the evidence? A growing literature answers this question in the affirmative. In most of this literature, CEO bias is studied using the trait of overconfidence. Overconfidence can mean several things. It could mean, for instance, assigning greater weight to the probability of a good outcome and less weight to poorer outcomes; this can be captured by non-linear probability weighting, as in Part 1 of the book. Or, it could mean an overestimate of the marginal product of one's efforts. One cause of overconfidence is the so-called *better than average effect* (Larrick et al., 2007; Benoit et al., 2014). A very large percentage of individuals rate their skills, e.g., driving skills, competence,

and IQ, better than the average or median values (Larwood and Whittaker, 1977; Svenson, 1981; Alicke, 1985). The persistence of overconfidence over time requires that individuals update information, as it accrues, in a biased and self-serving manner (Langer and Roth, 1975).

Weinstein (1980) suggests two domains in which managers are likely to be overconfident. First, in domains where managers have, or think that they have, control (*illusion of control*). Second, managers are more overconfident in domains where they have a *personal commitment*. Hong and Kubik (2003) examine the relation between accuracy and optimism in the earnings forecasts of security analysts with their job separations. Analysts who are more optimistic, rather than more accurate, are more likely to experience a favorable job separation, e.g., moving up to a high-status brokerage house. Brokerage houses apparently reward optimistic analysts who promote stocks more than relatively more accurate analysts. Other evidence of managerial overconfidence can be found in March and Shapira (1987) and Ben-David et al. (2013).

Entrepreneurs are typically overconfident of the success probability of their startups; an early set of experiments that supported this conclusion were conducted by Camerer and Lovo (1999). Only 5% of startup entrepreneurs believe that their odds are any worse than comparable enterprises and a third believe that their success is assured (Cooper et al., 1988). Based on French data, 56% expect “development” and only 6% of startup entrepreneurs expect “difficulty”; three years on, the respective figures are 38% and 17% (Landier and Thesmar, 2009). Empirically, only half of all startups survive beyond three years (Scarpetta et al., 2002) and the high failure rate among startups is widely reported in the popular press.

Unlike the correlation of some other behavioral phenomena with age, e.g., risk aversion, there is no clear relation between overconfidence and age. A positive relation is found in Hansson et al. (2008) while a negative relation is found in Tournon and Hertzog (2004). For an overview of the literature, see Glaser et al. (2004). Menkhoff et al. (2013) find that different measures of overconfidence need not be highly correlated. They also find that, in their sample, investment advisors are most overconfident while institutional investors are least overconfident.

What are the economic implications arising from biased managerial judgment? Roll (1986) linked managerial overconfidence, or hubris, to the tendency of managers to assign too high a value on firms that they were keen to acquire. So, in this view, managers are subject to a sort of winner’s curse. The successful bidders in mergers bid too high. R&D is an activity with highly uncertain returns. It is not surprising that managerial overconfidence is associated with higher levels of R&D activity and higher patent counts (Hirshleifer et al., 2012). Yet another manifestation of CEO overconfidence is the practice of holding on to the stock of their company for too long, hence, forgoing a profitable opportunity to sell company stock (Meulbroeck, 2001; Hall and Murphy, 2000, 2002). Indeed, this is the proxy used to determine managerial overconfidence in several empirical studies starting with Malmendier and Tate (2005).

Malmendier and Tate (2005) show that overconfident CEOs are more than one and a half times likely to engage in merger activities with other firms relative to the fully rational benchmark. Malmendier and Tate (2008) confirm the relation between overconfident CEOs and mergers. They also find that the market reaction to mergers is smaller when investors perceive CEOs to be more overconfident, suggesting a degree of sophistication in the market. Malmendier et al. (2011) show that more overconfident managers are also more likely to believe that their stocks are undervalued by the market and external finance is overpriced.

One implication of managerial overconfidence is that they believe that the prospects of their company are much better relative to the market perception. Hence, overconfident managers will believe that their stocks are undervalued by the market. For this reason, they will be reluctant to sell equity for investment or for merger activities. If the firm does not have access to adequate

levels of internal finance and/or is incapable of absorbing greater debt, then managerial overconfidence will result in lower levels of investment and merger activity. On the other hand, if sufficient internal finance is available, then overconfidence might lead to excessive levels of investment/mergers (Heaton, 2002; Gervais et al., 2011). In this case, high-powered managerial incentives will make a bad situation worse by making the manager too risk loving.

How can a firm rein in an overconfident manager? High levels of previous debt can reduce the overconfident manager's desire to overinvest. An impartial outside observer, whose consent might be needed by the manager before the board of directors will allow actual investment can also play a positive role. Set against these negative effects, one possible benefit of managerial overconfidence arises in team production (Gervais and Goldstein, 2007). In this setting, a team may contain an overconfident member who overestimates his own marginal product of effort and works harder. Due to complementarities in effort, this reduces the extent of the free-rider problem and increases total output.

Aktas et al. (2015) study the link between narcissism and mergers. Narcissism, a human trait, possibly linked to overconfidence, was measured by the ratio of the number of times that CEOs used first person singular pronouns to the total number of first person pronouns in transcribed speeches. Narcissists were more likely to play the role of acquirers in mergers, negotiate faster, and more likely to have initiated and completed mergers. In their roles as managers of target firms, they are more likely to have successfully secured higher bid premia.

21.7.2 *Rational managers, irrational investors, and merger/acquisition activity*

Three interesting waves of mergers have taken place from the 1960s to the 1990s. The merger movement in the 1960s is sometimes referred to as the *conglomerate wave*. This took the form of mergers between firms belonging to different industries. The *hostile takeover wave* of the 1980s was different in nature from that in the 1960s in at least two respects. The acquirers were mainly financiers and they paid in cash rather than in stock. The merger wave of the 1990s, on the other hand, had similarities with that of the 1960s wave. Mergers took place largely between firms in the same industry, the payment was in stock, and stock market valuations, unlike the 1980s wave, were very high.

Traditional corporate finance largely views mergers as a means to improving efficiency in the presence of industry-specific shocks. By improving efficiency, the prediction is that the profits of the merged firms should increase. However the existing empirical evidence is not able to give a clear answer to this prediction. For instance, what is the appropriate length of time over which profits should increase, and what is the relevant measure of profits? Furthermore, traditional corporate finance cannot explain specific features of the different waves of mergers. For instance, why does payment for a target in a merger sometimes take the form of stocks, but cash at other times? There are also other grounds on which the traditional theory is incompatible with the evidence from the stock market, e.g., the stock market might not react to news of the merger in the predicted manner (Shleifer and Vishny, 2003). Shleifer and Vishny (2003) use behavioral insights to enrich the standard model to take account of such considerations. We now outline this simple, stylized, and reduced-form model of mergers and acquisitions.

Consider two firms, labeled 1 and 2, who own capital stocks K_1 and K_2 , respectively. The stock market assigns values v_1, v_2 per unit, respectively, to these capital stocks, such that $v_1 < v_2$. In the spirit of the models considered in this chapter, it is assumed that the stock market is not efficient. Rather, it is subject to investor sentiment, but its precise source is not modeled here.

Assume that there is some *synergy* between the two firms if they merge; synergy could arise, for instance, from the sharing of information, technology, client lists, and market niches. The combined equity of the two firms, $K_1 + K_2$, is valued at v per unit, so that the total market value of the merged firm is given by

$$V = v \times (K_1 + K_2). \quad (21.77)$$

The following five cases are possible.

$$(a) v = v_1, (b) v < v_1, (c) v = v_2, (d) v_2 < v, (e) v_1 < v < v_2. \quad (21.78)$$

The unit value of the merged firm, v , is either the same or lower than the value of the less valuable of the two merged firms (cases (a) and (b)). Or the market could be very optimistic and value the combined firm the same as the more valuable firm (case (c)), or the market might be extremely euphoric (case (d)).

The most reasonable case seems to be (e), which is the only one that we pursue below.

Definition 21.14 *The no-synergy point is defined to be a value v^* such that*

$$v^* \times (K_1 + K_2) - v_1 K_1 - v_2 K_2 = 0. \quad (21.79)$$

From (21.79), if $v > v^*$, then the synergy level is high enough to ensure that the merged firm is more valuable than two independent firms, and if $v < v^*$, then a merger erodes the value of the two independent firms.

A simple distinction is made between the short run and the long run. In the long run, all assets, whether they belong to any of the independent firms or to the merged firm, are valued by the market at $\bar{v}$ per unit. Thus, the long-run values of firm 1, firm 2, and the merged firm, are, respectively, equal to $\bar{v}K_1$, $\bar{v}K_2$, and $\bar{v}(K_1 + K_2)$. Thus, there are no long-run gains or losses from a merger; any gains/losses only accrue in the short run.

For simplicity, we define a merger between the two firms in one of two ways; as in many modern analyses, the boundaries between mergers and acquisitions are quite blurred. Either firm 1 acquires firm 2, or vice versa. We consider only the case when firm 2, the more valuable firm, acquires firm 1. In this case, we refer to firm 2 as the *acquirer* and firm 1 as the *target*. The market is assumed not to draw any inferences from the method used by one firm to acquire another. Thus, in particular, the beliefs of the market, which are summarized by v_1 , v_2 , v , are not affected by alternative methods of payment, e.g., cash or stock, to acquire the target; this contrasts with the classical case that employs a signaling explanation that is based on the mode of financing (Myers and Majluf, 1984).

Suppose that the acquirer pays a price p per unit of equity to acquire the target, so the total money that is paid to acquire the target is pK_1 . The bargaining process is unmodeled, but some of the interesting possibilities, depending potentially on the relative bargaining strengths of the two firms, are the following.

$$(a) p = v_1, (b) p = v, (c) p < v, (d) v_1 < p < v. \quad (21.80)$$

In case (a), the target receives no *takeover premium*. In case (b), the target has enough bargaining power to receive a price that equals the short-run valuation of the merged firm. Case (c) reflects a somewhat lower bargaining power for the target firm. Case (d) recognizes that both firms have

some bargaining power. In this case, the target firm captures some, but not all, of the benefits of the market's perceived synergy between the two firms. The following proposition is self-evident and stated without proof.

Proposition 21.10 *The short-run effect of the merger on the profit levels of various firms is as follows.*

(a) *Combined market value*

$$v \times (K_1 + K_2) - v_1 K_1 - v_2 K_2. \quad (21.81)$$

(b) *Profits of the target firm*

$$(p - v_1)K_1. \quad (21.82)$$

(c) *Profits of the acquiring firm*

$$v \times (K_1 + K_2) - pK_1 - v_2 K_2 \equiv (v - p)K_1 + (v - v_2)K_2. \quad (21.83)$$

Notice that in (21.81)–(21.83) the appropriate opportunity cost in each case has been taken into account to derive the net benefits. Suppose that $v_1 < p < v$ (case (d) in (21.80)). Then, from (21.82), (21.83) the target certainly benefits from the merger. The acquirer can also potentially benefit from the merger; there is a gain from an increase in the value of the target ($v - p > 0$), but a loss on account of the merged firm being less valuable than the acquirer ($v - v_2 < 0$). If the target has no bargaining power at all, $p = v_1$, then, from (21.82), the target firm derives no net benefit from the merger.

Continue to assume that $v_1 < p < v$ (and recall that we are assuming the plausible case (e) in (21.78), $v_1 < v < v_2$).

The long-run effects on the values of various firms is immediate from the assumptions made above; this is formally stated in Proposition 21.11.

Proposition 21.11 *Suppose that the target is acquired by means of a cash payment. The long-run effect on the target shareholders from being acquired is*

$$(p - \bar{v})K_1. \quad (21.84)$$

The long-run effect on the acquirer shareholders from acquiring the target firm is

$$(\bar{v} - p)K_1. \quad (21.85)$$

From (21.84), (21.85), the long-run effect of the merger on the combined shareholders is

$$(p - \bar{v})K_1 + (\bar{v} - p)K_1 = 0. \quad (21.86)$$

From (21.86), in the long run, the shareholders of the two firms play a zero-sum game when one acquires the other. So why should the acquirer wish to acquire the target? From (21.85), if $\bar{v} > p$, then the acquirer makes a long-run profit at the cost of the target. Hence, short-run undervaluation of the target firm relative to its long-run valuation ($\bar{v} > p$) is a necessary condition for the acquisition. The managers of the target firm would benefit their shareholders in the long run if they can resist takeovers at a price $p < \bar{v}$.

Now consider a merger in which the acquiring firm buys shares (rather than paying cash) of the target firm. In this case, the fraction of the merged firm, λ , owned by the target firm is given by

$$\lambda = \frac{pK_1}{v \times (K_1 + K_2)}, \quad (21.87)$$

i.e., it is the value placed on the target firm in the acquisition, relative to the total value of the merged firm. The long-run value of this share to the shareholders of the target firm is $\bar{v}\lambda (K_1 + K_2)$, which on using (21.87) is

$$\bar{v}\lambda (K_1 + K_2) = \frac{\bar{v}pK_1}{v}. \quad (21.88)$$

The next result is evident from (21.87), (21.88).

Proposition 21.12 *In the long run, the gain to the shareholders of the target firm from being acquired for stock is*

$$\bar{v}\lambda (K_1 + K_2) - \bar{v}K_1 = \bar{v}K_1 \left(\frac{p}{v} - 1 \right). \quad (21.89)$$

Since the game between the acquirer and the target is zero-sum (see Proposition 21.11), the long-run gain to the shareholders of the acquiring firm from acquiring the target for stock is

$$\bar{v}K_1 \left(1 - \frac{p}{v} \right). \quad (21.90)$$

From (21.90), when using stock for acquisition, the shareholders of the acquiring firm gain in the long run only if $p < v$. This is more likely to occur when the acquiring firm has greater bargaining power in the takeover, which drives down the price of the acquisition, p . Conversely, shareholders in the target firm gain in the long run if $p > v$.

Suppose, that two conditions hold. (C1) Profits of the acquiring firm, given in (21.83), are negative, so $(v - p)K_1 + (v - v_2)K_2 < 0$, and (C2) $p < v$. In this case, because of (C1) and Proposition 21.10, the short-run value of the acquiring firm falls when the merger takes place. However, because of (C2) and Proposition 21.12, in the long run, the shareholders of the acquiring firm gain. In the absence of the acquisition, the shareholders would have been even more worse off in the long run. Thus, when the acquiring firm (firm 2) is relatively overvalued ($v < v_2$), and $p < v$ (target is relatively undervalued), then it is worthwhile for the shareholders of the acquiring firm to take a hit in short-term share prices in order to achieve long-run gains. These are the conditions under which theory predicts mergers for stock to take place.

How does the acquisition of firm 1, using stock, compare with the acquisition of an identical amount of capital, i.e., K_1 in the market at some price per unit of capital, P ? Suppose that the market places a value V per unit on the capital acquired by firm 2 from firm 1. Proceeding as in Proposition 21.12, and analogous to (21.90), the long-run gain to the shareholders of firm 2 is given by

$$\bar{v}K_1 \left(1 - \frac{P}{V} \right). \quad (21.91)$$

Comparing (21.90), (21.91), the acquisition of a firm by stock is preferred to acquiring an equivalent amount of capital on the market if

$$\frac{p}{v} < \frac{P}{V}.$$

One expects that the cost of new capital is lower than the cost of acquiring the same capital by buying a firm, i.e., $P < p$. However, it is also likely that $V < v$ (perceived synergies of a merger are likely to be higher than the simple acquisition of new capital). Thus, the result can go either way. In general, mergers do not always dominate investment in new capital or vice versa, hence, we expect to observe both.

Proposition (21.12) raises another interesting issue. By merging, one firm always loses out relative to the other in the long run. Since the acquirer would not acquire if it loses out, this begs the question of why the managers of the target firm would agree to a deal that harms the interests of its long-run shareholders. The reason lies in the different time horizons of the managers. As Shleifer and Vishny (2003) point out, target firms are expected to be those whose managers want to sell out, for reasons of retirement or ownership of illiquid stock options.

Similarly, the managers of the acquirer firm are expected to be ones who are locked into the firm (e.g. relatively younger managers who have a long time left for retirement) or those who have a relatively large and long-term equity stake in the firm. Target managers might be given several kinds of inducements to sell out the interests of their long-term shareholders. These include, generous severance pay, continuation of the managers in top positions in the merged set up, and acceleration of the exercise of stock options. The managers of the acquiring firm benefit by the acquisition of undervalued equity, hence, managers of both firms benefit.

From Proposition 21.11, acquisitions for cash are likely to take place when the target firm is undervalued relative to its long-run value. From Proposition (21.12) we see that acquisitions for stock are likely to take place when $p < v$. This happens when the market has a strong belief in a synergistic merger and the bargaining power of the acquiring firm is much greater than that of the target firm. Furthermore, it helps in this regard if the managers of the target firm are willing to sell-out. Why might the market hold a strong belief in a synergistic merger, particularly when so many mergers fail? It is difficult to believe that investors are entirely rational in this case.

Overall, the results of this model are consistent with a great deal of empirical evidence on mergers. For instance, the prediction that long-run bidder returns from cash acquisitions should be positive (this requires $\bar{v} > p$ in Proposition 21.11) is supported by the evidence (Loughran and Vijh, 1997; Rau and Vermaelen, 1998). The misvaluation motive for mergers, given above, has also been supported by the empirical results in Dong et al. (2006). It has also been found that overvaluation increases the probability of firms becoming acquirers (Ang and Cheng, 2006); condition C1 is more likely to hold when v_2 is high relative to v .

In the face of potential investor sentiment, rational managers in modern behavioral corporate finance theories have the following three main objectives. (1) Maximizing fundamental values. (2) *Catering*, which is an attempt to increase prices beyond fundamental values. (3) *Market timing*, which is a response to temporary mispricing of securities. Thus, managers sell their securities when they perceive that they are overpriced and repurchase them when they perceive that they are underpriced. Indeed, the Shleifer and Vishny (2003) models of mergers may be considered to be an example of a market timing model; acquire the target when it is undervalued and one's own value is overvalued. An important factor in empirically identifying these objectives is to identify not only fundamental value, but also mispriced stocks. This is often a difficult task (Baker and Wurgler, 2012).

Several empirical studies test the catering and timing objective by correlating the investment decisions of managers with proxies for mispricing of stocks. There is a danger that these proxies

might be correlated with fundamental values, but the newer empirical literature has attempted to deal with this problem. For instance, Polk and Sapienza (2009) conjecture that investment made by managers who have a short horizon; or whose assets are more difficult to value; or who are not cash or debt constrained, will be more sensitive to perceived market mispricing. This conjecture is confirmed by the evidence. Similar proxy-based evidence on the relation between investment and mispricing is reported in Chirinko and Schaller (2001) and Gilchrist et al. (2005). Baker et al. (2003) extend a model based on Stein (1996) to predict that equity-dependent firms will exhibit a stronger correlation between investment and mispricing; their empirical results confirm the prediction.

Survey evidence also supports the market timing hypothesis. In surveys, managers report that they typically issue new securities when they perceive an overvaluation of their securities and repurchase when they perceive an undervaluation (Graham and Harvey, 2001). These results are confirmed by Brav et al. (2005) who also point to the growing importance of repurchases relative to dividends. The basic motivation for issuing dividends to take advantage of market timing issues has been found in diverse markets; for instance, for IPO issues, this motivation has been found in Italian firms (Pagano et al., 1998) and in biotech firms (Loughran et al., 1994), for UK data (Marsh, 1982) and US data (Jung et al., 1996; Erel et al., 2012). The timing of opportunistic sales of equities to take advantage of mispricing is particularly targeted at new shareholders through commitment offers that exclude ongoing shareholders (Burch et al., 2004). Evidence suggests that managers are generally successful in earning higher subsequent returns based on their buying and selling decisions that are motivated by market timing issues (Ikenberry et al., 1995, 2000).

Many other examples of the catering objective can be given. These include catering to the market sentiment that favoured diversification mergers in the 1960s conglomerate wave. In the 1960s, news about a diversification merger commanded a huge premium, while by the late 1960s, this sentiment had petered out. In the mid to late 1970s, news about diversification mergers had little or no effect on stock prices, and in the 1980s, it had a negative impact (Matsusaka, 1993; Klein, 2001; Morck et al., 1990). When diversification mergers fell out of fashion, a reverse wave of divestiture and focus followed, with corresponding premia for such activities (Porter, 1987; Kaplan and Weisbach, 1992).

Name changes of firms that reflect the current market sentiment is another form of catering. Examples include the trionics boom of 1959–1962 during which firms made attempts to insert the word “electronics” in their names (Malkiel, 1990). A similar phenomenon was found during the dotcom bubble during which many firms altered their names with an Internet connotation, which had a positive effect on share prices (Cooper et al., 2001). When the dotcom bubble crashed, many firms then moved again to change names that no longer reflected an Internet connotation; again there was a positive effect on share prices of this name change announcement (Cooper et al., 2005).

21.7.3 *Managerial overconfidence with rational investors*

We now use the model of Gervais et al. (2011) to illustrate the second strand of the behavioral corporate finance literature: irrational managers and rational investors. Consider a two-period model; time is denoted by $t = 1, 2$. Suppose that a firm has \$1 in cash at $t = 1$. It can keep the cash, or invest it in a risky project that matures at $t = 2$ with a random payoff π . The random variable π takes one of two values: $\pi = z > 1$ (with probability p), or $\pi = 0$ (with probability $1 - p$). The discount rate and the interest rate are both normalized to zero. The expected net present value of the risky project is negative,

$$pz - 1 < 0. \quad (21.92)$$

Hence, the firm decides not to undertake the project.

Alternatively, the firm can hire a manager to make the investment decision on its behalf. The value added by the manager is that he can observe some signal s of the profitability of the project. With probability $q \in (0, 0.5]$, the signal equals the payoff of the risky project, π ; this captures the skill of the manager. With the complementary probability $1 - q$, the signal s equals a random variable $\tilde{\pi}$, which is independent of π , but has exactly the same probability distribution as π . Thus, the signal s is only useful with probability q .

The manager is overconfident of his skill and overestimates the usefulness of the signal by mentally assigning it a probability $q + h$, where $h \in [0, 0.5]$; the symbol h for overconfidence denotes the “hubris” of the manager (Roll, 1986). Hence, with complementary probability $1 - (q + h)$, the signal is perceived by the overconfident manager to take a value equal to the random variable $\tilde{\pi}$. This is schematically shown in Figure 21.7. Collapsing the decision tree from the end nodes, using the multiplicative law of probabilities, the manager’s signal takes on two possible values, z (good signal) and 0 (bad signal).

Definition 21.15 A measure of the manager’s “skill” is the magnitude of q . A measure of the manager’s “overconfidence” is the magnitude of h .

We now use Bayes’ rule to calculate the probabilities of different realizations of π , conditional on different values of the manager’s signal that takes values either z or 0 .

$$\Pr(\pi = z | s = z) = \frac{\Pr(s = z | \pi = z) \Pr(\pi = z)}{\Pr(s = z | \pi = z) \Pr(\pi = z) + \Pr(s = z | \pi = 0) \Pr(\pi = 0)}. \quad (21.93)$$

From Figure 21.7, the unconditional probabilities are

$$\Pr(\pi = z) = p, \Pr(\pi = 0) = 1 - p.^{21} \quad (21.94)$$

Suppose that $\pi = z$. What is the conditional probability of $s = z$? Recalling that $\pi, \tilde{\pi}$ are independent, Figure 21.7 implies the following calculation.

Figure 21.7 A decision tree depiction of the model of Gervais et al. (2011).

Source: Gervais, Simon, J. B. Heaton, and Terrance Odean (2011), “Overconfidence, compensation contracts, and capitals budgeting,” *Journal of Finance* 66: 1735–77. © American Finance Association. With permission from John Wiley & Sons.

²¹ Note that the unconditional probability $\pi = z, \pi = \tilde{\pi}$ are independent.

$$\Pr(s = z \mid \pi = z) = (q + h) + (1 - q - h)p. \quad (21.95)$$

Similarly, when $\pi = 0$, Figure 21.7 implies the following calculation.

$$\Pr(s = z \mid \pi = 0) = (1 - q - h)p. \quad (21.96)$$

Substitute (21.94) to (21.96) in (21.93) to get

$$\Pr(\pi = z \mid s = z) = p + (q + h)(1 - p) \equiv \bar{c}. \quad (21.97)$$

Proceeding analogously, we get

$$\Pr(\pi = z \mid s = 0) = (1 - q - h)p \equiv \underline{c}. \quad (21.98)$$

For a rational, i.e., unbiased manager, hubris, $h = 0$, and the probabilities stated in (21.97), (21.98) are respectively given by

$$\bar{c}|_{h=0} = p + q(1 - p); \quad \underline{c}|_{h=0} = (1 - q)p. \quad (21.99)$$

From (21.97), (21.98) we get the following result immediately.

Lemma 21.1 $\bar{c}$ is increasing in h, p, q . $\underline{c}$ is decreasing in q, h and increasing in p .

In Lemma 21.1, the most important comparative static result for our purposes is with respect to overconfidence or hubris, h . An increase in hubris increases the probability that the manager assigns to a high payoff, z , on receiving the good signal $s = z$. Conversely, he reduces the probability of a high payoff far too much, on receiving the bad signal, $s = 0$.

The only observable and verifiable event for the firm is the actual realization of the payoff. There are three possible payoffs. If the risky project is not undertaken, the payoff equals the firm's initial cash holding of \$1. If the project is undertaken, then the payoff is a random variable π that has two possible outcomes, $\$z > 1$ and $\$0$. Dropping the dollar sign, we can order these three outcomes as $y_0 = 0, y_1 = 1, y_2 = z$. To incorporate the manager's risk aversion when there are three discrete outcomes, we proceed as follows.

Notice that if the outcome is 0 (failed project) the firm loses its cash balance of \$1 (cost of investment) so, it has nothing to pay the manager with. Hence, in this case, the wage received by the manager must be zero; we denote this by $w_0 = 0$. Denote the wage of the manager contingent on y_1 and y_2 to be, respectively, w_1 and $w_1 + \Delta$, where $\Delta > 0$ is the incremental wage when the outcome improves from $y_1 = 1$ to $y_2 = z$. We may summarize the manager's compensation contract by $\{w_1, \Delta\}$. The manager's utility, u , is assumed to be piecewise linear such that

$$u(w_0) = u(0) = 0; \quad u(w_1) = w_1; \quad u(w_2) = u(w_1 + \Delta) = w_1 + (1 - r)\Delta; \quad 0 < r < 1. \quad (21.100)$$

From (21.100), the incremental utility of Δ is $(1 - r)\Delta$. The size of r , therefore, captures the manager's degree of risk aversion.

THE RATIONAL MANAGER BENCHMARK

Suppose that the manager is rational in the sense of exhibiting no overconfidence, so $h = 0$ and (21.99) applies. The firm uses information on the rational manager's skill (summarized by the parameter q) to decide whether to undertake the project.

Suppose that the rational manager receives the bad signal $s = 0$. From (21.98), (21.99), $\Pr(\pi = z | s = 0) = \underline{c}|_{h=0} = (1 - q)p < p$. Hence, using net present value calculations, the project is undertaken if $\underline{c}|_{h=0} z - 1 > 0$. But $\underline{c}|_{h=0} < p$, hence, using (21.92), the project is never undertaken when a rational manager receives a bad signal.

Now suppose that the rational manager receives the good signal, $s = z$. From (21.97), (21.99), $\Pr(\pi = z | s = z) = \bar{c}|_{h=0} = p + q(1 - p) > p$. Hence, the condition for the project to be undertaken is

$$\bar{c}|_{h=0} z - 1 > 0. \quad (21.101)$$

Substituting $\bar{c}|_{h=0}$ from (21.99) in (21.101) we get that (21.101) is equivalent to the condition:

$$q > 1 - \frac{z - 1}{z(1 - p)} = \bar{q}. \quad (21.102)$$

From (21.101), (21.102), the following result is a straightforward implication.

Proposition 21.13 *Suppose that the manager is rational.*

- (a) *If $q < \bar{q}$, then the project is never undertaken.*
- (b) *If $q > \bar{q}$, then the project is undertaken if and only if the signal is good, i.e., $s = z$.*

Suppose that the skill level of the manager is high enough, in the sense that $q > \bar{q}$ and the manager is rational ($h = 0$). Then the ex-ante gross value, V , of the firm before any signal is received by the manager, is

$$V = \Pr(s = z) (\bar{c}|_{h=0}) z + \Pr(s = 0) 1. \quad (21.103)$$

In (21.103), the first term $\Pr(s = z) (\bar{c}|_{h=0})$ is the joint probability, $\Pr(\pi = z, s = z)$, that the signal and the actual outcome are both equal to z . In this case the project is undertaken and the expected payoff is $\Pr(\pi = z, s = z)z$. However, when the signal is $s = 0$ the project is never undertaken and the firm retains its original cash endowment of \$1; this is the second term.

Using Figure 21.7, $\Pr(s = z) = p(q + h) + p(1 - q - h) = p$; similarly, $\Pr(s = 0) = 1 - p$. Substitute these calculations and (21.99) in (21.103) to get

$$V = pz[p + q(1 - p)] + (1 - p). \quad (21.104)$$

From Proposition 21.13, the firm acts on the manager's signal, s , only if the skill level of the manager is high enough, in the sense that $q > \bar{q}$. Otherwise, if the skill level of the manager is low ($q < \bar{q}$), the manager's signal is ignored. If $q > \bar{q}$, then, from (21.104), the value of the firm is increasing in the skill level of the manager. From (21.102), the critical skill level, $\bar{q}$, is decreasing in z and p . The intuition is that if a successful project is associated with a high reward, z , and/or the probability of its success, p , is too high, then the firm does not need a particularly skillful manager.

THE OVERCONFIDENT MANAGER'S INVESTMENT DECISION

Suppose that the overconfident manager's compensation scheme $\{w_1, \Delta\}$ is taken as given. The firm cannot observe or verify the information possessed by the manager. Hence, it must rely on the manager to make the investment decision.

Proposition 21.14 *Let the manager be overconfident ($h > 0$).*

(a) *Suppose that the manager observes $s = z$. Then the manager decides to undertake the project if*

$$\frac{\Delta}{w_1} \geq \frac{1 - \bar{c}}{\bar{c}(1 - r)} = \frac{(1 - p)(1 - q - h)}{1 - (1 - p)(1 - q - h)} \frac{1}{1 - r} \equiv \bar{\phi}. \quad (21.105)$$

(b) *Suppose that the manager observes $s = 0$. Then the manager decides to undertake the project if*

$$\frac{\Delta}{w_1} \geq \frac{1 - \underline{c}}{\underline{c}(1 - r)} = \frac{1 - p(1 - q - h)}{p(1 - q - h)} \frac{1}{1 - r} \equiv \underline{\phi}. \quad (21.106)$$

Proof: Suppose that the manager observes $s = z$. Using (21.97), he believes that with probability $\bar{c}$, the project generates a good outcome, z , and with probability $1 - \bar{c}$, it generates the bad outcome, 0. The wage of the manager in these two cases is, respectively, $w_1 + \Delta$ and 0. Using (21.100), the expected utility of the manager in this case is

$$\bar{c}[w_1 + (1 - r)\Delta] + (1 - \bar{c})0 = \bar{c}[w_1 + (1 - r)\Delta]. \quad (21.107)$$

If on observing $s = z$, the manager decides not to undertake the project, then he retains the \$1 cash, which is the firm's initial endowment. From (21.100), the manager's wage in this case is w_1 . Thus, on observing $s = z$, the manager invests in the risky project if

$$\bar{c}[w_1 + (1 - r)\Delta] \geq w_1. \quad (21.108)$$

Substituting $\bar{c}$ from (21.97) into (21.108), we get (21.105), as claimed.

Now suppose that the manager receives the signal $s = 0$. Proceeding, as above, the expected utility of the manager from undertaking the project is

$$\underline{c}[w_1 + (1 - r)\Delta] + (1 - \underline{c})0 = \underline{c}[w_1 + (1 - r)\Delta].$$

Comparing this with a wage of w_1 from not investing, the condition for investing requires $\underline{c}[w_1 + (1 - r)\Delta] \geq w_1$. Substituting $\underline{c}$ from (21.98) we get (21.106), as claimed. ■

The following observations can be drawn from Proposition 21.14.

1. From (21.105), (21.106), $\underline{\phi} > \bar{\phi}$. Thus, the barrier to undertaking the project when the manager receives the good news ($s = z$) is lower than when he receives the bad news ($s = 0$).
2. The interpretation of $\frac{\Delta}{w_1}$ is that it is a measure of the convexity of the manager's compensation contract. To see this, plot the outcomes $(0, 1, z)$ on the horizontal axis and the manager's compensation on the vertical axis. The wage corresponding to these three outcomes is 0, w_1 , $w_1 + \Delta$. Clearly an increase in Δ relative to w_1 makes the wage profile

more convex. Suppose now that the manager's risk aversion, as captured by r , increases. This makes the utility function of the manager more concave. From (21.105), (21.106), an increase in r increases both $\underline{\phi}, \bar{\phi}$, so the manager's investment policy becomes more conservative. Hence, to ensure that the project is undertaken, an even larger $\frac{\Delta}{w_1}$ (which is the convexity of the compensation scheme) is called for. In other words, the convexity of the compensation scheme compensates for concavity of the manager's utility function.

3. An increase in the manager's overconfidence, h , reduces $\bar{\phi}$. In this case, the manager's investment policy becomes more aggressive towards investment, following a good signal $s = z$. On the other hand, an increase in h , increases $\underline{\phi}$. Hence, following a bad signal, $s = 0$, the manager's investment policy becomes more conservative. A manager with higher overconfidence places greater reliance on privately observed signals; if the signal is bad then the manager assigns a relatively high posterior to the bad outcome. Thus, risk aversion and overconfidence have different implications for the manager's investment policy; risk aversion increases both $\underline{\phi}, \bar{\phi}$, but overconfidence reduces $\bar{\phi}$ and increases $\underline{\phi}$.

Definition 21.16 (*Underinvestment*): The overconfident manager overinvests (underinvests) if his investment policy is more (less) aggressive relative to the one followed by the firm if it had the same information (i.e., under the rational manager benchmark).

Using Propositions 21.13, 21.14, overinvestment, therefore, implies either of two conditions.

$$(1) q < \bar{q} \text{ and } \frac{\Delta}{w_1} > \bar{\phi} \text{ or } (2) q > \bar{q} \text{ and } \frac{\Delta}{w_1} > \underline{\phi}. \quad (21.109)$$

In (21.109), condition (1) requires that the skill level of the *rational manager* is not high enough for the firm to invest, even when the manager receives a good signal (see Proposition 21.13). However, the *overconfident manager* nevertheless goes ahead and invests because $\frac{\Delta}{w_1} > \bar{\phi}$ (see Proposition 21.14). In condition (2), the skills of the rational manager are high enough for the firm to invest, based on a good signal, but not if the signal is bad (see Proposition 21.13). However, since $\frac{\Delta}{w_1} > \underline{\phi}$, we know, from Proposition 21.14, the overconfident manager will invest if he receives a bad signal.

Using Definition 21.16 and (21.109), underinvestment is characterized by

$$q > \bar{q} \text{ and } \frac{\Delta}{w_1} < \bar{\phi}. \quad (21.110)$$

In this case, the firm would like the rational manager to invest if the signal is good. However, the overconfident manager does not invest.

By looking at the dependence of $\underline{\phi}, \bar{\phi}$ on the parameters of the model, we can draw further inferences about the comparative static results of the model.

Proposition 21.15 *Factors conducive to overinvestment are the following. (a) Small z . (b) Small r . (c) Large $\frac{\Delta}{w_1}$. When $q < \bar{q}$, an increase in the manager's overconfidence, h , creates greater overinvestment. Conversely when $q > \bar{q}$, an increase in the manager's overconfidence, h , creates either lower overinvestment or lower underinvestment.*

Proof: From (21.102), $\bar{q} = 1 - \frac{z-1}{z(1-p)}$, thus, $\bar{q}$ is decreasing in z . Hence, a smaller z increases $\bar{q}$, but does not affect $\underline{\phi}, \bar{\phi}$. From (21.109), if we start with, $\frac{\Delta}{w_1} > \bar{\phi}$, then an increase in $\bar{q}$ makes it more likely that the condition $q < \bar{q}$ will be satisfied, therefore, making overinvestment more

likely. Now consider a reduction in r . This does not affect $\bar{q}$. However, the reduction in r reduces both $\underline{\phi}$, $\bar{\phi}$, which makes it more likely that the conditions for overinvestment in (21.109) are satisfied. It is also straightforward from (21.109) that an increase in $\frac{\Delta}{w_1}$ is more likely to satisfy both conditions for overinvestment. Finally, using (21.105), (21.106), when h increases, $\bar{\phi}$ falls and $\underline{\phi}$ increases. When $q < \bar{q}$, condition (1) in (21.109) is more likely to be satisfied resulting in overinvestment. However, because an increase in h increases ϕ , if $q > \bar{q}$, condition (2) in (21.109) is less likely to hold, so there is less likely to be overinvestment. However, (21.110), the condition for underinvestment, is also less likely to be satisfied because as h increases, $\bar{\phi}$ falls. ■

From Proposition 21.15, when the manager is more risk averse (high r) and receives a smaller incentive payment (low $\frac{\Delta}{w_1}$), then he is more likely to underinvest. Thus, if the firm wishes to remove greater conservatism brought about by an increase in risk aversion, it must convexify the compensation contract even more.

When the manager is not skilled enough, $q < \bar{q}$, then overconfidence creates greater overinvestment. The intuition is that an overconfident manager is too confident of his signal and so places a lower weight on the riskiness of his investment decision. This makes him overinvest. However, when the manager is skilled enough, $q > \bar{q}$, then, both overinvestment and underinvestment fall. In this case, the manager's decisions become closer to the first best with rational managers.

One expects in real life that following a string of successful decisions, the overconfidence of the manager may increase even further (Daniel et al., 1998; Gervais and Odean, 2001). For a fixed compensation scheme $\{w_1, \Delta\}$, this is good news for the firm if the manager is skilled enough ($q > \bar{q}$). But if $q < \bar{q}$, this is bad news for the firm as it causes the overconfident manager to behave in an even more reckless manner relative to a rational manager.

Yet another application is the following. Suppose that a firm has a sequence of projects. The normal expectation is that the firm will take up the projects in a sequential manner. The projects with the highest net present value are undertaken first and so on. Suppose that the success of the initial projects increases overconfidence and that the manager's skill level is not high enough ($q < \bar{q}$). Then the manager is likely to prove detrimental to the firm for subsequent projects. This is because overconfidence induces the manager to take on too much risk, for projects where the net present value is not high enough.

21.7.4 *Behavioral corporate signaling*

In classical corporate finance, dividends are explained by using signaling models (Bhattacharya, 1979; John and Williams, 1985; Miller and Rock, 1985; Guttman et al., 2010). A feature of these and other classical signaling models in finance is that signaling is costly in the sense that it can reduce the value of the firm. However, firms who have better future prospects can take relatively costly actions because this allows them to separate from firms whose prospects are not as good. For classical signaling models used in corporate finance to address a range of issues such as capital restructuring, debt, and IPO underpricing, see Ross (1977), Myers and Majluf (1984), Harris and Raviv (1985), Grinblatt and Hwang (1989), and Allen and Faulhaber (1989).

In contrast, survey evidence shows that executives reject the basic assumptions of the costly signaling models for dividends. These assumptions include the following: dividends destroy firm value; dividends are used instead of cheaper borrowing; dividends are used to forgo profitable investments; dividends are used to signal strength. Indeed, only 4.4% of the executives agreed with the transmission mechanisms used in traditional explanations of dividends based on costly

signaling. Yet most executives agree that dividends are used to provide some sort of a signal to the markets (Brav et al., 2005). They write (p. 45): “However, this information conveyance does not appear to be consciously related to signaling in the academic sense. Managers reject the notion that they pay dividends as a costly signal to convey their firm’s true worth or to purposefully separate their firm from competitors.”

Baker and Wurgler (2011) propose a simple behavioral model of signaling that better explains some of the styled facts associated with issuing dividends. We now consider this model. Suppose that there are two time periods, $t = 1, 2$, and there are two economic actors: the manager of a firm and an investor or holder of equity in the firm. The structure of the model is as follows.

1. The firm and its decisions: The firm is synonymous with a benevolent manager who maximizes the utility of the investor. The cash earnings of the firm at time $t = 1, 2$ are denoted by y_t . The first period earning, y_1 , is private information to the manager. It is common knowledge to both players that y_2 is uniformly distributed over $[0, 2]$. The manager decides on the level of dividends in the first period, d_1 , and the liquidating dividend in the second period, d_2 . The expectation operator in period 1 with respect to the information set of the manager is denoted by E_M .
2. The investor’s preferences: The investor does not know y_1 , but uses first period dividends, d_1 , to form an inference about y_1 . The expectation operator in period 1 with respect to the information set of the investor is denoted by E_I . Thus, the investor’s conditional expectation of the first period cash flow is $E_I[y_1 | d_1]$. The investor has an exogenously given reference point, d^* , for first period dividends. Actual first period dividends, d_1 , constitute the reference point for second period dividends. Define the function

$$v(x) = \begin{cases} 0 & \text{if } x \geq 0 \\ \lambda x & \text{if } x < 0 \end{cases}, \quad (21.111)$$

where $\lambda > 0$ is the parameter of loss aversion.²² Then, the long-term utility of the investor is given by

$$u(d_1, d_2 | d^*) = d_1 + d_2 + v(d_1 - d^*) + v(d_2 - d_1). \quad (21.112)$$

Thus, the investor derives utility from the dividends received in both periods and experiences disutility if the dividends fall below the reference dividend levels in any period.

3. Preferences and constraints of the manager: The main difference from the classical model is that the manager has no control over the cash flow of the firm, y_1, y_2 . There is no agency problem either and the manager cannot engage in costly signaling in the sense of destroying the current value of the firm to signal the strength of the firm. The manager cannot finance dividends from any source (such as new equity or debt) other than current cash flows. Hence, the constraints are:

$$d_1 \in [0, y_1] \text{ and } d_2 = (y_1 - d_1) + y_2. \quad (21.113)$$

We consider a reduced-form approach. The expectation $E_I[y_1 | d_1]$ influences the demand for equity of the firm in the first period and, hence, its price. The manager maximizes a

²² Note that given the formulation for gains, we do not need to specify that $\lambda > 1$ in order to capture loss aversion.

weighted average of these price concerns and the utility of the investor in (21.112). Thus, the objective function of the manager is

$$W = E_M [\theta E_I [y_1 | d_1] + (1 - \theta)u(d_1, d_2 | d^*)], 0 < \theta < 1. \quad (21.114)$$

This completes the model setup. We now solve for the equilibrium. An increase in first period dividends, d_1 , has three effects. First, it leads to an upward revision in $E_I [y_1 | d_1]$ through equilibrium beliefs (see below), which is liked by the manager because it increases the (unmodeled) share prices. Second, an increase in d_1 up to the reference level d^* or beyond, avoids loss aversion in the first period. Third, an increase in d_1 increases the second period reference point, which makes it more likely that u may decrease due to loss aversion in the second period.

Substituting (21.111), (21.112), (21.113) in (21.114) we get

$$W = (1 - \theta)v(d_1 - d^*) + \theta E_I [y_1 | d_1] + (1 - \theta)E_M (y_1 + y_2) + (1 - \theta)E_M v(d_2 - d_1). \quad (21.115)$$

By definition,

$$\begin{aligned} E_M v(d_2 - d_1) &= \lambda \int_0^{2d_1 - y_1} (y_1 + y_2 - 2d_1) dy_2 \\ &= \frac{-\lambda}{2} (2d_1 - y_1)^2 \Big|_{d_1 > \frac{y_1}{2}} + k. \end{aligned} \quad (21.116)$$

where k is a constant of integration,²³ and

$$E_M (y_1 + y_2) = y_1 + 1 \quad (21.117)$$

Substitute (21.116), (21.117) in (21.115) and only writing terms relevant for d_1 we get

$$(1 - \theta)v(d_1 - d^*) + \theta E_I [y_1 | d_1] - (1 - \theta)\frac{\lambda}{2} (2d_1 - y_1)^2 \Big|_{d_1 > \frac{y_1}{2}}. \quad (21.118)$$

The manager chooses d_1 in order to maximize (21.118), conditional on the beliefs of the investors about d_1 . The next proposition describes a separating equilibrium and full set of beliefs in a perfect Bayesian equilibrium.

Proposition 21.16 (Baker and Wurgler, 2012) *Let y^* be the solution to the equation*

$$\frac{\theta}{2} (y^* - d^*) - (1 - \theta)\lambda \left[\left(\frac{\theta}{1 - \theta} \frac{1}{\lambda} \right)^2 - \left(d^* - \frac{y^*}{2} \right)^2 \right] = 0. \quad (21.119)$$

There exists a perfect Bayesian equilibrium (not necessarily unique) in which equilibrium first period dividends are given by

$$d_1 = \begin{cases} y_1 & \text{if } y_1 < d^* \\ d^* & \text{if } d^* < y_1 < y^*, \\ \frac{y_1}{2} + \frac{\theta}{1 - \theta} \frac{1}{\lambda} & \text{if } y^* < y_1 \end{cases} \quad (21.120)$$

²³ The notation $x \Big|_{d_1 > \frac{y_1}{2}}$ means that x is defined for $d_1 > \frac{y_1}{2}$.

and equilibrium beliefs are given by

$$E_I [y_1 | d_1] \begin{cases} d_1 & \text{if } d_1 < d^* \\ \frac{y^* + d^*}{2} & \text{if } d_1 = d^* \\ 2d_1 + \frac{2\theta}{1-\theta} \frac{1}{\lambda} & \text{if } d_1 > \frac{y^*}{2} + \frac{\theta}{1-\theta} \frac{1}{\lambda} \end{cases} . \quad (21.121)$$

From (21.120), firms whose cash flow is lower than the dividend expectations ($y_1 < d^*$) pay out their entire cash flow as dividends in order to minimize loss aversion costs to the investor. Firms who can afford to pay the reference level of dividends or more up to some level y^* , bunch together at the level d^* because of two considerations. First, to eliminate loss aversion costs in the first period. Second, to prevent the buildup of too high a reference level of dividends in the second period (second period reference dividends are d_1); this minimizes expected loss aversion costs in the second period. Finally, firms who have very high levels of incomes ($y^* < y_1$) can afford to pay even higher first period dividends. This increases $E_I [y_1 | d_1]$, which managers desire because of the effects on stock prices. The high income ($y^* < y_1$) also provides a cushion against second period dividends falling short of the second period reference point.

From (21.119), as λ increases and θ decreases, y^* increases. Therefore, from the second row of (21.120), more firms cluster at the reference level of dividends, d^* . The equilibrium described in Proposition 21.16 is also consistent with the partial adjustment model of Lintner (1956). From (21.120), on average, dividends increase less than one for one with an increase in first period income, y_1 .

21.8 Exercises for Part 7

- (Kahneman, 2011) (a) In a sample of 3,141 counties in the United States, counties in which the incidence of kidney cancer is lowest are rural, sparsely populated, and located in the traditionally Republican states in the Midwest, the South, and the West. What inferences can you draw from this statement?
(b) The Bill Gates Foundation poured \$1.7 billion into small schools based on the finding that most successful schools, on average, are small. In Pennsylvania, 6 of the top 50 schools are small (an overrepresentation in the sample by a factor of 4). This data induced the Gates Foundation to invest in creating small schools, sometimes even splitting large schools into smaller schools. Was this money necessarily well spent?
- Rabin (2002) provides the following experimentally observed conditional probabilities when there are two equally possible and mutually exclusive signals (A and B), using data from Table 7 of Rapoport and Budescu (1997).

$$P(A | B) = 58.5\%,$$

$$P(A | AB) = 46.0\%,$$

$$P(A | AAB) = 38.0\%,$$

$$P(A | AAA \dots) = 29.8\%.$$

Is this data consistent with classical probability theory? How might you explain this data? Is this data likely to have come from an underlying *inanimate process* (roulette wheel, throw of a dice, or toss of a coin) or an *animate process* (successful dunks by a player in basketball, or first serve aces by a tennis player)?

- (Clotfelter and Cook, 1989) Gamblers have a tendency to redeem winning lottery tickets for more tickets rather than for cash. What might account for this behavior?
- Kahneman (2011) describes the following findings from Lichtenstein et al. (1978). How might you explain these findings?
 - Strokes cause almost twice as many deaths as all accidents combined, but 80% of respondents judged accidental death to be more likely.
 - Tornadoes were seen as more frequent killers than asthma, although the latter caused 20 times more deaths.
 - Death by lightning strikes was judged to be more likely than death by botulism, even though the latter is 52 times more frequent as a cause of death.
 - Death by accidents was judged to be more than 300 times more likely than death by diabetes, but there are 4 diabetes caused deaths for every death in an accident.
- (Kahneman, 2011) Do you expect the conjunction fallacy to arise in the following problem? Give reasons for your answer.
Which alternative is more probable?
John works in a school.
John is a worker in a school who walks to work.
How does this problem differ from the Linda problem considered above?
- Tversky and Kahneman (1983) gave subjects a choice among one of the following options about the outcome of a match played by the then top tennis player Björn Borg. Please judge the relative probabilities of the choices.

- A. Borg will win the match.
- B. Borg will lose the first set.
- C. Borg will lose the first set but win the match.
- D. Borg will win the first set but lose the match.

72% of the subjects assigned the event B a lower probability than C. Is this outcome consistent with the axioms of probability theory? How can you explain these results?

7. (Hsee, 1998; Kahneman, 2011) Subjects were asked to make a choice between two dinner sets, H and L, shown in Table 7.E1.

Table 7.E1 A summary of the composition of two different dinner sets.

	Set H includes 40 pieces	Set L includes 24 pieces
Dinner plates	8, all in good condition	8, all in good condition
Soup/salad bowls	8, all in good condition	8, all in good condition
Dessert plates	8, all in good condition	8, all in good condition
Cups	8, 2 of them broken	
Saucers	8, 7 of them broken	

Source: Hsee (1998).

In the first condition, subjects had to place a valuation on both dinner sets when they are presented together. The mean willingness to pay (WTP) for set H was \$32.03 and for set L it was \$29.70. In the second condition, subjects had to state their WTP when presented with the two dinner sets separately. In this case, the WTP for L was higher (\$32.69) as compared to H (\$23.25). How might you explain these findings?

8. (Tversky and Kahneman, 1983) Two groups of subjects were given, separately, the problems shown in the separate columns in Table 7.E2.

Table 7.E2 Two different problems given to two groups of subjects in a between-groups design.

First group of subjects	Second group of subjects
A health survey was conducted in a sample of adult males in British Columbia, of all ages and occupations. Please give your best estimates of the following values: What percentage of the men surveyed have had one or more heart attacks? What percentage of the men surveyed are both over 55 years old and have had one or more heart attacks?	A health survey was conducted in a sample of 100 adult males in British Columbia, of all ages and occupations. Please give your best estimates of the following values: How many of the 100 men surveyed have had one or more heart attacks? How many of the 100 men surveyed are both over 55 years old and have had one or more heart attacks?

Source: Kahneman (2011).

65% of the subjects in the first group engaged in the conjunction fallacy. However, only 25% of the subjects in the second group engaged in the conjunction fallacy. What accounts for the difference?

9. (Slovic et al., 2002) Provide explanations for the following.
- Why do entertainers often change their names once they enter the entertainment industry (e.g., the real names of the actors John Denvers, Sandra Dee, and Judy Garland, were, respectively, Henry Deutschendorf, Alexandra Zuck, and Frances Gumm)?
 - Why do movies have background music? After all, can't we understand the events we are watching and the dialog we are hearing without the music?
 - Why are all the models in the mail-order catalog smiling?
 - Why do packages of food products carry all those little blurbs such as: *New*, *Natural*, or *Improved*?
 - Why do traditional cigarette advertisements show images of rugged cowboys and lush waterfalls?
 - Why is genetically modified food promoted as *enhanced* by proponents and *Franken-food* by opponents?
10. (Schwarz, Strack, and Mai, 1991) Consider the following two questions that were asked of subjects in experiments.
- Q1. How happy are you with your life in general?
- Q2. How often do you normally go out on a date?
- When the questions were asked in numerical order the answers were not correlated. However, when they were asked in reverse order, Q2 followed by Q1, then the responses were highly correlated. Which judgment heuristic would you use to explain these results, and why?
11. (Hoff and Pandey, 2006, 2014) In empirical studies conducted on children of different castes in India, children were classified into high and low castes and given a set of mazes to solve in a fixed amount of time. The results are shown in Figure 7.E1. In the *anonymous condition*, high caste children solved 7% more mazes than low caste children. However in *mixed caste groups*, where caste is revealed, the difference rises to 34%. When caste is revealed but the groups are not mixed, then again there is little difference in the number of mazes solved. How would you explain the results? How would you test for the possibility that the

Figure 7.E1 Average number of mazes solved.

Source: Hoff and Pandey (2006) with permission from the American Economic Association.

announcement of castes in mixed groups reduces the self-confidence of low caste participants, thereby reducing their performance?

12. (Englich and Mussweiler, 2001) In a hypothetically constructed case of rape, 42 experienced legal professionals were asked to determine the appropriate sentence, based on carefully prepared case material. After the legal professionals had studied the case material but before they had passed the sentence, they received a call from a journalist who asked if the sentence would be 1 year (first treatment) or 3 years (second treatment). The average sentences passed in the two cases were 25.43 months and 33.38 months. Is this consistent with neoclassical economic theory. If not, how would you explain the result? Can you derive a numerical index of the bias that might have caused the difference in the results in the two treatments?
13. (Wansink et al., 1998) In a field study in Iowa, shoppers in three supermarkets encountered a sales promotion for Campbell soup at about 10% off the regular price. On some days the shelf sign imposed a limit of 12 per person and on other days there was no limit per person. Shoppers purchased an average of 7 cans when the limit was in force and 3.5 when the limit was not in force. Similar findings were made in four studies spanning 89 supermarkets. How can you account for these findings?
14. Can you give reasons for the following two phenomena?
 - (a) Kahneman (2011) notes that we drive too fast when we just come off a highway onto city streets.
 - (b) Consider the following quote adapted from LeBoeuf and Shafir (2006): "A well-intentioned child who turns down exceptionally loud music to meet a parent's demand that it be played at a 'reasonable' volume may fail to adjust sufficiently from a high volume, and may feel that genuine attempts at compromise are being overlooked."
15. (Gigerenzer and Hoffrage, 1995) Give your answer separately to the two problems below before you read beyond the statement of Problem 2.

Problem 1: The probability of breast cancer is 1% for a woman at age forty who participates in routine screening. If a woman has breast cancer, the probability is 80% that she will get a positive mammography. If a woman does not have breast cancer, the probability is 9.6% that she will also get a positive mammography. A woman in this age group had a positive mammography in a routine screening. What is the probability that she actually has breast cancer?

Problem 2: 10 out of every 1,000 women at age forty who participate in routine screening have breast cancer. 8 out of every 10 women with breast cancer will get a positive mammography. 95 out of every 990 women without breast cancer will also get a positive mammography. Here is a new representative sample of women at age forty who got a positive mammography in routine screening. How many of these women do you expect to actually have breast cancer? ___ out of ___

Make sure that you have given your answers to Problems 1 and 2 before you read on. Clearly this test works best in a between-subjects design which is not possible when you do both problems. Do your answers to Problems 1 and 2 tally or differ? If not, can you think why not? Try doing these problems with different sets of friends to induce a between-subjects design. What results do you get in this case?

16. (Stanovich and West, 2000) Imagine that AIDS occurs in 1 in every 1,000 people. Imagine also there is a test to diagnose the disease that always gives a positive result when a person has AIDS. Finally, imagine that the test has a false positive rate of 5%. This means that the test incorrectly indicates that AIDS is present in 5% of the cases where it is actually absent.

Suppose that we choose a person randomly, administer the test, and discover that it yields a positive result (presence of AIDS). What is the probability that the chosen individual actually has AIDS, assuming that we know nothing else about the individual's personal or medical history?

What are the implications of your answer for the problem of base rate neglect?

17. Prove the assertion in (19.41), in Example 19.2.
18. (Kahneman, 2011) One often hears people saying: "Highly intelligent women tend to marry men who are less intelligent than they are." Assuming that this assertion is true, how can one explain this?
19. (Stanovich and West, 2000) Suppose there are four cards lying on a table showing two letters and two numbers (A, D, 3, 7). Subjects are told that (i) each card has a number on one side and a letter on the other, and (ii) the experimenter has the following rule in mind with respect to the four cards: "If there is an A on one side then there is a 3 on the other." Which cards will you turn over to determine whether the experimenter's rule is true or false?
20. (Banerjee and Duflo, 2011) Consider the following description of an empirical study, done on fruit vendors in Chennai, India, from WDR (2015, p. 32): "Each day, the vendors buy fruit on credit to sell during the day. They borrow about 1,000 rupees (the equivalent of \$45 in purchasing parity) each morning at the rate of almost 5% per day and pay back the funds with interest at the end of the day. By forgoing two cups of tea each day, they could save enough after 90 days to avoid having to borrow and would thus increase their incomes by 40 rupees a day, equivalent to about half a day's wages. But they do not do that." How would you explain the behavior of these fruit vendors?
21. (Gabaix and Laibson, 2006) Complete the proof of Proposition 19.5(i),(ii).
22. (Gabaix and Laibson, 2006) Consider the model of shrouded attributes in Section 19.16.2. Show that in a shrouded prices equilibrium, (i) social welfare loss is given by $(1 - \alpha)e$, and (ii) sophisticated consumers are $\bar{p} - e$ units better off than myopic consumers. In the unshrouded equilibrium, show that there is no inefficiency and all consumers (sophisticated and myopic) are equally well-off.
23. Show that the categorization in Example 19.5, $\{(1, 0), (1, 1), \{(0, 0), (0, 1)\}\}$, is optimal on the criterion that among all possible categorizations it minimizes the "sum across categories of the total variation of the mean from each category."
24. (Thaler, 2008) In a set of experiments, the instructions given to the students were: Below you will find four pairs of scenarios. In each case, two events occur in Mr. A's life and one event occurs in Mr. B's life. You are asked to judge whether Mr. A or Mr. B is happier. Would most people rather be A or B? If you think the two scenarios are emotionally equivalent, check "no difference." In all cases, the events are intended to be financially equivalent. The four problems used and the number of responses of each type follow. Explain the choice of the majority of the subjects for each of the four problems.
 1. Mr. A was given tickets to lotteries involving the World Series. He won \$50 in one lottery and \$25 in the other. Mr. B was given a ticket to a single, larger World Series lottery. He won \$75. Who was happier?
56 subjects chose A, 16 chose B, and 15 chose no difference.
 2. Mr. A received a letter from the IRS saying that he made a minor arithmetical mistake on his tax return and owed \$100. He received a similar letter the same day from his state income tax authority saying he owed \$50. There were no other repercussions from either mistake. Mr. B received a letter from the IRS saying that he made a minor arithmetical mis-

take on his tax return and owed \$150. There were no other repercussions from his mistake. Who was more upset?

66 subjects chose A, 14 chose B, and 7 chose no difference.

3. Mr. A bought his first New York State lottery ticket and won \$100. Also, in a freak accident, he damaged the rug in his apartment and had to pay the landlord \$80. Mr. B bought his first New York State lottery ticket and won \$20. Who was happier?

22 subjects chose A, 61 chose B, and 4 chose no difference.

4. Mr. A's car was damaged in a parking lot. He had to spend \$200 to repair the damage. The same day the car was damaged he won \$25 in the office football pool. Mr. B's car was damaged in a parking lot. He had to spend \$175 to repair the damage. Who was more upset?

19 subjects chose A, 63 chose B, and 5 chose no difference.

25. (Thaler, 2008) Provide a mental accounting explanation for the puzzles listed below.
 - (a) Why do so many late night television advertisements for kitchen utensils sell items that (i) have multitude of uses, and (ii) include several bonus items?
 - (b) In buying a new house, why is there such an extensive list of optional add-ons that are quite pricey?
 - (c) Why do we observe manufacturer's recommended retail price on so many items of sale even if the recommended retail price is not followed by the retailer?
26. (Prelec and Loewenstein, 1998) Last year, just after his 25th college reunion, Jones bought a slightly used red two-seater car, financing the purchase with a standard car loan. Although the car performed well enough, he found that suitable driving occasions were less frequent than he had anticipated, and that the thrill of recreating the college years dissipated quickly. The monthly payments became regular reminders of what was in truth a rather expensive indulgence: It was hard to justify each bill with the pleasures of an occasional weekend drive. After a bout of worrying and procrastination, he decided to pay off the entire loan. Writing the check was painful but produced relief, and restored some of the pleasures of driving. Now that he owned the car, he was no longer concerned with driving a certain amount each month, and he let suitable occasions arise spontaneously. He even began to enjoy how the thing looked in the driveway Show how this example can be rationalized in terms of the theoretical model of the red and black of mental accounting in Section 20.5.
27. (Prelec and Loewenstein, 1998) In Section 20.5, we considered the choice between prepaying and postpaying for a vacation. Consider now the case of consumer durables, which is dealt with in Example 20.20. Construct the relevant sequence of hedonic costs and benefits, analogously to Figure 20.1. [Hint: In this case, the benefits (unlike the vacation example) accrue over a much longer period. Hence, at any instant in time, the residual benefits, $\sum_{t>k} u_t$, are high enough, thus, hedonic benefits remain higher relative to the vacation example and never become negative.] Which of the two methods of payment, prepayment or postponement of payment, is preferred?
28. Soman (2001) posed the following question to subjects in an experiment. "Imagine that you recently saw an advertisement on the bulletin board. A literature professor was looking for a research assistant to work for about 15 hours. The payment was in terms of a front row seat to a professional theater performance. On the same bulletin board, a music professor was also looking for a research assistant to work for about 5 hours and this assistant would be paid with a front row ticket to a rock concert by a band that you like. You had recently seen posters for both the theater performance and the rock concert. You think you will like to see both these events, although you expect to like the rock concert more. You work for both professors (15 hours for literature and 5 hours for music) and get paid

with the two tickets to the theater and the rock concert respectively. As you are putting the tickets in your wallet, you notice that both events are scheduled for the same evening and both are at good locations on campus. The tickets are non-transferable, nor can they be exchanged. You can use only one of the tickets, and not the other. Which ticket will you use?" 95.2% of the subjects choose the rock concert.

In a second version of the experiment, subjects were told that they had purchased the tickets. The respective prices are HK\$450 and HK\$150. Now 61.7% of the subjects choose the theater performance. What does this experiment tell us about the monotonicity of sunk-time costs and the difference between sunk-time costs and sunk-dollar costs?

29. Shafir and Thaler (2006) pose the following question to 203 Princeton University students. Try to imagine the following scenario. It is the spring of your sophomore year and you plan to be on campus for your last two years. A student organization has decided to arrange a new concert series featuring just the sort of music you enjoy most. The organizers have taken the unusual step of selling two year subscriptions to this series. The subscription guarantees you great seats to eight concerts, four concerts next year and four concerts the following year. The prices on advance booking are quite attractive: Single concert tickets will cost \$25, but your series only costs \$120 (for an implied per concert price of \$15). You have talked to the organizers and you like the performers they intend to bring to campus, so you decide to buy the subscription.

At the time you make the purchase, how well does each of the following statements capture your feelings? I feel that I (a) just spent \$120, (b) made a \$120 investment, and (c) just saved \$80. Subjects were asked to rank each option from 1 (strongly agree) to 5 (strongly disagree). The mean scores were 3.63, 2.20, 2.65.

This question was followed up by another one. It is now the spring of your senior year and there is one remaining concert in the series to which you subscribed two years ago. In fact, the last concert is a group that has become very popular, and tickets are currently selling for \$50 around campus. You are about to go to the concert.

Which of the following best captures your feeling of the cost to you of attending this concert. (a) \$50 cost (b) \$25 cost (c) \$15 cost (d) \$0 cost (e) \$35 saving. The mean scores were 3.96, 4.37, 2.37, 2.48, 2.40.

The final question posed was the following. It is now the spring of your senior year and there is one remaining concert in the series to which you subscribed two years ago. In fact, the last concert is by a group that has become very popular, and tickets are currently selling for \$50 around campus. Unfortunately, you have lost your ticket, and there is no way of obtaining a replacement ticket from the organizers.

Which of the following best captures your feeling of the cost to you of losing this ticket. (a) \$50 cost (b) \$25 cost (c) \$15 cost (d) \$0 cost. The mean scores were 2.43, 4.06, 3.60, 4.33.

(a) What does this experiment indicate about the investment versus cost option at the time of buying the ticket?

(b) What does this experiment indicate about the historical cost, no cost, and the profit felt at the time when only one concert remains and the ticket is not lost?

(c) How is the answer to (b) changed when one suddenly loses the ticket?

In conjunction, how do (a)–(c) support the title of the Shafir and Thaler (2006) paper: *Invest now, drink later, spend never?*

30. (Shafir and Thaler, 2006) Consider the following problem that illustrates the framing effects arising from *local* versus *global* representations. Imagine that you have a membership to a gym in a nearby town that you travel to for business on a regular basis. You go to this gym

exactly once a week: every Monday night when you're in town. Two options given were: The membership allows you to pay \$20 (non-refundable) per each visit./The membership costs you \$1000 a year (i.e., roughly \$19.23 per visit).

One Monday, just after you have arrived and changed, you receive a phone call that requires you to leave and forgo your exercise that evening. How well does each of the following statements capture your feelings about the cost of the missed workout? Please indicate your response on a scale 1 (strongly agree) to 5 (strongly disagree).

- a. I feel like I just wasted \$20, which is what I paid to work out that evening. (1.98/2.70)
- b. I feel like I wasted nothing, since my visit had already been paid for, and sometimes you just can't take full advantage of things to which you are entitled. (3.77/3.03)
- c. I feel like I wasted something, perhaps time, perhaps money, but no specific amount or measure readily comes to mind. (2.95/2.40)

The pair of numbers in the brackets separated by a forward slash, just after each option, is the actual mean choice when one pays a per visit fee and a per year fee respectively. How does framing alter the results? Should gyms encourage patrons to buy tickets on a per visit basis or a per year basis? Why should anyone buy a per visit basis ticket at all?

31. (Rajagopal and Rha, 2009) Two different scenarios are presented to subjects in experiments in scenario-based experiments. Payments to subjects were given in terms of course credits. Scenario A: Jim is a business management consultant who travels every week on business. Last week, he was booked on the 4:30 p.m. flight to Memphis on Sunday. After he reached the airport at 3:30 p.m., he finds out that his flight is delayed by an hour. Since his first business appointment is scheduled for Monday morning, the delay will not affect his work commitments at all.

Scenario B: Jim is a business management consultant who travels every week on business. Last week, he was booked on the 4:30 p.m. flight to Memphis on Sunday to begin a family vacation with his family who were traveling to Memphis from California. After he reached the airport at 3:30 p.m., he finds out that his flight is delayed by an hour. Since his family is scheduled to join him in Memphis the next day, the delay will not affect their holiday plans at all.

Subjects in Experiments were asked to rate on a scale of 1–7, how upset Jim would be in each of the two scenarios. Letting M_i , $i = A, B$ be the mean numbers representing how upset Jim is in each scenario, the findings were as follows. $M_A = 4.54$ (1.34), $M_B = 3.37$ (1.49), $F(1, 45) = 7.76$, $p < .05$; figures in brackets represent the standard deviations.

How do these results inform our view about the fungibility of time across various uses?

32. Prove Proposition 21.8.

PART 8

Behavioral Welfare Economics

INTRODUCTION TO PART 8

In neoclassical economics, rational individuals are considered to be the best judges of their own welfare, and their choices reflect informed judgment of their welfare. One can then use revealed preference arguments to derive an individual's preferences based on observed choices. The findings from behavioral economics show that individuals suffer from a range of biases and misperceptions. Here, and throughout the book, the terms *biases* and *misperceptions* only make sense, relative to the rational benchmark in neoclassical economics. There should be no presumption that, in any absolute sense, the actual behavior of humans should either be termed as a bias or a misperception. In the presence of biases and misperceptions, individuals can no longer be considered to be making informed judgments of their welfare. This calls for a modification of the methods of neoclassical welfare economics, because classical revealed preference analysis does not apply. These issues form the subject matter of Part 8.

Libertarianism and *paternalism* are loaded words. Economists have typically used these terms to mean, respectively, respect for individual choices, and interference with individual choices in a direction that improves welfare. Relative to behavioral interventions, neoclassical forms of paternalism are sometimes referred to as *heavy-handed paternalism*. Examples include banning of certain substances, such as narcotics; protection of the vulnerable against usury laws; health and safety regulations; warnings on cigarette packs; and regulation of the “approval process” for drugs.

The main approach advocated in behavioral economics is *soft paternalism*. This is an umbrella term that nests several kinds of interventions, such as *libertarian paternalism*, *asymmetric paternalism*, and *light paternalism*. The main thrust of these approaches is to design interventions, or *nudges*, that improve the welfare of boundedly rational individuals, but impose minimal costs on fully rational individuals. A leading example is *default options* that address a range of potential biases of boundedly rational individuals; these biases include, but are not limited to, present-biased preferences, temptations, and limited attention. Appropriate defaults improve the decisions of boundedly rational individuals, but impose small, if any, costs on rational individuals.

We also consider a range of other important topics in this part that we briefly allude to now.

We examine the case for *mindless economics* versus the case for *mindful economics*. This debate is about the very scope of economics and addresses the question: Should economics be limited to choice data alone, or are non-choice data admissible too? The reader will not be surprised to learn that this book strongly advocates the use of choice and non-choice data, such as survey evidence, experimental evidence, and neuroeconomic and biometric evidence. The extreme view that economics ought to be restricted to choice data and revealed preference arguments only is not subscribed to in this book.

We consider formal models of choice-based welfare. While these directions are promising, they also show up the limitations of the approach, even when the choice-based approaches are stretched to their limits. Choice-based models must address the issue of choices that depart from those expected under the rational benchmark. In a leading model, one deals with this issue by trimming-away the anomalous choices. However, such trimming-away necessitates the use of either non-choice data, or the invocation of a welfare criteria for trimming the choices, which is what one is trying to construct in the first place. We also consider the extension of this framework to issues of limited attention.

The limitations of the choice-based approach, despite commendable progress in this direction, have prompted some to focus on preferences rather than choice. We also consider the development of alternative frameworks such as the *contractarian approach* in which interventions take the form of directly providing information to individuals about their behavioral biases.

In the last section, we give readers a flavor of the rapidly developing literature in behavioral public economics. We discuss how we might formulate traditional public finance concepts such as tax incidence and the excess burden of taxes in the presence of behavioral factors, such as limited attention. We also briefly comment on reduced-form approaches to behavioral welfare economics that nest a range of behavioral explanations.

None of the frameworks considered in Part 8 will persuade all readers of the book. This, despite scholarship of a high quality, flags up the inherent and deep difficulty of dealing with the underlying issues that straddle neoclassical economics, behavioral economics, philosophy, and ethics.

CHAPTER 22

Behavioral Welfare Economics

22.1 Introduction

Neoclassical welfare economics follows the liberal tradition in economics. The primitives in the model are unobserved individual *preferences* over a set of outcomes. Observed *choices* reflect underlying preferences. In neoclassical theory, policymakers and society respect observed choices because they reflect a *considered judgment* of one's welfare. For this reason, these preferences are sometimes known as *normative preferences*. The neoclassical approach is encapsulated in *revealed preference analysis*. Individuals make choices based on normative preferences and the aim is to see if the observed choices can be rationalized by some underlying utility function (Samuelson, 1948; Houthakker, 1950; Afriat, 1967).

Neoclassical economics allows for the regulation of the behavior of individuals in some cases. In the behavioral economics literature, neoclassical paternalism is sometimes referred to as *heavy-handed paternalism* (Loewenstein and Haisley, 2008). Not everyone will agree on this terminology, but I use it simply as a convenient way of describing the neoclassical benchmark. Its main motivation is that individuals may impose externalities on others, or even on themselves, that they can be made to internalize by appropriately designed regulation or *Pigouvian taxes*.¹ Examples include compulsory helmets for drivers of two-wheelers, seat belts in cars, mandatory third party vehicle insurance, and certificates of roadworthiness of vehicles. These regulations are often justified by a lack of adequate awareness of the risks on the part of individuals, or by the externalities imposed on others from careless behavior. In other cases, individuals might not provide inadequately towards a public good. In this case, the neoclassical solution is either government provision, financed by taxes, or Lindahl taxes. There are also regulations on firms in markets that depart from the perfectly competitive ideal, as encapsulated in, say, antitrust laws and environmental regulations.

The evidence from behavioral economics contests the neoclassical view that individuals always make considered judgments of their welfare. A large body of evidence suggests that there is a wedge between revealed and normative preferences. The wedge may be exacerbated by complexity, long horizons, and limited personal experience (Beshears et al., 2008). The relevant evidence is discussed throughout the book so here we give only a brief outline and suppress the references as far as possible.

Individuals exhibit a range of judgment heuristics and biases that are reflected in actual choices; see Chapter 19 for details. Examples include anchoring, representativeness, law of small numbers,

¹ The interested reader can pursue these arguments in any standard book on public economics (Atkinson and Stiglitz, 1980; Stiglitz, 2000) or in microeconomic theory (Mas-Collel et al., 1995).

base rate underweighting, affect heuristic, hindsight bias, conjunction fallacy, confirmation bias, ignoring regression to the mean, and false consensus effect. In other cases, individuals might not have well-defined preferences and choices may be unduly influenced by informationally equivalent frames and contexts. Individuals might also make important decisions, such as buying consumer durables, or marriage/divorce, in an emotional hot state of the mind that they regret later, once they are in a cold state. Individuals can sometimes exhibit self-control problems on account of present-biased preferences that lead to suboptimal outcomes such as inadequate savings for retirement, obesity, procrastination, and drug use. Furthermore, many individuals report that they would prefer to save more, or prefer the median portfolio to their own, and others pay to kick a bad habit, indicating that they recognize their choices to be suboptimal (Camerer et al., 2003; Beshears et al., 2008).

Data from the US shows that many individuals do not utilize the full limits of their 401(k) pension plans. There is also inadequate diversification of portfolios. For instance, individuals often use the $1/n$ heuristic to allocate their portfolio, where n is the number of options available. This skews their pension portfolios towards equities, particularly company equity, which can have adverse consequences, as it did for Enron employees. Individuals often overutilize payday loans. These are loans that are repaid when the next paycheck arrives; the short-term interest rates on these loans are excessively steep. Individuals often suffer from limited attention. For instance, they react more to sales taxes that are more salient, and there are discontinuous drops in the prices of used cars at 10K thresholds.

Given this evidence, what welfare or normative significance can one attach to individual choices, and how can we modify neoclassical methods to take account of observed choices? This forms the main subject matter of this part of the book.

The main thrust in *behavioral welfare economics* has been on reconstructing the informed underlying judgment of individuals. This has given rise to a range of suggestions under the umbrella term of *soft paternalism* that we describe in more detail below. Camerer et al. (2003) view the relaxation of normative preferences in welfare economics as a natural progression of the relaxation of other restrictive assumptions in economics, such as perfect competition, perfect information, certainty, etc.

We begin, in Section 22.2, by outlining a simple framework of analysis (Dalton and Ghosal, 2011, 2016; Dalton et al., 2016). Individuals derive utility from actions and psychological states. A feedback function maps actions to psychological states. Classical decision makers, who have no behavioral biases or misperceptions, take account of the feedback. However, behavioral decision makers ignore the feedback, hence, their revealed choices differ from normative choices and their welfare level is also lower. We explore a range of policy interventions that can raise the welfare levels of behavioral decision makers to the same level as neoclassical decision makers. These include *direct paternalism* (directly choosing an action for the decision maker), *indirect paternalism* (using Pigouvian taxes/subsidies), and *soft paternalism* (appropriate nudges that impose minimal costs on rational individuals but confer maximal benefits to boundedly rational individuals).

In contrast to *heavy-handed paternalism* in neoclassical economics, the generic form of paternalism in behavioral economics is known as *soft paternalism* or *light paternalism*. In Section 22.3, we consider a range of proposals that have been made under this umbrella term. These include *libertarian paternalism* (Thaler and Sunstein, 2003, 2009; Sunstein and Thaler, 2003), *asymmetric paternalism* (Camerer et al., 2003), and *light paternalism* (Loewenstein and Ubel, 2008).

At the heart of most proposals under the ambit of soft paternalism is the need to distort individual choices as little as possible, and use as little coercion as possible. The idea is that the mistakes,

or misperceptions, of boundedly rational individuals will be *nudged* in the direction of a beneficial correction by a *benevolent planner* or a *choice architect*. At the same time, the minimum intrusion associated with soft paternalism is designed to impose little or no cost on the actions of the fully rational individuals.

Let us consider an example. A *choice architect* or *benevolent planner* might arrange food items in a cafeteria in a certain order. Boundedly rational consumers who pay inordinate attention to items placed at eye level, could benefit from the placement of healthy options at eye level; this is an example of a *nudge*. Neoclassically rational consumers are not influenced by the arrangement of items, so little cost is imposed on them. The intervention of the choice architect is a form of paternalism. However, ultimately it is the consumer who exercises choice; in this sense, the proposal respects *consumer sovereignty*, which is a form of liberalism. Hence, one is led to the term libertarian-paternalism. We consider the effects of several concrete policy proposals in this tradition; these include the role of default options, deadlines, and cooling-off periods.

These proposals are by no means perfect and dissenting views have been given (Sugden, 2008, 2013). Under soft paternalism, the choice architect proposes welfare improving nudges to individuals, based on designing choices, *as judged best by the individuals* under perfect information, unlimited cognitive abilities, and complete self-control. While the preference for median portfolios rather than their own, and checking into rehab to kick a habit, provide tantalizing evidence of individuals judging their choices to be poor, it might not always be clear what individuals judge to be in their best interests.

To operationalize light paternalism, one needs to specify what a mistake/misperception is. Furthermore, in the light of these mistakes/misperceptions, how should we judge the outcomes of light-paternalistic policies? The latter question requires us to have some behavioral welfare criteria. The reason that a traditional welfare criterion is not suitable is that actual choices might not be indicative of an individual's best interests. Thus, we cannot directly use existing measures of welfare, such as equivalent variation and/or compensating variation, to determine the direction in which individual welfare is improving. As Loewenstein and Haisley state (p. 12): "Clearly, it doesn't make sense to assess whether someone is committing an error using a measure that is premised on the assumption that people don't commit errors."

In the typical case considered in economics, consumers have greater information about their own type, for instance, their demand for a good or their health status, relative to the firm. In Section 22.4, we consider the opposite possibility. Namely, that firms are better informed about the consumer's usage of their product, say, energy usage, perhaps because consumers exhibit limited attention (Kamenica et al., 2011). In particular we focus on the *RECAP regulation* suggested by Thaler and Sunstein (2009). Among other things, it requires firms to improve the transmission of information to consumers about their own usage of a product.

As an example, energy firms may be required to install home power meters for their clients, allowing consumers to monitor their own usage. We show that, under exogenous prices, this regulation can reduce the expenditure of consumers, and increase their welfare. However, this regulation may also induce consumers to switch firms. If endogenous prices are allowed, it is not possible to say whether prices will increase or decrease, although intuition suggests that the switching decisions will put downward pressures on prices.

Section 22.5 considers the appropriate scope of economics. An extreme position holds that the only admissible data in economics is *choice data*, and the scope of economics is solely to infer preferences from observed choices (Gul and Pesendorfer, 2008). In this view, non-choice data, such as survey data, self-reported measures of well-being, neuroeconomic data, data based on pupil dilation or skin conductance, or pulse rates, and data generated by mouselab software, are

considered outside the scope of economics. Indeed, in the most extreme view, even experimental data may be viewed as non-choice data, or at least, minimally, with great suspicion. In this view, economists should restrict themselves to observing pairs of quantities and prices, remaining agnostic about the reasons for choice. A second component of the Gul–Pesendorfer position is that the neoclassical framework is flexible enough to account for unexpected observations.

Most behavioral economists do not subscribe to the Gul–Pesendorfer position; certainly this book does not. The edited volume by Caplin and Schotter (2008) gives a range of views on this matter and we describe some selected views. Definitions are inherently subjective, and one need not subscribe to the one suggested by Gul–Pesendorfer. Furthermore, the record of non-choice data in estimating economic parameters of interest, and in illuminating diverse economic phenomena, has been impressive (Camerer, 2008). Misusing the flexibility of the neoclassical model to take account of unexpected observations by introducing ad-hoc auxiliary assumptions, produces *wacky models* (Köszegi and Rabin, 2008a; Camerer, 2008). It is possible to show that by taking account of behavioral misperceptions, one may be able to recover underlying preferences from choices (Köszegi and Rabin, 2008a,b). Experiments have been hugely influential in exploring parameter spaces that may not be observed in actual choice data, and in allowing for treatments that are difficult to observe outside the experimental lab; this has allowed for stringent testing of economic theory (Schotter, 2008). The introductory chapter considers many of these issues in greater detail.

In Section 22.6, we consider *choice-based welfare criteria* with a focus on the Bernheim–Rangel proposal (Bernheim and Rangel, 2009; Salant and Rubinstein, 2008; Rubinstein and Salant, 2012). One begins with a domain of sets of outcomes, and *ancillary conditions* or *frames*, over which individuals have preferences that need not be complete or transitive. If the domain is trimmed-down to a “welfare relevant domain”, then one can define preference relations that are complete but possibly intransitive. However, intransitivity does not preclude a welfare analysis. The preference relations on the trimmed-down domain allow one to define criteria for welfare improvement. Under the assumption that each ancillary condition corresponds to a different self of the same individual, and frame-independent choices, one can relate the preference relations to the neoclassical Pareto criterion. Rubinstein and Salant (2012) depart from the Bernheim–Rangel framework by proposing a welfare criterion based on preference orderings that are frame dependent. They explain inconsistent choices by invoking switches in preference orderings between frames.

The developments in choice-based measures of welfare under behavioral biases are promising, but they also illustrate the great difficulty in making progress in this direction. For instance, in the Bernheim–Rangel model, it is not clear who will trim-down the original domain to a welfare relevant domain, or indeed how it could be done. Presumably, in order to do so, one will need to use some non-choice data or invoke some other welfare criteria, which runs into the danger of an infinite regress of welfare criteria. This has led some to make calls for advocating welfare criteria based on preferences rather than choice (Loewenstein and Haisley, 2008).

Section 22.7 takes account of *limited attention* in the choice-based approach to revealed preference (Masatlioglu et al., 2012). For instance, consumers might simply choose between the two cheapest suppliers, ignoring all others; or in choosing a car, potential buyers might first focus on a car with the best fuel efficiency, and then choose the cheapest car in this category, ignoring all others. In the Bernheim–Rangel approach, an alternative x is unambiguously preferred to y , if y is never chosen when x is available. However, under limited attention, in some choice situations, the individual might choose y simply because he does not pay attention to x . We jointly consider the twin phenomena of *revealed preference* and *revealed inattention* and propose an appropriate modification of the weak axiom of revealed preference under these conditions. We close by

briefly considering the relation with related approaches (Cherepanov et al., 2013; Manzini and Mariotti, 2007).

Section 22.8 outlines the *contractarian approach* (Sugden, 2013) that draws on an older literature in normative economics (Buchanan, 1968, 1975, 1986). This approach criticizes the paternalism advocated in neoclassical economics, and under soft paternalism, because proposals addressed to a social planner lack a valid *addressee*. The contractarian approach advocates addressing recommendations directly to the individuals who exhibit the relevant biases; for instance, through a public information campaign that disseminates information about the harmful effects of smoking.

The recommendations made by a contractarian appeal to the self-interest of individuals in improving their own welfare, rather than to the general or larger interests of a group of people. Nudges are not allowed in this approach if individuals choose not to be nudged. However, providing information directly to individuals under the contractarian approach may also be viewed as a nudge. Furthermore, it is not clear who will decide how the relevant information will be framed; this is particularly important if framing effects are important, or unclear. Thus, the contractarian approach also suffers from some of the same drawbacks that it finds wanting in other theories.

Section 22.9 continues our discussion of *behavioral public finance* from Part 7. It considers welfare issues and public policy in the presence of behavioral factors, particularly, limited attention. Section 22.9.1 considers the problem of computing the relative *tax incidence* on producers and consumers of an increase in the sales tax under limited attention (Chetty et al., 2009). Under limited attention, producers bear a lower burden of the tax increase and the tax incidence falls relatively more on the consumers. While the final outcome is similar to the case of a fall in the elasticity of demand, tax elasticity and limited attention have different effects that we explain.

Section 22.9.2 derives the formulae for the *excess burden* of taxation under limited attention (Chetty et al., 2009). We show that the excess burden increases with the square of a parameter, θ , such that lower values of θ denote higher inattention. When there are no income effects, then limited attention may reduce the excess burden of taxation, which is welfare improving. Finally, in Section 22.9.3, we consider some reduced-form approaches to behavioral welfare analysis. We mainly focus on models that make a distinction between *decision utility* and *experienced utility* (Mullainathan et al., 2012). We also briefly discuss other promising approaches that extend classical optimal tax theory by incorporating behavioral factors such as limited attention (Farhi and Gabaix, 2015).

22.2 Fixing basic ideas

In this section, we introduce some of the issues in behavioral welfare economics, using a simple motivating framework.

22.2.1 The basic framework

Consider the simple theoretical framework in Dalton and Ghosal (2011). Suppose that an individual chooses from the set of actions $A = [\underline{a}, \bar{a}] \subset \mathbb{R}$ and experiences the set of possible psychological states $\Theta = [\underline{\theta}, \bar{\theta}] \subset \mathbb{R}$. Examples of psychological states include moods, aspirations, temptations, reference points, motivations, and degree of self-confidence.²

² The framework is easily extended to the case where A and Θ are subsets of a finite dimensional Euclidean space.

Psychological states are modeled using the theory of *reciprocal determinism* (Bandura, 1977). This implies that psychological states influence the actions of the individual, but are also, in turn, influenced by actions through a feedback function. For instance, more confident/adventurous individuals are more likely to try out a bungee jump. Once they have made the jump (action), their confidence and sense of adventure might be further increased (feedback).

Formally, we assume that the individual has well-defined preferences and the utility function is given by $u : A \times \Theta \rightarrow \mathbb{R}$; u is twice continuously differentiable in both arguments up to order 2, and has continuous cross partial derivatives. The *feedback function* that maps actions to psychological states is given by $f : A \rightarrow \Theta$; f is twice continuously differentiable. We assume that

$$\text{For all } a \in A, \exists \theta \in [\underline{\theta}, \bar{\theta}] : \theta = f(a). \quad (22.1)$$

Definition 22.1 A consistent decision state is a pair (a, θ) , where $a \in A$ and $\theta \in \Theta$, such that $\theta = f(a)$.

Thus, for $(a, \theta) \in A \times \Theta$, the decision maker's utility is $u(a, \theta)$ and for a consistent decision state, $(a, \theta) = (a, f(a))$, utility is $u(a, f(a))$.

Formal models of behavioral welfare economics typically consider two kinds of decision makers. *Classical* decision makers conform to the assumptions of neoclassical economics. *Behavioral* decision makers, in most behavioral welfare models, typically exhibit some behavioral departures relative to classical decision makers. The main distinction between the two decision makers in the model, in this section, is the degree of awareness of the feedback function.

Classical decision makers take account of f , and solve the following *classical decision problem* (CDP).

$$a^c \in \arg \max_{a \in A} v(a) \equiv u(a, f(a)). \quad (22.2)$$

v is a continuous function on a compact interval, hence, a maximum exists, although there is no guarantee that it is unique.

Behavioral decision makers do not take account of the feedback function, f . The solution to a *behavioral decision problem* (BDP) is a pair $(a^b, \theta^b) \in A \times \Theta$ that solves two conditions.³

1. For a given psychological state, θ , the chosen action is optimal, i.e.,

$$a^b \in \arg \max_{a \in A} u(a, \theta). \quad (22.3)$$

u is a continuous function on a compact interval, so a maximum exists.

2. The psychological state is influenced by the feedback rule in equilibrium, i.e.,

$$\theta^b = f(a^b), \quad (22.4)$$

although this is not recognized in the BDP.

³ For an axiomatic characterization of the choice theoretic foundations of the CDP and the BDP and their welfare implications, see Dalton and Ghosal (2016).

For pedagogical reasons, we assume that the global maximum lies in the interior of $[a, \bar{a}]$ for both kinds of decision makers. Our assumptions do not guarantee the existence of a unique equilibrium because neither u nor v are strictly concave. If there are several maxima, then the global maximum is the upper bound of this set. For pedagogical reasons, we shall only be interested in the global maximum below. We use the notation u_1 and u_2 , respectively, for partial derivatives of $u(a, f(a))$ with respect to the first and the second arguments. First and second order partial derivatives of f are written, respectively, as f' and f'' .

The first order condition for an interior optimum to the CDP, evaluated at the optimal values, is

$$u_1(a^c, f(a^c)) + u_2(a^c, f(a^c))f'(a^c) = 0. \quad (22.5)$$

The first order condition and the equilibrium condition for an interior optimum to a BDP are given by

$$u_1(a^b, f(a^b)) = 0 \text{ and } \theta^b = f(a^b). \quad (22.6)$$

In the first order condition, the behavioral decision maker does not take account of the feedback rule between actions and psychological states. The welfare criteria is defined next.

Definition 22.2 Let $(a_1, \theta_1), (a_2, \theta_2), (a, \theta) \in A \times \Theta$. The pair (a_1, θ_1) dominates the pair (a_2, θ_2) if $u(a_1, \theta_1) > u(a_2, \theta_2)$. A consistent decision state (a, θ) is optimal if there is no other consistent decision state that dominates it.

Consider the solution to the BDP (a^b, θ^b) in (22.6), so $\theta^b = f(a^b)$. Using (22.5), let a' be the solution to

$$u_1(a', f(a^b)) + u_2(a', f(a^b))f'(a^b) = 0. \quad (22.7)$$

Then, it follows that

$$u(a^b, \theta^b) < u(a', f(a^b)) \leq u(a^c, f(a^c)). \quad (22.8)$$

The first inequality in (22.8) follows from (22.7), while the second follows from the optimality (but also possibly non-uniqueness) of the optimal solution $(a^c, f(a^c))$ to the CDP. Hence, the solution to the BDP is welfare dominated by the solution to the CDP. Hence, one might think of designing policy interventions to improve the decisions taken by behavioral decision makers.

It is useful to distinguish between the following classes of policy interventions. The first two play a major role in neoclassical economics that does not take into account the existence of behavioral decision makers; yet, many such interventions appear designed for a world that has behavioral decision makers. The third plays a prominent role in behavioral welfare economics.

1. *Direct paternalism*: A third party may directly choose an action for the behavioral decision makers that forces them to take account of the feedback effect. Alternatively, the third party may make these actions legally binding. In neoclassical economics, direct paternalism takes the form of legal requirements such as wearing seat belts; minimum driving age; minimum age for various kinds of consent; prohibition on using mobile phones while driving; purchase of compulsory car insurance; and the definition and prohibition of publicly obscene behavior.

2. *Indirect paternalism*: This takes the form of policy interventions, typically through changes in prices, that induce decision makers to internalize externalities caused to others, or to themselves. Examples are vehicle road taxes based on CO₂ emissions, emissions taxes on factories, subsidies to charitable giving, and child tax credits.
3. *Libertarian paternalism or soft paternalism*: These interventions (see Section 22.3, below) impose low costs on classical decision makers. However, a third party, typically a benevolent planner, controls the menu of options, for instance, defaults, faced by behavioral decision makers. This is a form of *nudging* and embodies various degrees of paternalism, depending on how intrusive the nudges are. The behavioral decision makers are, however, free to choose an option from the menu given, for instance, they can override the default option without the threat of legal sanctions that arises under direct paternalism. This aspect of the intervention respects individual liberty.

Hence, these policies are said to exhibit *libertarian paternalism*. Given that individuals ultimately choose their own actions, despite facing a paternalistic third party, this class of interventions is also sometimes given the generic name of *soft paternalism*. Dalton and Ghosal (2011) use this term to include psychological therapies such as cognitive behavioral therapy and expert advice.

In the context of the simple model used in this section, the nudge takes the form of a choice by the planner of some $\bar{\theta} \in \Theta$, where $\bar{\theta}$ may be thought as a reference point, or a default option.

Insofar as behavioral interventions are about making recommendations, for instance, to nudge consumers, it is worth asking who the relevant *addressee* of such recommendations is. In neoclassical economics one does not typically ask this question. The normative benchmark addressee is a benevolent social planner. This is also the approach taken in most of modern behavioral welfare economics such as under soft paternalism as well as in choice-based or revealed preference approaches; see Sections 22.6 and 22.7, below.

In contrast, Sugden (2008, 2013), in advocating the *contractarian approach* (see Section 22.8, below) questions the usefulness of the social planner benchmark on the grounds that this is a purely hypothetical construct (i.e., lacks a valid addressee). His approach is to respond to behavioral biases by identifying directly the relevant addressee, i.e., the individual who exhibits these biases. This takes the form of policy interventions that provide information “directly” to individuals who “choose” to be nudged.

Once we move away from the normative benchmark of a social planner, the relevant addressee for behavioral recommendations could be an executive agency, a regulatory body, or any policy making department in the government. Such an entity, which we simply term as a policymaker, might have the following two kinds of informational disadvantages, singly, or in conjunction.

Definition 22.3

- (a) *Under Type 1 asymmetric information, the policymaker is uncertain about the degree of behavioral biases of individuals. We capture this by assigning respective probabilities $\mu_1 \in [0, 1]$ and $1 - \mu_1$ that the decision maker solves a CDP and a BDP.*
- (b) *Under Type 2 asymmetric information, the policymaker is uncertain about the correct preferences of the decision maker but knows the type, classical or behavioral, of the decision maker. The policymaker assigns a probability $\mu_2 \in [0, 1]$ to the correct utility function (v for a CDP and u for a BDP). But with probability $1 - \mu_2$, the policymaker has the following incorrect beliefs about the decision maker's preferences.*

- (bi) If the decision maker is classical, then the policymaker believes that preferences are given by $\tilde{v}(a) \equiv \tilde{u}(a, \tilde{f}(a))$, where $\tilde{v} : A \rightarrow \mathbb{R}$ is twice continuously differentiable.
- (ii) If the decision maker is behavioral, then the policymaker believes that preferences are given by $\hat{u}(a, \theta)$, where $\hat{u}$ is twice continuously differentiable in both arguments at least up to order two and has continuous cross partial derivatives.

We now consider the solution under various regimes.

22.2.2 Direct paternalism

Under direct paternalism, the policymaker directly chooses an action for the individual under one of the two kinds of information asymmetries in Definition 22.3. Consider first Type 1 asymmetric information. The objective function of the policymaker is

$$a_1^d \in \arg \max_{a \in A} \mu_1 u(a, f(a)) + (1 - \mu_1) u(a, \theta), \quad (22.9)$$

and the consistency requirement is

$$\theta_1^d = f(a_1^d). \quad (22.10)$$

The first order condition to the optimization problem in (22.9) is

$$\mu_1 \left[u_1 \left(a_1^d, f(a_1^d) \right) + u_2 \left(a_1^d, f(a_1^d) \right) f'(a_1^d) \right] + (1 - \mu_1) u_1(a_1^d, \theta_1^d) = 0. \quad (22.11)$$

Jointly solving (22.10) and (22.11) we get the solution (a_1^d, θ_1^d) ; a solution always exists because the objective function is continuous over a compact interval. In the special cases of $\mu_1 = 1$, and $\mu_1 = 0$, respectively, we get the solution under CDP and BDP.

Consider Type 2 asymmetric information in which the planner believes that the decision maker solves a CDP, but is uncertain of the exact preferences (Definition 22.3(bi)). The objective function of the policymaker is

$$a_2^d \in \arg \max_{a \in A} \mu_2 u(a, f(a)) + (1 - \mu_2) \tilde{u}(a, \tilde{f}(a)), \quad (22.12)$$

subject to the consistency requirement

$$\theta_2^d = f(a_2^d). \quad (22.13)$$

The first order condition to the problem in (22.12) is

$$\begin{aligned} \mu_2 \left[u_1 \left(a_2^d, f(a_2^d) \right) + u_2 \left(a_2^d, f(a_2^d) \right) f'(a_2^d) \right] + (1 - \mu_2) \left[\tilde{u}_1 \left(a_2^d, \tilde{f}(a_2^d) \right) \right. \\ \left. + \tilde{u}_2 \left(a_2^d, \tilde{f}(a_2^d) \right) \tilde{f}'(a_2^d) \right] = 0. \end{aligned} \quad (22.14)$$

Jointly solving (22.13), (22.14), we get the solution (a_2^d, θ_2^d) . If there is no misperception of preferences ($\mu_2 = 1$) then the solution is identical to the CDP, (a^c, θ^c) .

Interventions under direct paternalism are more attractive if μ_1 is low (i.e., it is more likely that the decision maker is solving a BDP), and if μ_2 is high (the policymaker has greater knowledge

of the underlying preferences). At the other extreme (high μ_1 and low μ_2), direct paternalism may do more harm than good.

22.2.3 Indirect paternalism

Under indirect paternalism, the policymaker is the Stackelberg leader and imposes taxes/subsidies, t , on the actions taken by the decision maker; t is also known as a Pigouvian tax. The behavioral decision maker observes t , takes it into account, and then chooses his optimal action. Thus, the BDP in this case is

$$a^i \in \arg \max_{a \in A} u(a, \theta) - ta,$$

where t is the tax ($t > 0$) or subsidy ($t < 0$) per unit of action, a , imposed by a policymaker. The solution is given by the analog of (22.6):

$$u_1(a^i, f(a^i)) - t = 0 \text{ and } \theta^i = f(a^i). \quad (22.15)$$

In the absence of any information asymmetries, the policymaker can implement the solution to the CDP. Comparing (22.5) and (22.15), and choosing

$$t = -u_2(a^c, f(a^c))f'(a^c), \quad (22.16)$$

ensures that the solution is $(a^i, \theta^i) = (a^c, \theta^c)$. The tax/subsidy gives the correct incentives to the decision maker to internalize the own-produced externality of ignoring the feedback effect.

We now consider the presence of asymmetric information. We distinguish between two kinds of solutions. The solution, which arises under asymmetric information on the part of the policymaker (the ex-ante solution) and the solution that arises when the asymmetric information is resolved (the ex-post solution). For instance, the policymaker may assign probabilities that the decision maker to be regulated is classical or behavioral (asymmetric information). Yet, once the appropriate regulations are announced, the actual decision maker, either classical or behavioral, takes actions under the given regulations (resolution of asymmetric information).

Proposition 22.1 (Dalton and Ghosal, 2011): Consider Type 1 asymmetric information (Definition 22.3a).

- (a) Ex-ante solution: The following level of Pigouvian tax, $t = t_1$, ensures the ex-ante solution is identical to that in the CDP, (a^c, θ^c) ,

$$t_1 = (1 - \mu_1) u_1(a^c, \theta^c). \quad (22.17)$$

- (b) The ex-post solution: The ex-post solution, i.e., once the decision maker turns out to be a classical or behavioral decision maker, is not necessarily identical to (a^c, θ^c) .

Proof: (a) Consider Type 1 asymmetric information. The objective function of the policymaker is

$$a_1^i \in \arg \max_{a \in A} \mu_1 [u(a, f(a)) - t_1 a] + (1 - \mu_1) [u(a, \theta) - t_1 a] \quad (22.18)$$

subject to the consistency requirement

$$\theta_1^i = f(a_1^i). \quad (22.19)$$

The first order condition to this optimization problem is

$$\mu_1 [u_1(a_1^i, f(a_1^i)) + u_2(a_1^i, f(a_1^i))f'(a_1^i) - t_1] + (1 - \mu_1) [u_1(a_1^i, \theta_1^i) - t_1] = 0, \quad (22.20)$$

which can be rewritten as

$$u_1(a_1^i, f(a_1^i)) + u_2(a_1^i, f(a_1^i))f'(a_1^i) = \frac{1}{\mu_1} [t_1 - (1 - \mu_1) u_1(a_1^i, \theta_1^i)]. \quad (22.21)$$

Setting $t_1 = (1 - \mu_1) u_1(a^c, \theta^c)$ ensures that the RHS of (22.21) equals zero. Comparing with (22.5) and using (22.19), the solution is $(a_1^i, \theta_1^i) = (a^c, \theta^c)$, as claimed. This is the ex-ante solution, prior to the resolution of the asymmetric information faced by the policymaker.

(b) The Stackelberg leader, the policymaker, announces the Pigouvian tax given in (22.17), under uncertainty about the type of the decision maker: classical or behavioral. Having observed the tax, the decision maker, or Stackelberg follower, who privately knows his type to be either classical or behavioral, chooses an action $a \in A$. The ex-post solution, say $(\tilde{a}, \tilde{\theta})$, is unlikely to equal (a^c, θ^c) . For instance, the optimization problem of a behavioral decision maker is given by

$$\tilde{a} \in \arg \max_{a \in A} u(a, \theta) - [(1 - \mu_1) u_1(a^c, \theta^c)] a,$$

subject to the consistency condition $\tilde{\theta} = f(\tilde{a})$. A similar argument can be applied if, ex-post, the decision maker solves a CDP. ■

The difference between the ex-ante and ex-post solutions reflects the distortions created by an indirect policy intervention. From (22.17), the size of the intervention depends on the size of μ_1 . The size of the distortion diminishes as $\mu_1 \rightarrow 1$, i.e., the closer the decision maker turns out to be a classical one.

22.2.4 Libertarian paternalism

Under libertarian paternalism, boundedly rational individuals are *nudged* in a beneficial direction by a benevolent planner and minimum costs are imposed on the fully rational individuals. We consider a simple example that illustrates some of the implications of libertarian paternalism. Suppose that the action set $A = \{a_l, a_h\}$, where $a_l < a_h$ and a_l is the status quo. To fix ideas, think of a_l as the action “stay at home” and a_h as the action “go to college.” The set of psychological states is given by $\Theta = \{\theta_l, \theta_h\}$; let us interpret these states as the aspiration levels. The utility function of the individual is given by

$$\begin{cases} u(a_l, \theta) = 0, \theta \in \{\theta_l, \theta_h\} \\ u(a_h, \theta_l) < 0, u(a_h, \theta_h) > 0 \end{cases} \quad (22.22)$$

Thus, staying at home gives utility, normalized to zero, irrespective of the psychological state. Going to college is a relatively better option under the good psychological state, but not if the psychological state is bad (e.g., the individual cannot study properly if depressed, and fails, but

must pay fees and other college expenses). Denote the optimal choice of an action under libertarian paternalism by a^* .

Behavioral decision makers ignore the feedback between actions and psychological states. Hence, under the assumptions made so far, they choose as follows.

$$\begin{cases} u(a_l, \theta_l) > u(a_h, \theta_l) & \Rightarrow a^* = a_l \\ u(a_l, \theta_h) < u(a_h, \theta_h) & \Rightarrow a^* = a_h \end{cases} \quad (22.23)$$

In contrast, classical decision makers take account of the feedback function, f . Assume that

$$\theta_l = f(a_l) < \theta_h = f(a_h). \quad (22.24)$$

A classical decision maker realizes that if he went to college, his aspiration level will be raised (see (22.24)), thus, going to college is a dominant action for such a decision maker.

In contrast, for behavioral decision makers, the decision is critically dependent on the initial aspiration levels (see (22.23)). Those who have low aspiration levels, $\theta = \theta_l$, choose not to go to college, so $a = a_l$. In contrast, those with high aspirations, $\theta = \theta_h$, do go to college, so $a = a_h$. Since $u(a_l, \theta_l) = 0$, and $u(a_h, \theta_h) > 0$, if the initial aspiration level of a behavioral decision maker is θ_l , a nudge to the decision maker that either raises aspiration levels to θ_h , or makes going to college a *default option*, is welfare improving. This does not alter the optimal decision of the classical decision makers but improves the decision of the behavioral decision makers. This is the basic idea behind libertarian paternalism. For an interpretation of θ as aspirations in a model that explains poverty arising from aspiration failures, see Dalton et al. (2016).

22.2.5 Effect of other policies

In neoclassical economics, providing more information to decision makers, or expanding their set of actions typically improves the welfare of individuals. In the present framework, this need not be the case because behavioral decision makers ignore the feedback between actions and psychological states. Exercise 5 illustrates these issues.

22.3 Soft paternalism

In economics, *paternalism* may be taken as any infringement of *consumer sovereignty* that is intended to improve the well-being of economic actors. For instance, parents might choose healthy snacks for children and limit access to the TV, or the kinds of websites they can visit on the Internet. Paternalism has been viewed with suspicion in neoclassical economics. However, as Jolls et al. (1988, p. 1545) note in their *anti-antipaternalistic approach*: “No axiom demonstrates that people make choices that serve their best interests; this is a question to be answered based on evidence.”

Soft paternalism is an umbrella term that is associated with several kinds of behavioral welfare frameworks that advocate limited and light interventions, for instance, the choice of default options. These interventions impose little or no costs on classically rational individuals but intend to improve the welfare of boundedly rational individuals by suggestions or *nudges*, while allowing them the liberty to choose their actions, e.g., overriding the default option.

22.3.1 *Libertarian paternalism*

The main target for soft paternalism is boundedly rational individuals. The interventions are designed to influence the choices of such individuals for the better; in this sense the interventions are *paternalistic*. Yet, the interventions do not infringe the liberty of the individuals to make the eventual choices; in this sense the interventions are liberal. Thaler and Sunstein (2003, 2009) and Sunstein and Thaler (2003) argue that their *libertarian-paternalism* proposal is not an oxymoron. In their proposal, Sunstein and Thaler take it that they are advising a *planner* or a *choice architect* whose job is to decide on the options to be presented to an individual. The planner decides on the menu of choices for individuals, based on his judgment about what options are in their best interests, as would be judged by the individuals if one could invoke their underlying rational selves.

Sunstein and Thaler (2003) note that most economists are libertarians, a position associated with the respect for freedom of individual choice. They argue that the unfavorable response to paternalism in economics and law, which they call *dogmatic paternalism* (p. 1163), is based on one false assumption and two misconceptions that we describe now.

The false assumption is that (Sunstein and Thaler, 2003, p. 1163): “almost all people, almost all of the time, make choices that are in their best interest or at the very least are better, by their own lights, than the choices that would be made by third parties.” A range of evidence in behavioral economics that runs contrary to this assumption is highlighted in this book; it is also briefly alluded to in the introduction. Thaler and Sunstein mainly refer to the evidence on context dependence of preferences and the instability of preferences. Within behavioral economics, this is uncontroversial. Furthermore, individual choices are influenced by the individual’s psychological state and by self-control problems. Finally, the choices made by individuals are sometimes not consistent with the choices that they endorse in their role as consumers. For instance, this is the case when individuals visit a rehab centre to kick a habit or prefer the median portfolio of a savings plan to their own (Sunstein and Thaler, 2003, p. 1169).

If a choice architect or planner has to act in a paternalistic manner then he needs to discover what is best for an individual. Sunstein and Thaler (2003, p. 1162) treat individuals as not acting in their best interests if they make “decisions that they would change if they had complete information, unlimited cognitive abilities, and no lack of self-control.” Sugden (2008, 2013) terms this as the *informed desire criterion*. How does the choice architect figure out what is best for the individual? The choice architect could use a cost–benefit analysis or employ insights from psychology to figure out when more options will be beneficial (Sunstein and Thaler, 2003, p. 1166). Or, the choice architect could use simple rules of thumb and experiment as in automatic defaults and the Save More Tomorrow plan (Sunstein and Thaler, 2003, p. 1190).

The two misconceptions, in Thaler and Sunstein’s view, are the following (Sunstein and Thaler, 2003, p. 1163). First, there is a viable alternative to paternalism. Second, paternalism necessarily involves coercion. The behavioral biases and misperceptions of individuals show that they can potentially benefit from the “steer” provided by the choice architect (subject to the caveats about the choice architect’s role discussed below). Furthermore, paternalism need not be coercive. The essence of libertarian paternalism is that the choice architect respects the freedom of choice of the individual, once a menu of choices is offered to the individual. This view is not universally agreed upon. For instance, a literature in Law and Economics defends the rationality assumption and views paternalism with suspicion on account of regulatory capture and the bounded rationality of bureaucrats (Posner, 1986).

In Thaler and Sunstein's view, a policy is paternalistic if it alters the choices of individuals in a manner which makes them "better off". The term better off is not formally defined. Furthermore, in this view, primacy is given to preferences rather than choices, for choice might, for a variety of reasons, not faithfully reflect preferences. If this is the case and the two misconceptions are accepted, then Thaler and Sunstein (2003, p. 175) conclude that: "we can abandon the less interesting question of whether to be paternalistic or not and turn to the more constructive question of how to choose among paternalistic options." Let us clarify these issues further with a concrete example.

Example 22.1 *(The cafeteria example; Sunstein and Thaler, 2003): The "cafeteria example" features prominently in the work of Thaler and Sunstein and nicely illustrates the essentials of libertarian paternalism. It is typically the case that the arrangement of food items (a form of framing) has a significant effect on what people choose in a cafeteria or a supermarket. For instance, people might be more inclined to choose items that are placed at "eye level" or items that are placed at the front end. Consider a cafeteria in which the manager must decide on the arrangement of food items in the store. Suppose that the cafeteria manager has the following options:*

1. *She could make choices that she thinks would make the customers best off, all things considered.*
2. *She could make choices at random.*
3. *She could choose those items that she thinks would make the customers as obese as possible.*
4. *She could give customers what she thinks they would choose on their own.*

Anti-paternalism dictates choosing option 4. However, it is difficult to determine what the consumers would choose on their own if the cafeteria manager were not to first choose one of the options. As Sunstein and Thaler (2003, p. 1164) write: "If the arrangement of the alternatives has a significant effect on the selections the customers make, then their true 'preferences' do not formally exist." Ruling out option 4, the only reasonable option is option 1. Hence, a degree of paternalism is inevitable. Furthermore, option 1 illustrates why coercion is not an inevitable part of paternalism in the following sense. The cafeteria manager simply engages in framing the choices without reducing the number of choices. This should hardly have an effect on the neoclassical fully rational consumers, so it imposes no change in their well-being. However, by perhaps placing the healthy options at eye level, the cafeteria manager may improve the well-being of boundedly rational consumers who might be subject to self-control problems and choose unhealthy snacks otherwise.

One may also think about the likely outcomes if the cafeteria manager were purely a profit maximizer (Sugden, 2008, p. 236). However, if the cafeteria manager believes that current preferences are not well formed and she anticipates that in the longer run consumers will like healthier options, then profit maximizing and welfare issues could be closely related.

In actual practice, the job description of a choice architect already exists in many domains. For instance, doctors often advise patients on a choice menu of treatments chosen by them, architects often advise clients about house designs, interior decorators often choose a subset of designs to show to clients, based on their perceived suitability, and so on. However, the strict definition of a choice architect is satisfied when the suggested interventions are designed to make individuals better off, *as judged by themselves* (Thaler and Sunstein, 2009, ch. 5). Furthermore, the choice architect does not unduly limit the freedom of choice of individuals. Hence, *nudges* are not only

admissible, they are the primary means of producing outcomes from the choice architecture. Nudges are believed to be most effective when the decisions of individuals are infrequent and their decisions give rise to noisy feedback; when the choice architect has more experience and expertise; and when individual heterogeneity is low (Thaler and Sunstein, 2009, ch. 4).

In the actual practice of public policy, one observes a wide variety of nudges that could be imagined to originate from a choice architect. For instance, cash machines dispense cash only when the relevant bank card has been taken out first; nozzles for dispensing different kinds of car fuel, e.g., diesel and petrol, are often of a different size or color to prevent incorrect use of fuel; many cars produce a beeping sound if the driver is not wearing a seat belt; automatic electric switches in cars and offices are often used to conserve energy or prevent batteries from running out; default options in savings and pension plans enable people to invest better; the Save More Tomorrow plan takes account of current self-control problems to enable greater savings in the future as income grows over time (see Section 22.3.4 below); color coded labels on food (red for high fat and green for low fat) and government mandated guidelines on the number of fruit portions a day; warnings on cigarette packs; and prohibition of advertising of cigarettes.

Thaler and Sunstein (2009, pp. 102–3) give an example of a regulation called RECAP, short for *record, evaluate, and compare alternative prices*, that allows better across-firms comparability of prices. This regulation calls for a personalized electronic summary of the consumer's use of the good/service sold by the firm in a standardized form, that allows comparison of prices from alternative suppliers. This is similar, in spirit, to the practice in UK supermarkets of separately stating sticker prices of goods of different brands/sizes in standardized units, say per 100 grams, or per 100ml.

In each case, the justification for these nudges in the libertarian-paternalistic framework is that some people are making undesirable choices, as judged by themselves (Thaler and Sunstein, 2009, p. 5). Thaler and Sunstein present a range of evidence to underpin the claim that individuals would wish to be nudged in many cases. Examples include, preference for the median savings portfolios relative to the own portfolio; New Year resolutions for smoking and other addictions that often fail, or activities that involve procrastination; evidence from statistics that show health related risks from temptation activities such as smoking, drinking, and obesity inducing foods (Thaler and Sunstein, 2009, ch. 1, 4). This evidence is certainly impressive but some have doubted if it clinches the argument that people wish to be nudged (Sugden, 2009, p. 371).

22.3.2 Asymmetric paternalism

Concurrently and independently of the development of the idea of libertarian paternalism, Camerer et al. (2003) propose the closely related concept of *asymmetric paternalism* or *paternalism for conservatives*. They define and describe the main features of asymmetric paternalism as follows (p. 1212). “A regulation is asymmetrically paternalistic if it creates large benefits for those who make errors, while imposing little or no harm on those who are fully rational. Such regulations are relatively harmless to those who reliably make decisions in their best interest, while at the same time advantageous to those making suboptimal choices.”

How should alternative paternalistic policies be evaluated? Camerer et al. (2003) propose a simple cost–benefit framework. Suppose that a fraction p of the consumers are boundedly rational, while the rest are fully rational. Consider a proposed paternalistic policy that is implemented by incurring some implementation costs, I . The policy imparts some benefits $B > 0$ to the bound-

edly rational consumers, but also imposes some costs $C > 0$ on the fully rational consumers. Suppose that the incremental effect on the profits of the firms on account of the change in consumer behavior is $\Delta\pi$ which could be positive or negative. The proposed policy is beneficial if

$$pB - (1 - p)C - I + \Delta\pi > 0. \quad (22.25)$$

An asymmetrically paternalistic policy is characterized by a high value of B and low values of C and I . In the limit, the purest case of asymmetric paternalism arises when $C = 0$. There is still no guarantee that I will be low, although this would seem to be an important requirement of asymmetric paternalism. Asymmetric paternalism becomes more attractive as the proportion of boundedly rational consumers, p , increases. The effect on and sign of $\Delta\pi$ depends on the precise context. For instance, if bounded rationality creates errors in the direction of buying too little, then under an asymmetric paternalistic policy, $\Delta\pi > 0$; and in the converse case, $\Delta\pi < 0$. While (22.25) is useful to organize our thoughts, in actual practice, the measurement of costs and benefits in the presence of behavioral biases is a vexed one. For instance, perceived benefits, B , may depend on behavioral factors such as one's psychological state, framing, context, and status-quo bias, which may be inherently hard to measure.

The class of policies that alters "default outcomes" comes closest to satisfying the requirements of asymmetric paternalism. This is particularly the case when a status-quo bias arises from procrastination. Think, for instance, of two alternative states s_1 and s_2 with respective benefits B_1 and B_2 such that $B_1 > B_2$; the states are chosen by the individual. If the status quo is s_1 and individuals exhibit a status-quo bias that prevents them from choosing s_2 then a paternalistic policy might wish to set the default option to s_2 . An example of a default option is automatic enrollment in 401(k) pension plans, which has been shown to improve participation rates (Madrian et al., 2001).

The paternalistic policy of automatic enrollment in 401(k) plans also alerts us to a careful consideration of unexpected aspects of the problem. In this case, in actual practice, the default enrollment meant choosing also the default contribution rates and the default portfolio of assets. The default rates were set quite low (2–3%) and the default portfolio was a conservative one (mostly money market funds). These defaults, however, turned out to be disadvantageous. The low default rates reduced the effectiveness of the default, while the conservative portfolio earned lower returns because stocks have traditionally outperformed bonds. This offset some of the beneficial effects of the increased enrollment rates arising from the new default option (Choi et al., 2004; Madrian et al., 2001).

A second example of unexpected outcomes comes from the detailed text that accompanies mortgage and lease contracts in the US. The detail in the text is a response to the Federal Truth in Lending Act. The text typically gives details of all costs and terms of the contract; multiple, mandatory, signatures certify that the reader has read the separate sections of the contract. Borrowers have to read the following statement and sign that they understand it: "If you obtain this loan, the lender will have a mortgage on your home. You could lose your home, and any money you have put into it, if you do not meet your obligations under the loan." This text exemplifies asymmetric paternalism because the rational types will not need to read the fine print while the boundedly rational types are expected to benefit from reading it. Furthermore, once the text is designed, the cost of producing copies is relatively low. However, a potentially unexpected outcome is that because individuals have limited attention (see Part 7 of the book), the boundedly rational types simply ignore the fine print, in which case the policy might have limited benefits. Indeed, such individuals might have read a more abbreviated version of the text (see the

relevant evidence in Part 7). The condition in (22.25) advocates taking account of all such relevant costs.

Many existing regulations discussed in this section can be interpreted as a form of asymmetric paternalism. Indeed, it is hard to give an interpretation of these regulations on traditional grounds of efficiency when all economic agents are rational. Hence, somewhat paradoxically for neoclassical economics, one might argue that the law reflects asymmetric paternalism (Camerer et al., 2003, p. 1223).

22.3.3 A pragmatic approach

Loewenstein and Haisley (2008) propose a pragmatic approach, light paternalism, in which welfare judgments can be made under two main conditions that they term as *dominance* and *self-officiating*.⁴ The dominance criteria comes into play if one strategy clearly dominates another, in terms of outcome or risk. For instance, full utilization of 401(k) matching programs typically dominates underutilization. Thus, light paternalism would advocate a default option that equals the maximum allowable contribution that is matched by the employers.

Self-officiating means that individuals choose their own goals and then they are provided with the necessary information and incentives to aid self-control. The choice of goals is to be made in a “cold” rather than a “hot” state (see Part 6 for this distinction). Consider the example of an office in which employees determine that they would be better off without a soda machine that dispenses unhealthy drinks. The self-officiating criterion allows for the removal of the machine from the premises provided that the employees make this decision in a cold state. This appears relatively heavy-handed but allows individuals to pursue their stated goals more directly.

The pragmatic approach also differs from the choice-based approach of Bernheim and Rangel (2007) in that it focuses on preferences rather than choice. Loewenstein and Haisley (2008, p. 223) capture the spirit and thrust of their approach in the following quote.

Our own opinion is that the welfare criterion for evaluating paternalistic policies should be based on preference. Much as a psychotherapist would likely take at face value a client's professed desire to become happier, more sociable, or less anxious, even if she engaged in patterns of thinking and behavior that led to the opposite result, we would argue that the economist-as-therapist should treat verbal statements of preference as useful information, even if choice is not in line with professed preference. If people express a desire to lose weight but make choices that cause them to gain weight; if they express a desire to be financially solvent, but make choices that lead to burdensome debt; if they want to stop smoking but continue to smoke; if they want to take prescription medications but fail to do so, these are all situations in which paternalistic interventions could be helpful.

22.3.4 Some applications of soft paternalism

We briefly consider some applications of soft paternalism. Our discussion is abbreviated because these issues have been considered in varying degrees elsewhere in the book.

⁴ A third criterion, *clearly negative outcomes*, is also identified. However, it appears that in a broader definition this criterion can be subsumed within the dominance criteria.

THE ROLE OF DEFAULTS

The status-quo bias is a well-documented finding in behavioral economics.⁵ Suppose that there are two possible actions/policies, x and y , with respective benefits to an individual equal to b_x and b_y . Suppose that the cost of changing from any action to the other is c . Then there is a status-quo bias in favor of x if $b_y - b_x > c$, but the individual prefers to persist with x . Concurrently, there might be a status-quo bias in favor of y too.

Camerer et al. (2003) note several sources of status-quo bias. (1) Loss aversion: If a change in policy is associated with a potential loss, then the status-quo policy is preferred. (2) Asymmetric experienced regret: There is some evidence that people regret bad outcomes that result from their own actions as compared to bad outcomes that result purely from inaction. (3) Hyperbolic discounting: Current-bias might cause individuals to procrastinate in shifting to the economically more beneficial policy.

Status-quo bias opens the possibility that paternalism, in the form of default options, in the form of the policy associated with higher welfare, may be effective. The status-quo bias ensures the individuals are unlikely to override default options. The stickiness of default options has been widely documented: for instance, in decisions to donate one's organs (Johnson and Goldstein, 2003; Abadie and Gay, 2004); default options in car insurance plans (Park et al., 2000); and pension and savings plans (Thaler and Sunstein, 2009). Defaults can be viewed as a form of asymmetric paternalism because they can be set in a manner that is beneficial for a boundedly rational consumer, but impose little or no cost on the rational individuals who can easily override them.

Consider the following natural experiment that illustrates the effect of default rules for insurance policies. In New Jersey, the default was a limited right to sue the other party following an accident, while, in Pennsylvania, the default was a full right to sue. In each state, customers could switch to the other possibility by either paying more (full right to sue in New Jersey) or by receiving a discount (for a limited right to sue in Pennsylvania). Johnson et al. (1993) show that when offered a choice to alter the defaults, only 20% of drivers in New Jersey chose full rights to sue while 75% of drivers in Pennsylvania retained full rights to sue.

RETIREMENT SAVINGS AND DEFAULTS

We have shown in Part 3 that in the presence of present-biased preferences, such as hyperbolic discounting, individuals may save insufficiently for retirement. Other behavioral factors may also reduce savings; we give two examples. (1) By reducing current consumption relative to a reference level of consumption, an individual with a mental account for consumption may suffer loss aversion. Thus, individuals might be reluctant to save more. (2) If the default is zero savings/contributions to a retirement plan, the status-quo bias could further weaken the desire to save.

The idea behind Benartzi and Thaler's (2004) SMarT ('save more tomorrow') plan is to take account of behavioral features in such a manner that encourages more savings. Essentially, under a SMarT plan, individuals agree to save a part of their next pay increase. Since only a fraction of the pay increase in the future is used towards savings, loss aversion from a fall in consumption does not kick in sufficiently. Furthermore, since the saving is made in the future, it is not influenced by the current-bias in preferences arising through, say, hyperbolic discounting. Finally,

⁵ See, for instance, Samuelson and Zeckhauser (1988), Kahneman et al. (1991), and Kahneman and Tversky (2000).

the status-quo bias can be exploited by altering the default option to contribute rather than not-contribute. In the spirit of soft paternalism, individuals can choose to opt-out if they wish to.

Evidence supports the “savings enhancing effects” of changing the default option (Choi et al., 2004; Madrian and Shea, 2001). An alternative to using the default option is to ask employees when they begin their jobs if they would like to enroll or not. Choi et al. (2004) show that this method increases enrollment relative to the case of the opt-in option (default is not-contribute) but less relative to the opt-out option (default is to contribute).

Loewenstein and Haisley (2008) note two limitations of empirical studies that suggest a positive welfare effect of paternalistic savings policies. First, where does an increase in retirement savings come from? If other items of expenditure are compromised and there is an associated increase in credit card debt, then these factors need to be factored in. Second, a range of behavioral factors come into play in many policies. For instance, in the operation of SMarT savings plans, these factors include hyperbolic discounting, loss aversion, and status-quo bias. What is the individual contribution of each of these factors? These are pertinent questions for future research.

OBESITY

Loewenstein and Haisley (2008) report on their research on the effects of deposit contracts in countering obesity. People who would like to lose weight are asked to pay a deposit of \$90/month, or \$3 a day. Individuals are set a target of losing a pound of weight over a week. They are weighed each day against a target. If the weight is below the target, the experimenter doubles the deposit and gives the money, \$6, to the subject. If the weight is greater than the target then the subject loses the deposit.

The scheme works on two behavioral principles; the various components are described in Parts 3 and 7 of the book. First, initial overconfidence contributes to the decision to join the plan. One could also use a hyperbolic discounting argument similar to the optimistic take-up of annual versus daily offers in gym memberships. Second, a loss of the deposit money is viewed as out-of-pocket costs, which are overweighted relative to forgone-gains, on account of loss aversion. Hence, individuals are more reluctant to avoid out-of-pocket costs, which contributes to their efforts to get their weight below the target. The take-up of deposit contracts is a voluntary decision (liberalism). Rational individuals have no need for them. However, boundedly rational individuals can benefit from them (paternalism). Furthermore, the idea of respecting individually chosen goals in a cold state of the mind, and aiding in the achievement of these goals is consistent with the *self-officiating criterion* under light paternalism (see Section 22.3.3).

Wisdom et al. (2010) consider two kinds of interventions to reduce calorie intake in fast food restaurants. In the first, individuals are simply provided with information about the calorie content of their food items. This is consistent with recently proposed laws and the contractarian approach that we outline in Section 22.8. The second proposal is a form of nudge, consistent with soft paternalism, that simply makes choosing high calorie foods more inconvenient, for instance by altering the placement of items on a menu.

Both interventions were effective in reducing calorie intake. However, each intervention had drawbacks. Providing calorie information did not reduce the calorie intake of overweight people who presumably are the main target of these interventions. The nudge worked less well in a weak form as compared to a strong form. An unexpected effect of the nudge was that individuals reduced consumption of high calorie sandwiches but increased their consumption of higher calorie side orders and drinks. These results show that a combination of the two policies may work

better and nudge proposals may have unexpected effects on complementary activities. Hence, careful pilot studies must precede actual policy recommendations.

COOLING-OFF PERIODS

Consumers might sometimes regret a purchase decision on account of several factors. These include: buying in an emotional hot state (see Part 6); or being subject to projection-bias that overstates the future need for the purchase (see Part 6); or present-biased preferences, arising, say, from hyperbolic discounting, that make the benefits of the current purchase salient relative to its future costs (see Part 3). Regulation, in the form of *cooling-off periods*, protects consumers from potential future regret arising from current decisions. Cooling-off periods typically take one of two forms.

(a) Individuals are free to choose but allowed to reverse their decision within some legal time horizon, T . This typically occurs with the purchase of consumer durables and many services such as insurance products.

(b) Having made their initial decision, individuals are not free to exercise their choice until some time, $\tau > 0$, has passed. For instance, once one files for a divorce, the divorce is not granted until some time has elapsed. There might be a mandatory period of separation that precedes the divorce. Often, there is also a mandatory period (usually, a few days) between filing for a marriage request and the granting of a marriage license.

Several examples of cooling-off periods for the US, for the two cases, (a), (b) above, are given in Camerer et al. (2003). Cooling-off periods are an example of asymmetric paternalism. Rational individuals do not need such periods, and when cooling-off periods take the form in (b), a delay of a few days is probably not too costly for such people. Indeed, being rational, they would take the waiting period into account. However, for boundedly rational individuals, cooling-off periods can be welfare improving on account of the various behavioral features noted above.

DEADLINES

One implication of hyperbolic discounting is the tendency of individuals to procrastinate in the completion of some task (see Part 3). In a multiple selves interpretation, the current self typically believes that the future selves will suffer from fewer self-control problems. Hence, the current self, rationally, puts off completion of the task to some future date. If this optimism about future self-control problems is misplaced, the task might never be completed.

Deadlines can often be self-imposed. However sometimes they are externally imposed, and are legally binding. The paternalistic aim of deadlines is to ensure the completion of a task when the planner perceives that the benefits exceed the costs, say, in the sense of (22.25). For instance, in order to contribute to the tax-exempt individual retirement account (IRA), individuals not only must respect the constraint of a given maximum amount each year, but also the deadline of April 15. Thus, if individuals procrastinate beyond this deadline, their entitlement to the maximum allowed tax allowance for the year is lost. This magnifies the effect of missing the deadline. Presumably, this deadline should help individuals who procrastinate, to take advantage of the investment opportunity.

Ariely and Wertenbroch (2002) run the following experiment using MIT students. Students had to write three short term papers for a course and they were sorted into two groups. One of the groups was given three equally spaced deadlines for completion of the term papers (the restricted choice condition). The other group could decide to hand in their term papers any time before the end of term (the free choice condition). An identical late submission penalty applied to both groups. Few students in the free choice condition chose to impose equally spaced deadlines on themselves but most did impose some sort of deadlines on themselves. In general, students who

were subjected (externally or internally) to evenly spaced deadlines performed better in terms of grades. One possible reason is that this allowed for better budgeting of time. In the absence of such deadlines, students might try to do too much, too late, lowering their grades.

22.3.5 A critique of soft paternalism

Recall the *informed desire criterion* in our discussion of libertarian paternalism in Section 22.3.1. Essentially, the criterion suggests that individual choices may be suboptimal, as judged by themselves, in the presence of incomplete information, limited cognitive abilities, and self-control problems. Sunstein and Thaler (2003, p. 1162) treat individuals as not acting in their best interests if they make “decisions that they would change if they had complete information, unlimited cognitive abilities, and no lack of self-control.” Sugden (2008, 2013) questions the empirical usefulness of the informed desire criterion on the following grounds.

The concepts of incomplete information, limited cognitive abilities, and self-control need a formal definition. Even if one could define these concepts in a satisfactory manner, it might still be difficult to pin down human behavior if these factors were taken into account. Should we expect preferences to be consistent when we relax these constraints? For instance, a preference for status quo or anchoring might be hardwired, so the informed desired criterion might not eliminate such preferences. This is clearly an unresolved issue and should be a interesting area of research for the future. As Sugden (2008, p. 234) puts it: “Thus, while we can understand how planners might be motivated by paternalism, we are entitled to be sceptical about how far the planners’ judgements about other people’s well-being are justified, either objectively or inter-subjectively.”

How does the choice architect figure out what is best for the individual? The suggestion in libertarian paternalism is that the planner uses cost–benefit analysis (as in (22.25)) or rules of thumb. These recommendations may appear to many readers as vague (Sugden, 2008, p. 233). Guala and Mittone (2015) propose that if it is the case that individual welfare is impossible or too costly to discover, then one may make a case for a political justification for nudging. They argue that since individual biases are likely to cause externalities to others (and to the individuals themselves), the associated social costs may justify nudging interventions on political grounds.

Soft paternalism is relatively silent about issues of political failure. Regulatory capture, where regulators are unduly influenced by special interest groups, and the bounded rationality of bureaucrats, does not ensure that paternalistic choices will be good ones (Glaeser, 2006). However, it is also true that, in a wide range of cases, government policies are the outcome of more deliberate and detailed information processing. These cases are all counterexamples to the proposition that the bounded rationality of governments will necessarily preclude the possibility of any beneficial paternalistic interventions. For instance, laws on cooling-off periods, various default options, mandatory third party car insurance, compulsory seat belts in cars, and reminders to fill-in tax returns by publicly known deadlines. Behavioral economists take great pains to stress caution, field testing, and pilot studies in the application of paternalistic policies.

Gul and Pesendorfer (2008) argue for a separation of the roles of economists as social scientists, in which they attempt to explain economic phenomena, and their roles as advisors/advocates, e.g., for public policy. Economists who do not respect the distinction between these two roles are termed by them as economist-therapists. We examine this critique in more detail in Section 22.5. Gul and Pesendorfer assign a relatively restricted role for economics and economists, a view that is not shared by all economists. Espousing the opposite view, Loewenstein and Haisley (2008, p. 9) write:

Although Gul and Pesendorfer seem to view “therapist” as a pejorative label, we see no reason to not embrace it. Therapy is, in fact, not a bad metaphor for the new types of policies that behavioral economists have been proposing. . . . Just as the therapist endeavors to correct for cognitive and emotional disturbances that detract from the well-being of the patient, such as anxiety, depression, or psychosis, the economist/therapist endeavors to counteract cognitive and emotional barriers to the pursuit of genuine self-interest.

Klick and Mitchell (2006) argue that soft paternalism ignores the long-run costs. By this, they mean (p. 1625), costs that “offset short-run gains because of the negative learning and motivational effects of paternalistic regulations.” Paternalistic policies, it is argued, interfere with the learning-by-doing process via a moral hazard argument. Individuals, because they are protected via paternalistic policies, may have a lower incentive to protect themselves against bad outcomes.

While this argument may be true in some cases, there are several counterexamples that apply in cases where learning is either very slow, feedback is poor, or where the outcomes of one’s actions are known with substantial delay. For instance, if an individual saves inadequately for his retirement on account of present-biased preferences, then by the time that the outcome (low savings, post-retirement) is revealed, it is too late to learn. This critique is also silent about the forms that learning takes. For instance, suppose that learning takes place through reinforcement learning. Then, presumably, soft paternalism, which nudges the individual in the direction of actions that produce a better outcome, reinforce the use of such actions in future.

22.3.6 *A note on behavioral welfare criteria*

Given the discussion so far, what is the appropriate welfare criterion? This is a difficult question on which there appears to be no consensus. This section briefly outlines some of the issues.

One approach is to use self-reported assessments of happiness as a proxy for welfare. This approach draws on the distinction between *experienced utility* and *decision utility*. These issues have already been discussed in Part 6, so our discussion here will be brief. Decision utility refers to the practice in economics of inferring utility functions from the observed choices of individuals. Experienced utility is the hedonic experience associated with an outcome (Bentham, 1789; Kahneman et al., 1997).

Since experienced utility is one’s subjective recollection of the satisfaction derived from a good or service in the past, its measurement can pose problems. For instance, it is well established that self-reported survey questions that report experienced utility are subjected to biases, such as *duration neglect*, and *peak-end evaluation* (Kahneman et al., 1997). However, evidence shows that subjective measures of well-being are consistent with the actual choices of the vast majority of subjects and these measures are the best predictors of choices (Benjamin et al., 2012). As shown in Part 6, such subjective measures successfully predict a range of phenomena such as job quits, probability of suicides, productivity, and probability of a future divorce among couples.

The phenomenal growth in the literature on happiness economics shows that an increasing number of economists take experienced utility as an objective and useful indicator of an individual’s welfare. Some have forcefully advocated the maximization of happiness as the goal of government policy (Layard, 2005). However, others continue to be skeptical (Loewenstein and Haisley, 2008). First, as noted above, the recollection of a past event could be influenced by current moods or emotions and subject to duration neglect and peak-end bias. Second, individuals might adapt to the current level of conditions in their life. For instance, the happiness levels of patients on dialysis were found to be very similar to a control set of healthy patients (Riis et al.,

2005; Ubel et al., 2005). Many would find the resulting policy recommendation that ill-health is not an undesirable outcome to be troublesome.

If people make mistakes in their choices, then one solution is to provide them with the correct information first. Individuals can then maximize their utility in the usual manner. This is the so-called *informed utility approach*. In actual practice, government regulation tries to impart a variety of information to consumers, such as warnings on cigarette packs, content-labeling on food items, and even, in the case of the UK, daily recommended amounts of fruits and vegetables etc. Armed with the appropriate information, the resulting debiased choice of individuals could then form the basis of welfare criteria.

A concern with this approach is that it does not specify the exact method of imparting information; this is important because there are potential framing effects associated with different methods of information provision. Recall, from Chapter 20, the well-known example from Tversky and Kahneman (1981) in which the outcomes are quite different when the instructions are phrased in terms of “lives lost” rather than “lives saved.” Indeed, deciding on the appropriate frame/context within which the information is to be presented will require some welfare criteria, but this takes us back to the original problem of constructing welfare criteria in the presence of behavioral biases. A second source of concern for the informed utility approach is that while it can potentially counter mistakes that are made on account of imperfect information, it does not address the issue of mistakes (relative to the neoclassical benchmark) that are made when all information is available. For instance, individuals might have self-control problems, or they might rely on a range of judgment heuristics (see Parts 3 and 7).

There is growing popularity of choice-based measures of welfare that correspond to decision utility (Bernheim and Rangel, 2007, 2009); see Sections 22.5 and 22.6 below. These measures assume that despite the enumeration of behavioral biases in behavioral economics, there is a strong systematic component to human behavior that is enriched by psychological considerations. Hence, choice data can be used to disentangle the systematic component. However, when choices are inconsistent as, for instance, in the evaluation of new products (see the discussion on coherent arbitrariness in Part 7) then one may trim the existing choices of these troublesome aspects. Once trimmed of “undesirable” choices, the choice criteria retain their usefulness. However, it is not always clear how choices are to be trimmed. Bernheim and Rangel (2009) suggest using non-choice data, for instance, data from brain scans. However, reservations have also been expressed about the ability of neuroeconomic studies to determine which choices are welfare enhancing (Loewenstein and Haisley, 2008).

22.4 Regulation under imperfect self-information

In neoclassical economics, the standard assumption is that consumers have better information about their types relative to firms. In the leading textbook example of asymmetric information, from the area of health insurance, consumers are better informed than firms about their own state of health. The firm then designs clever contracts to truthfully elicit the state of health of the consumers. However, in many cases, consumers might have limited information on their usage of a product, and the usage data collected by the firm could give an informational edge to firms. This could be the case, for instance, in information collected by cell phone companies or Internet search engines.

It is pertinent to explore the effects on consumer welfare when information is provided to consumers of their own usage. Examples include power companies in Britain offering to put

electricity meters in peoples' houses to enable them to monitor their usage on a continual basis. Once consumers are informed of their usage, they might wish to switch firms. Mullainathan et al. (2012) show this to be the case in a randomized field experiment in the usage of Medicare Part D prescription drug plans in the United States; 28% of the group of subjects that received a letter with personalized cost information switched their providers, as compared to 17% who switched in a comparison group.

The RECAP regulation that we considered above, highlights the welfare effects of information provision in this case. We now consider a model, due to Kamenica et al. (2011), that formalizes the effect of RECAP type regulations.

Suppose that consumers are distributed uniformly over the unit interval, $[0, 1]$. Any consumer uses $x \in \{1, 3\}$ units of service, per month, provided by a private firm. Half the consumers use 1 unit and the other half uses 3 units. However, consumers are imperfectly informed of their own private usage, say, due to limited attention.

Each consumer receives an iid signal, $\theta \in \{1, 3\}$, of her usage. Signal accuracy is captured as follows. Let $p(x | \theta)$ be the conditional probability that the usage is x , conditional on the signal, θ . Then,

$$p(x | \theta) = \begin{cases} \lambda \in [\frac{1}{2}, 1] & \text{if } x = \theta \\ 1 - \lambda & \text{if } x \neq \theta \end{cases},$$

thus, the signal is accurate about the true usage with probability λ . We can now determine the expected usage of each consumer, conditional on the signal received, $E[x | \theta]$.

$$E[x | \theta] = x_i p(x_i | \theta) + x_j p(x_j | \theta); x_i \neq x_j \in \{1, 3\}, \theta \in \{1, 3\}.$$

Thus,

$$E[x | \theta = 1] = 3 - 2\lambda \text{ and } E[x | \theta = 3] = 1 + 2\lambda. \quad (22.26)$$

The utility function of each consumer, on receiving the signal, θ , is given by

$$U(\theta, P) = 1 - E[x | \theta] - M, \quad (22.27)$$

where M is the monetary payment from the consumer to the firm. In this reduced-form model, utility is decreasing in expected usage to reflect the fact that often when consumers are informed about their usage, they are likely to be surprised by the level of usage, and often switch providers of the service in the hope of getting a better deal.

Suppose that there are two providers of the service, A and B . Firm A charges a fixed monthly price of $P_A = 2$, irrespective of usage, thus, $M = 2$ for $x \in \{1, 3\}$. Firm B charges a per unit price equal to $P_B = 1$, so $M = x$ for $x \in \{1, 3\}$.⁶ Thus, if consumers knew their own usage, those with $x = 3$ would prefer to buy from firm A and those with $x = 1$ from firm B . A simple calculation shows that consumers who receive a high usage signal will buy from firm A .

$$U(\theta = 3, P_A) - U(\theta = 3, P_B) = 3P_B - P_A > 0.$$

⁶ It is possible to endogenously derive the optimality of different pricing schemes for firms; see, for instance, Piccione and Spiegler (2012).

Similarly, those who receive a low usage signal purchase from firm B .

$$U(\theta = 1, P_B) - U(\theta = 1, P_A) = P_A - P_B > 0.$$

The expected expenditure of all consumers, given that half get a high signal and half get a low signal, is given by $Y = \frac{1}{2}P_A + \frac{1}{2}E[x | \theta = 1]P_B$. Using (22.26) and $P_A = 2, P_B = 1$, we get

$$Y = 1 + \left(\frac{3}{2} - \lambda\right). \quad (22.28)$$

The first term in (22.28) is the expected expenditure of those who receive a high signal and the second term is the expected expenditure of those who receive a low signal.

Proposition 22.2 *Consumer regulation that provides consumers information about their own usage, decreases expected consumer expenditure and increases their welfare.*

Proof: Regulation that provides consumers information about their usage is equivalent to increasing the accuracy of the signal, λ , in informing consumers of their usage. From (22.28), overall expected expenditure of consumers falls, as λ increases. From (22.27), this increases $U(\theta, P)$, which is a measure of consumer welfare. ■

In actual practice, providing information to consumers under regulations such as RECAP will also alter prices, which are assumed given in the model, above. Perhaps intuition might suggest that the resulting desire of consumers to change providers may also put downward pressure on prices. However, Kamenica et al. (2011) give the following useful analogy to show that this need not be the case.

Suppose that two firms with identical costs compete in prices under Hotelling price competition and consumers are uniformly distributed over the interval $[0, 1]$. When consumers do not know their own usage, $x \in \{1, 3\}$, and receive no signals, both firms appear identical to them. Thus, in a Bertrand equilibrium, the firms set prices equal to their marginal costs. However, now suppose that consumer regulation informs each consumer of their usage. Now firms can employ different pricing schemes (e.g., a fixed monthly price or a price based on usage). Based on their level of usage and travelling costs, consumers no longer find the firms to be symmetric. Firms can take advantage of this “new” market power by extracting some of the surplus. Thus, consumers may pay a higher price.

22.5 Choice and non-choice data: What is the scope of economics?

Should economics restrict itself to choice data alone, or should it also be open to the use of non-choice data? In “The case for mindless economics,” Gul and Pesendorfer (2008) present an extreme case for restricting the boundaries of economics to choice data. Indeed, it would not be surprising if many economists hold the same views, although most behavioral economists are unlikely to subscribe to it. Hence, it is important to examine the opposing arguments in more detail. Gul and Pesendorfer’s views can be summarized as follows under four main points, GPI to GP4, below.

GP1. Non-choice data is inadmissible in economics because the scope of economics is restricted to inferring an individual's preferences from observed choices. Using non-choice data, such as neuroeconomic data, or self-reported survey data, or non-incentivized experimental data, is inconsistent with the scope of welfare economics. It is not entirely clear if Gul and Pesendorfer approve of data from experiments conducted under proper incentive compatibility conditions or whether experimental data may also be classified as choice data.

Welfare and choice are identical. If an individual chooses option A over B then his welfare is higher under option A. The reasons why he chose A, for instance, impulsive buying, limited attention, free will, and biological necessity, are irrelevant to economics. They write (p. 5): "The standard definition of welfare is appropriate because standard economics has no therapeutic ambition; it does not try to improve the decision-maker but tries to evaluate how economic institutions mediate (perhaps psychologically unhealthy) behavior of agents."

Non-choice data cannot be used to invalidate neoclassical economics. In particular, data from neuroeconomics has no bearing on the validity of economic models because economic models make no assumptions about the neuroeconomic foundations of choice. They write (p. 7): "Our conclusion is that the neuroeconomic critique fails to refute any particular (standard) economic model and offers no challenge to standard economic methodology."

GP2. There is a limited role for insights from psychology in economics because the two disciplines ask different questions, and have different conventions and terms. They differentiate the scope of economics and psychology by writing (p. 10): "economics and psychology do not offer competing, all-purpose models of human nature. Nor do they offer all-purpose tools. Rather, each discipline uses specialized abstractions that have proven useful for that discipline." And on p. 22 they write: "Economics and psychology differ in the question they ask. Therefore, abstractions that are useful for one discipline will typically be not very useful for the other."

GP3. Economists are not advocates for any normative criteria, even when the "right normative criterion is unambiguous" (p. 29). They give the example of Bayes' rule, which could be advocated on normative grounds, yet economists typically do not do so. They write (p. 35): "Populating economic models with 'flesh-and-blood human' beings was never the objective of economists."

GP4. Neoclassical economics is sufficiently flexible that the observed departures from the neoclassical model can be explained by modifying the neoclassical model without changing its nature. Mistakes or biases that are highlighted in behavioral economics can be accommodated within neoclassical economics by changing the feasible strategies. They give the example of American tourists in the UK who suffer injuries and fatalities because they look to the left (Bernheim and Rangel, 2004). The solution proposed by Gul and Pesendorfer (p. 23) is as follows. The action "look right" is not in the feasible set of American tourists visiting the UK. However, if they are alerted with a sign "look right" then their feasible set changes and they will indeed "look right" eliminating the supposed mistake.

These views, and others expressed in the Gul–Pesendorfer paper, are the subject of an insightful set of contributions in the edited volume by Caplin and Schotter (2008). We mostly focus on three contributions, each with a fairly instructive title: Camerer (2008) replies under the title "The case

for mindful economics.” Schotter (2008) offers the views of an experimental economist under the title “What’s so informative about choice?” Köszegi and Rabin (2008a) give their views under the title: “Revealed mistakes and revealed preference.”⁷

GP1, GP2, and GP3 are subjectively defined boundaries of economics that are extremely narrow. Indeed, great progress has been made in behavioral economics by looking beyond these boundaries. Camerer (2008, p. 44) speaks for many behavioral economists, when, commenting on GP1 and GP2, he writes: “This argument is simply a definition of economics as inherently mindless, and there is no debating a definition. The definition simply draws a preferred boundary rather than makes an evidentiary ‘case’ for mindless economics.” He continues (p. 59): “Much of GP’s paper is linguistic gerrymandering by defining economics as the revealed preference approach, then constantly reminding the reader that anything else is, by their definition, not economics.”

This leaves only GP4 as the potentially interesting argument to ponder over. In fact, this argument goes to the heart of how economists should practice their craft; for a fuller discussion, see the introductory chapter. Economists have been extremely ingenious in constructing theoretical arguments to explain empirical phenomena. Indeed, given enough freedom to make auxiliary assumptions in standard neoclassical models, one can explain almost any observed behavior. Consider, for instance, the solution suggested by Gul–Pesendorfer to the problem of mistakes made by American tourists in GP4. Their suggestion is to keep the neoclassical framework intact, but explain the observation through changes in the feasible set.

A behavioral or an experimental economist would naturally ask: “Does the data on American tourists in the UK support the proposed explanation?” Indeed, many neoclassical economists would also agree with this suggestion. However, so rapid is the pace of theoretical proposals in the neoclassical tradition to explain departures from the neoclassical model that the supply of models has outstripped the supply of diagnostic data (Camerer, 2008, p. 47). In many cases, the freedom in the use of auxiliary assumptions in neoclassical economics to explain observed departures from the model, often by invoking bogus “as if” arguments, accords well with the definition of “ad-hoc” in science.

In some places, Gul and Pesendorfer (2008) appear to protect neoclassical theories from stringent diagnostic testing by suggesting that they should not be taken literally. For instance, commenting on the Kreps–Porteus explanation of a psychological phenomenon (the details are not relevant here), they write (p. 15): “While the formula is suggestive of a mental process, this suggestiveness is an expositional device not meant to be taken literally. The formula encapsulates the behavioral assumptions of the theory in a user-friendly way and thereby facilitates applications of the theory to (more complicated) economic problems”

Among some other important responses made by Camerer (2008) to the Gul and Pesendorfer framework are the following (the details of the neuroeconomic aspects are left for Part 9).

1. Firms that introduce brand new products (or services), and regulators asked to formulate regulations for these products often cannot depend on existing choice data to predict consumer behavior. Hence, choice data, by itself, has limitations to make predictions in some domains. Yet, in actual practice, firms do introduce billions of dollars worth of new products every year after market research that is largely based on non-choice survey data of potential consumers. Yet, most economists will not argue that these economically significant decisions lie outside the scope of economics.

⁷ The reader may also wish to consult the paper by Caplin (2008) in the same volume. Since we have covered similar ground elsewhere in Parts 4 and 6, we omit a repetition of these issues here.

2. When there are several competing theories that explain given choices, then studying the neural basis of these theories can potentially help us to choose among competing theories. Unlike the assertion of Gul and Pesendorfer, important economic variables of interest such as the coefficient of relative risk aversion and loss aversion have been measured using neuroeconomic data (p. 49). The neural correlates of several economic variables, such as discount rates have been discovered (p. 49). Deception is correlated with pupil dilation (non-choice data), hence, it can be used as the basis for predicting the state of the world from a message (p. 51).
3. Economists can benefit by importing terms from psychology (and vice versa). Consider the following case study. Gul and Pesendorfer (2008) give an example of the term *cue* that they feel is unsatisfactory for economists because it lumps together two distinct phenomena: *complements* and *externalities* (e.g., fries might be the cue to eat hamburgers). Hence, they argue (pp. 11, 12): “The concept of a ‘cue’ offers a good illustration of how abstractions from psychology are inappropriate for economics and, conversely, how the corresponding economic concepts are inappropriate for psychology and neuroscience.” They suggest that economists stick to defining terms in a manner that is underpinned by their own terminology and abstractions.
Camerer (2008) argues that precisely because we do not have words in economics that describe goods/states that are complements and externality causing, importing terms such as cues is useful. He writes (p. 55): “So we could adapt the language of economics to describe ‘cues’ as ‘dynamically adaptive, rapidly reinstatable asymmetric complements to consumption’.” Or we can just learn a new vocabulary word— ‘cue’ which summarizes certain kinds of complements.”
4. Let us revisit the example of the American tourist in GP4, above. Camerer (2008) suggests, sensibly, that one can interpret the American tourist looking for cars in the UK as engaged in a *Stroop task* (see Part 7) and his mistake in looking left and crossing a road is a *Stroop mistake*.⁸ The fact that people get better at a given Stroop task with experience, i.e., commit fewer Stroop mistakes, suggests that it is not very probable that changes in the feasible set account for the mistakes of American tourists in the UK.

Schotter (2008) examines the Gul–Pesendorfer arguments from an experimental economist’s point of view. We summarize some of his arguments below.

In making their case for using choice data, Gul and Pesendorfer (2008, p. 8) argue that: “Standard economics focuses on revealed preference because economic data come in this form.” Schotter (pp. 73–74) does not dispute this claim or the importance of choice data, however, he argues that we should not make a virtue out of a constraint (that most economic data comes in this form). Indeed, all sorts of data that help us to test the predictions of economic models should be used.

Furthermore, it is worth asking if actual choice data materializes for the reasons assumed in neoclassical economics, say, the maximization of a well-defined utility function. What if choice data also arises from other considerations such as emotions, advice from friends, satisficing heuristics, simply following the herd, or any of a range of judgment heuristics described in Part 7. Choice data does not reflect the reasons for choice. So, in order to test alternative theories, say,

⁸ A Stroop task is an automatic, practiced, response by System 1 (such as looking left while crossing a road) that can be incorrect (e.g., in the UK, the American tourist must look right before crossing a road). System 2, the deliberative system, may or may not be able to rein in System 1 while it is making a Stroop mistake.

	Left	Right
Top	$x, 40$	$40, 80$
Bottom	$40, 80$	$80, 40$

Figure 22.1 A 2×2 matching pennies game.

Source: Goeree and Holt (2001) with permission from the American Economic Association.

based on emotions or psychological game theory, it might be unavoidable to use non-choice data, for instance, based on elicited beliefs.

In some cases, it might be important to discover why choices are made in order to test the predictions of the relevant theory. Consider the 2×2 matching pennies strategic form game shown in Figure 22.1 from Goeree and Holt (2001). First, suppose that $x = 80$ in the payoff matrix in Figure 22.1. In this case, there is a unique Nash equilibrium in mixed strategies in which each player randomizes equally between the two pure strategies. In their experiments, Goeree and Holt find that the players played each of their pure strategies with nearly equal probabilities, which is consistent with the Nash outcome.

Now let $x = 320$. This should leave unchanged the behavior of the row player because, in neoclassical theory, his choice of a probability distribution over his pure strategies is designed to make the opponent indifferent between his equilibrium pure strategies. Thus, in the mixed strategy equilibrium, corresponding to $x = 320$, the row player plays Top and Bottom with equal probabilities while the column player plays Left with probability $\frac{1}{8}$ and Right with probability $\frac{7}{8}$. However, in contrast to the predictions of classical game theory, row players now choose Top, 96% of the time.

When $x = 80$, the outcome is close to a Nash equilibrium, yet the choice of a Nash equilibrium is accidental in the symmetric game. A researcher who construed support for a mixed strategy Nash equilibrium based on this choice data would be misled because in the asymmetric game, the outcome differs significantly from a Nash equilibrium. It would appear that some economists view experimental data, even when subjects are properly incentivized, as non-choice data. In this strict view, only market data, say, price–quantity pairs, are admissible. Yet, if the market was like the world with $x = 80$, but almost never like the world with $x = 320$, it would not be able to refute the mixed strategy Nash equilibrium. Furthermore, this example provides a neat illustration of why experiments in economics are critical.

Another example of non-choice data is the use of *mouselab software* to infer whether the pattern of search and look ups in experiment games is consistent with backward induction; see Johnson et al. (2002) and the discussion in Part 4. The observed pattern of lookups appears to be inconsistent with backward induction. For instance, subjects search forward, not backward, and some do not even look at the information in the last stage. These results are valuable, despite the fact that economic theory makes no direct assumptions about the pattern of search and lookups. In a clever experimental design, Johnson et al. (2002) find that when subjects are trained in backward induction, they are more likely to search backwards, giving credence to their proposed method. This highlights why the experimental method must be critical to economics. Indeed, one might never be able to stringently test economic theory otherwise.

Survey data, another form of non-choice data, has provided a major impetus to progress in the rapidly expanding literature on happiness economics. This is discussed in more detail in Part 6

Table 22.1 Fraction of subjects who pay the fee in each treatment.

Situation	Fee (\$)	Probabilities		Fraction of subjects who pay fee	
		$p_l(A)$	$p_h(A)$	Treatment 1	Treatment 2
3	0.50	0.61	1	0.783	0.063
6	2.00	0.51	1	0.565	0.125
12	0.50	0.51	1	0.739	0.125

Source: Schotter (2008).

and other observations on survey data are made in the introductory chapter, so we omit a discussion here.

Actual choice data might be restricted to a subset of the parameter space, which might not allow for stringent tests of theory. We have exploited this observation above, but consider another insightful example by Schotter (2008) based on the work of Eliaz and Schotter (2010).

There are two boxes, A and B. A monetary prize is hidden in one of the boxes. The probability that the prize is hidden in box A in state $i = h, l$ is $p_i(A)$ such that $0.5 < p_l(A) < p_h(A)$. In treatment 1, there are two stages. In the first stage, the subject can pay a fee to learn the state, $i = h, l$; if no fee is paid, then the state is not learnt. In the second stage, subjects choose a box, A or B followed immediately by the payment of the prize if the correct box is chosen. In treatment 2, in the first stage, subjects choose a box, A or B. In the second stage they can pay a fee to learn the state of nature before being paid a prize if they choose the correct box.

Since $0.5 < p_l(A)$, choosing box A first order stochastically dominates choosing box B, irrespective of the state or the individual's attitudes towards risk. Thus, anyone who pays a fee has non-classical preferences. Two alternative explanations for the payment of a fee are considered. The first is the Kreps and Porteus (1978) framework that can accommodate the payment of a fee because subjects have a preference for an early resolution of uncertainty. The second explanation is the *confidence effect*; here people pay a fee just to feel happier from choosing a box that has a higher probability of a prize.

The two frameworks make different predictions. For instance, if as in Kreps–Porteus, individuals have a preference for early resolution of uncertainty, then such a preference should manifest in both treatments. However, if behavior is explained by the confidence effect, then it should have bite only in treatment 1 where subjects learn of the state before they actually make their choice of a box. The results are shown in Table 22.1 for three situations, which correspond to different combinations of the fee and the probabilities (the situation numbers, 3, 6, 12, correspond to those in Eliaz and Schotter, 2010).

Since the fraction of subjects who decide to pay the fee is so starkly different in the two treatments, the results reject the Kreps–Porteus model for the given data. Furthermore, a far higher fraction of subjects are willing to pay the fee in Treatment 1, which is consistent with the confidence effect. Suppose that the real-world choice data came only from Treatment 1, but never from Treatment 2, then choices might suggest support for the Kreps–Porteus framework. However, appropriate experimental design allows for stringent testing of theory, leading to the opposite conclusion.

Yet another reason for looking beyond choice data comes from framing effects. A pervasive finding is that choices are sensitive to framing, hence, without considering the frame, incorrect inferences are likely to be made. Consider, for instance, the well-known problem from Kahneman

and Tversky (1984) in which the same information is framed either in terms of lives saved or lives lost (see Part 7). The results demonstrated that individuals make choices consistent with risk averse behavior in the domain of gains and risk-loving behavior in the domain of losses. However, if the frame is not explicitly considered as a part of the description of the problem, one may make an incorrect inference about the risk preferences of individuals from the observed choices.

Kőszegi and Rabin (2008a) chiefly address the issue raised in GP4. They argue (p. 198) that introducing ad-hoc auxiliary assumptions in neoclassical models can produce *wacky theories* if one is not willing to entertain the possibility that individuals may make mistakes in their choices. This is particularly disturbing when more plausible, psychologically well-founded, alternatives are available. They propose a framework, developed slightly more formally in Kőszegi and Rabin (2008b), that recognizes mistakes in choices, yet attempts to recover the underlying preferences.

The supposition is that despite the propensity of people to make mistakes, there is a underlying degree of coherence to preferences. Thus, choices are not simply random and mistakes are systematic. They propose proceeding along the following lines.

1. Impose as few restrictions as possible on preferences.
2. Compare the subjective beliefs of individuals against objective probabilities. If the two tally then choices reflect welfare.
3. If subjective and objective beliefs do not tally then propose a theory in which individuals have well-defined underlying preferences but they make mistakes.

Let us consider the possibility that individuals suffer from the *gambler's fallacy* (see Part 7 for details). Suppose that an individual observes a series of coin tosses and q is her elicited belief that the next toss will produce tails (T) rather than heads (H).⁹ When no flips are observed, the individual chooses $q = 0.5$; when the sequence of consecutive flips $HHHHHH$ is observed, $q = 0.55$; when the sequence of consecutive flips $TTTTTT$ is observed, $q = 0.45$. One may, as in GP4, propose a neoclassical model in which the individual has a preference to bet on T after observing the sequence $HHHHHH$ and a preference for betting on H after observing the sequence $TTTTTT$; but this is a “wacky” set of preferences that is hard to justify. A more compelling argument is that the individual's subjective beliefs differ from the objective beliefs, and the individual makes a mistake that is consistent with the well-known gambler's fallacy.

Conditional on the assumption that the individual suffers from the gambler's fallacy, we give examples of inferences about preferences that we could draw from these choices.

Example 22.2 *Suppose that following any sequence of coin tosses, the individual is asked which of the two fruits, blueberries or strawberries, would he commit to strictly preferring, following the outcome of the next toss. When the sequence is: (i) HHHHHH, he reveals that he strictly prefers blueberries to strawberries if a T comes up on the next toss (and the converse preference if H comes up). (ii) TTTTTT, he reveals that he strictly prefers strawberries to blueberries if a T comes up on the next toss (and the converse preference if H comes up). (iii) the null sequence (no flips of the coin yet), he reveals that he is indifferent between the fruits, irrespective of the outcome on the next toss. Given that the individual exhibits the gambler's fallacy and has preferences that do not depend on coin flips, therefore, he prefers blueberries to strawberries.*

⁹ For the details of the proposed modification to the Becker–DeGroot–Marshak mechanism that may be used to produce these elicited beliefs, see Kőszegi and Rabin (2008a).

Example 22.3 Consider two individuals, classical (C) and behavioral (B). They choose one of two consumption bundles (x_h, x_t) or (y_h, y_t) . The first and the second elements in each bundle can be consumed if the next toss turns out to be, respectively, H and T. Individual C chooses (x_h, x_t) over (y_h, y_t) if

$$0.5u(x_h) + 0.5u(x_t) > 0.5u(y_h) + 0.5u(y_t). \quad (22.29)$$

Individual B chooses as follows. For the null history (no observed flips) B chooses in accordance with (22.29). If the history is HHHHHH, then (x_h, x_t) is chosen over (y_h, y_t) if

$$0.45u(x_h) + 0.55u(x_t) > 0.45u(y_h) + 0.55u(y_t). \quad (22.30)$$

Finally, if the history is TTTTTT, then B chooses (x_h, x_t) over (y_h, y_t) if

$$0.55u(x_h) + 0.45u(x_t) > 0.55u(y_h) + 0.45u(y_t). \quad (22.31)$$

The behavior of individual C is unproblematic for neoclassical economics. Following GP4, if one stays within the neoclassical framework, then one will need to invoke ad-hoc auxiliary assumptions to explain the choices of individual B, interpreted now as a classical individual. For instance, one could postulate that the individual has a preference for betting on changes in coin flips. However, because the classical individual does know and use objective probabilities (see (22.29)), such wacky preferences will lose money for the individual.

A simpler explanation is that individual B is not a classical individual and suffers from the gambler's fallacy. Indeed, we can identify the preferences of B from the choice data. Such an individual is an expected utility maximizer who suffers from the gambler's fallacy. In an apparent response to the Gul–Pesendorfer framework, Köszegi and Rabin (2008a) write (p. 201):¹⁰ “We admit to not really understanding why we would at all be inclined to ban the study of B from economics departments, but we are especially chagrined at that prospect in light of the fact that we can use the same powerful tools of economics to study B as C in this case. B has well-ordered and coherent preferences. She is making an error in statistical reasoning. The two can be jointly identified. It is useful to do so.”

Example 22.4 There is one caveat to the explanation in Example 22.3. Choice behavior may indicate a mistake. However, there could be more than one competing explanation for the mistake, and the welfare implications are dependent on the chosen explanation. Consider an experiment in which pregnant women are asked, prior to going into labor, if they would ask for an epidural injection during childbirth. Suppose that most women choose natural childbirth, yet when they go into labor, they change their mind and ask for an epidural injection.

One potential explanation of this empirically observed phenomenon is projection-bias (see Part 6) in which pregnant women underappreciate how painful their labor will be. A second explanation is hyperbolic discounting in which the present bias at the time of labor tips the scales in favor of the epidural. There is no role for commitment under projection bias. Indeed, the decision to take an epidural at the time of labor is the welfare maximizing choice for the individual. However, if the source of the mistake is hyperbolic discounting, then the individual might find it optimal to invest in a commitment technology to bind herself to the original, ex-ante, choice. In this case, one will need extra information to determine which of the two explanations is the correct one.

¹⁰ In the quote we have replaced Fiona with individual B and Giles with individual C from the original quote.

22.6 Choice-based behavioral welfare economics

In this section, we consider the choice-based measure of welfare of Bernheim and Rangel (2007, 2009); the basic rationale is discussed in Section 22.3.6.

In neoclassical economics, one may proceed with standard welfare analysis in one of two possible ways. One can either specify preferences and then derive a *choice function* from it. Alternatively, one can directly specify a choice function and then derive the corresponding preferences. The two methods are equivalent; for a lucid account see Chapter 2 in Kreps (1990). Bernheim and Rangel choose the second method, i.e., begin with a choice function and then derive implications for preferences.

Suppose that X is the set of all possible choice objects. Choice objects are not restricted, so these could, for instance, be consumption bundles, or lotteries of dated profiles of intertemporal consumption. Denote the constraint set by $X \subseteq \mathbf{X}$. The general nature of the choice set allows this framework to address static and dynamic problems under risk. An ancillary condition, A , is any set of environment conditions such as default options, status quo, anchors or other framing conditions that are not relevant to the evaluation of an individual's welfare by a social planner.

Define a *generalized choice situation* (GCS) by $g = (X, A)$. Suppose that the individual must choose from n different GCSs: $(X_1, A_1), \dots, (X_n, A_n)$. These can be collapsed into a single GCS, $g' = (X', A')$ where $X' = \bigcup_{j=1}^n X_j$ and A' specifies how the choice is to be made from the n different GCSs. Denote by G^* , the universal set of all GCSs allowed by a theory; thus, G^* is theory-specific. For instance, anchors or defaults might play no role in some theories but play a central role in others. Let $G \subseteq G^*$ be a trimmed-down universal set that contains all the *welfare relevant* GCSs; G is the *welfare relevant domain* for normative analysis in which choices reveal “true objectives” of the decision maker. We discuss the issue of specifying G later.

Next, we define a choice correspondence that maps any GCS into a set of choice objects.

Definition 22.4 (*Choice correspondence*): A choice correspondence is defined as $C : G^* \rightarrow \mathbf{X}$ and $C(g) \subseteq X$ for all $g = (X, A) \in G^*$.

We now define the set of all constraint sets, X , such that for some ancillary condition, A , the resulting GCS, (X, A) is in the welfare relevant domain, i.e.,

$$\chi = \{X : \exists A \text{ such that } (X, A) \in G\}. \quad (22.32)$$

The following two assumptions are needed to make further progress.

A1: Every nonempty finite subset of $\mathbf{X}$ is a member of the set χ , defined in (22.32).

A2: $C(g)$ (see Definition 22.4) is nonempty for all $g \in G$.

The assumptions made so far allow for intransitive choices, and choices that are influenced by irrelevant alternatives or context. The constraint sets are not required to be compact. In conjunction with the general nature of choice objects, this framework allows a very wide range of questions to be asked.

Example 22.5 (*The cafeteria problem; Sunstein and Thaler, 2003; Thaler and Sunstein, 2003*): Consider the cafeteria example from Section 22.3.1. Suppose that there are only two choice objects: healthy snacks, h , and unhealthy snacks, u , so $\mathbf{X} = \{h, u\}$ and $X = \{h, u\}$; from

assumption A2, choices from singleton sets are trivial, hence, we suppress them. The ancillary condition specifies which object is placed at eye level where it is more salient. Let the ancillary conditions A_1 and A_2 denote, respectively, healthy and unhealthy snacks placed at eye level. Let $g_1 = (\{h, u\}, A_1)$, $g_2 = (\{h, u\}, A_2)$, then the universal set of all GCSs is (also recall that singleton choice sets are suppressed)

$$G^* = \{g_1, g_2\}.$$

Suppose that the welfare relevant domain is defined to be the one where the healthy snacks are always placed at eye level, so

$$G = \{g_1\}.$$

Using (22.32),

$$\chi = \{\{h, u\}, \{h\}, \{u\}\}.$$

Suppose that the choice correspondence is defined by

$$C(g_1) = \{h\}, C(g_2) = \{u\}. \quad (22.33)$$

The non-empty subsets of X are $\{h, u\}$, $\{h\}$ and $\{u\}$ and all three sets are in χ so assumption A1 is satisfied. Furthermore, from (22.33), assumption A2 is also satisfied (note that we have suppressed singleton sets in (22.33)).

Example 22.6 (Time inconsistency): Consider an example motivated by time inconsistency of preferences, say, due to hyperbolic discounting. Suppose that $X = \{x, y\}$, where x and y are time t payoffs. Two ancillary conditions, A_1 , A_2 , respectively, denote choices made at time $t - 1$ and time t , respectively. Thus, $g_1 = (\{x, y\}, A_1)$, $g_2 = (\{x, y\}, A_2)$ and $G^* = \{g_1, g_2\}$. The generalized choice problem g_1 specifies the choice set from which the choice is made at time $t - 1$; g_1 plays the corresponding role at time t . Suppose that the choices of the individual are

$$C(g_1) = \{x\}, C(g_2) = \{y\}. \quad (22.34)$$

Thus, the decision maker reveals preference reversals in dated choices. Since choice-based measures can only rely on the choices made, thus, the choices in (22.34) provide conflicting guidance to the planner. One way out for the planner is to treat the welfare relevant domain either as $G = \{g_1\}$ or $G = \{g_2\}$. In this case, inconsistent choices are trimmed away. But which of the two welfare relevant domains should the planner choose?

This aspect of the framework has been criticized by Sugden (2008) and Loewenstein and Haisley (2008). Clearly, one is then forced to rely on non-choice data to discover the welfare relevant domain. But if some welfare criteria has to be employed by the planner to resolve this problem, then we are back to square one. One suggestion by Bernheim and Rangel (2009) is to use neuroeconomic data to see which of the two choices really reflects the individual's welfare. Whether advances in neuroeconomics will allow us to do so is an open question.

Let us now develop the analogs of the neoclassical weak and strong choice relations. We restrict ourselves to the welfare relevant domain, G , ignoring questions about how it might have been discovered, or whether it could ever be discovered.

Definition 22.5 (Weak unambiguous choice): Let $x, y \in X$ and let G be the welfare relevant domain.

(a) We say that x is “weakly unambiguously chosen” over y , written xRy , if

For all $(X, A) \in G$ and $x, y \in X$, if $y \in C(X, A)$ then $x \in C(X, A)$.

(b) Let P denote the asymmetric component of R , so

$$xPy \Leftrightarrow xRy \text{ but not } yRx.$$

(c) Let I denote the symmetric component of R , so

$$xIy \Leftrightarrow xRy \text{ and } yRx.$$

This means that whenever x is chosen, y is also chosen and vice versa.

Example 22.7 Let $X_1 = \{x, y\}$, $X_2 = \{y, z\}$, $X_3 = \{x, z\}$, $X_4 = \{x, y, z\}$, $X_5 = \{x\}$, $X_6 = \{y\}$, $X_7 = \{z\}$ and $\chi = \{X_1, \dots, X_7\}$. We ignore the singleton sets X_5, X_6, X_7 because the choice from these sets is trivial, given assumption A2. Suppose that we observe the following choices for all ancillary conditions, A_i , $i = 1, 2, \dots, n$

$$C(X_1, A_i) = \{x\}, C(X_2, A_i) = \{y\}, C(X_3, A_i) = \{z\}, C(X_4, A_i) = \{x, y\} \quad (22.35)$$

Given (22.35), we can conclude that xRy . But yRx does not hold because in the set X_1 , x is chosen but y is not. Hence, xPy .

Definition 22.6 (Strict unambiguous choice): Let $x, y \in X$ and let G be the welfare relevant domain. We say that x is “strictly unambiguously chosen” over y , written xP^*y , if

For all $(X, A) \in G$ and $x, y \in X$, $y \notin C(X, A)$.

Since the choice set is non-empty (assumption A2), thus, when $X = \{x, y\}$ then x is chosen but y is not. In general, whenever x and y are available in any constraint set then y is never chosen.

Example 22.8 (Example 22.7 continued . . .): From (22.35), we cannot conclude that xP^*y because in the set X_4 , both x, y are available, yet y is also chosen. If instead $C(X_4, A_i)$ was $\{x\}$, or $\{z\}$, or $\{x, z\}$, then we have xP^*y . Suppose that $C(X_4, A_i) = \{x\}$, while the choices in all other cases are given by (22.35). In this case, we have xPy and xP^*y , thus, P and P^* coincide

Definitions 22.5 and 22.6 get around the problem of human choice that is coherent but not well behaved in the sense of being intransitive, or influenced by irrelevant contexts or alternatives. However, they do not get around the problem where decision makers appear to act against their own interest such as not making full use of 401(k) plans, addictions, and low aspirations; see Dalton and Ghosal (2016) for some progress in this direction.

Whenever $C(X, A)$ is unique for each $(X, A) \in G$ then P (Definition 22.5) and P^* (Definition 22.6) coincide (see Example 22.8). Otherwise they can differ. For several binary relations, P^* is the asymmetric part, as, for instance, is the case in the next definition.

Definition 22.7 For all $(X, A) \in G$ and for all $x, y \in X$ the binary preference relation, R^* , on G is defined as follows

$$xR^*y \Leftrightarrow \text{not } yP^*x,$$

i.e., y is never strictly unambiguously chosen over x . So there exists some GCS such that x and y are available and x is chosen. Similarly, one may define the indifference relation I^* as follows

$$xI^*y \Leftrightarrow xR^*y \text{ and } yR^*x,$$

i.e., there is some GCS for which x is chosen when y is available and another for which y is chosen when x is available.

In the absence of ancillary conditions, the binary relations (1) R and R^* are equivalent to the standard weak revealed preference relation in neoclassical economics, and (2) P and P^* are equivalent to the standard strong revealed preference relation in neoclassical economics. Thus, the neoclassical case is subsumed within this framework.

Proposition 22.3 (Bernheim and Rangel, 2009): For all $(X, A) \in G$ and for all $x, y \in X$, we have

$$xP^*y \Rightarrow xPy \Rightarrow xRy \Rightarrow xR^*y,$$

so P^* is the coarsest and R^* the finest of these binary relations.

Example 22.9 (Intransitivity of P^* and incompleteness of R): Let $X_1 = \{a, b\}$, $X_2 = \{b, c\}$, $X_3 = \{a, c\}$, $X_4 = \{a, b, c\}$, $X_5 = \{a\}$, $X_6 = \{b\}$, $X_7 = \{c\}$, and $\chi = \{X_1, \dots, X_7\}$. There are no ancillary conditions, so the welfare relevant domain comprises the sets $X_1, \dots, X_7$. The choices are given by (choices are trivial for singleton sets so these are not listed):

$$C(X_1) = \{a\}, C(X_2) = \{b\}, C(X_3) = \{c\}, C(X_4) = \{a\}. \quad (22.36)$$

In choice sets X_1 and X_4 , the options a and b are available but b is never chosen, while a is chosen from both choice sets, so aP^*b . In choice sets X_2 and X_4 , options b and c are available yet c is never chosen and b is chosen once, so bP^*c . In contrast, consider choice sets X_3 and X_4 where options a and c are present. Option c is chosen from X_3 and option a is chosen from X_4 . Thus, we have both cases $\sim aP^*b$ and $\sim bP^*a$, so using Definition 22.7, we have aI^*b . Thus, P^* is intransitive. From (22.36) we neither have aRc nor cRa so R is incomplete.

Example 22.10 (Incompleteness of R when the ancillary condition varies): Consider two GCSs (X, A) , $(X, A') \in G$ where $X = \{x, y\}$. Suppose that we have the following choices

$$C(\{x, y\}, A) = \{x\} \text{ and } C(\{x, y\}, A') = \{y\}.$$

The second choice prevents xRy and the first choice prevents yRx . Thus, R is not complete in this case. In contrast, R^* is always complete.

While Example 22.9 shows that P^* is intransitive, none of the binary relations defined so far need to be transitive. The next example illustrates intransitivity of P ; an exercise asks you to show that R^* is intransitive.

Example 22.11 (Intransitivity of P and R): Consider the setup in Example 22.9 but replace (22.36) by the following choices

$$C(X_1) = \{a\}, C(X_2) = \{b\}, C(X_3) = \{c\}, C(X_4) = \{a, b, c\}.$$

We have aRb but not bRa , so using Definition 22.5 we have aPb . We can analogously check that bPc . But we do not have aRc so it is not the case that aPc . Thus P is intransitive. R is also intransitive because aRb and bRc but not aRc .

Intransitivity does not prevent a welfare analysis. If a preference relation on a finite set is acyclic then a maximal element exists. The binary relation P^* is acyclic, as shown in the next proposition, however, P need not be acyclic.

Proposition 22.4 (Bernheim and Rangel, 2009):

- (a) Consider outcomes $x_1, \dots, x_N$ such that $x_1Rx_2, \dots, x_{N-1}Rx_N$ and for some $1 \leq k \leq N-1$ we have $x_kP^*x_{k+1}$. Then $\sim x_NRx_1$.
- (b) P^* is acyclic, so for outcomes $x_1, \dots, x_N$ such that $x_1P^*x_2, \dots, x_{N-1}P^*x_N$ we have $\sim x_NP^*x_1$.

Next we give the welfare criteria for improving choices.

Definition 22.8 (Welfare improvement):

- (a) (Strict welfare improvement): Given any choice $x \in X$ we can “strictly improve” upon the choice if there exists some $y \in X$ such that yP^*x . When a strict improvement is impossible then x is a weak individual welfare optimum.
- (b) (Weak welfare improvement):
Given any choice $x \in X$ we can “weakly improve” upon the choice if there exists some $y \in X$ such that yPx . When a weak improvement is impossible then x is a strict individual welfare optimum.

The following proposition is an implication of Definition 22.8.

Proposition 22.5

- (a) If $x \in C(X, A)$ for any $(X, A) \in G$ then it is a “weak individual welfare optimum” in X . If $x \in C(X, A)$ is unique then it is a strict welfare optimum.
- (b) x is a weak welfare optimum in X if and only if for each $y \in X$ such that $y \neq x$ there is some GCS (X', A') in which x is chosen when y is available (although y might be chosen as well).

Proof: (a) Since $x \in C(X, A)$ there does not exist any $y \in X$ such that yP^*x . Hence, it is not possible to strictly improve on x , so x is a “weak individual welfare optimum” in X . If x is unique then there does not exist any element y such that yPx . Thus, a weak improvement is impossible, which implies that x is a strict welfare optimum.

(b) Since there exists some GCS (X', A') in which x is chosen when y is available, we cannot have yP^*x . Thus, we cannot strictly improve welfare starting from x , so x is a weak welfare optimum. ■

Choice sets are non-empty (assumption A2), thus there always exist some $x \in C(X, A)$. Hence, from Proposition 22.5(a), a weak individual welfare optimum always exists within any X such that $(X, A) \in G$. This is the sense in which the welfare criteria respects individual liberty because, by definition, x is voluntarily chosen. Thus, within any welfare relevant domain, G , it is not possible

to improve upon individual decisions by a third party. This is not the case when we choose the universal domain of GCSs, G^* . But this is precisely the role of the choice architect under soft paternalism: to trim down the universal domain of GCSs to the welfare relevant domain. Indeed, no assumptions such as continuity and compactness are needed for this result because of our assumption of well-behaved choice correspondences.

Example 22.12 *Let us revisit Example 22.9. The choices are given in (22.36), which give rise to an intransitive P^* . In the set X_4 , a is the unique choice element, so it is a strict welfare optimum (Proposition 22.5a) in X_4 while b and c are not even weak welfare optima in X_4 . Also using Proposition 22.5a, in set X_1 , b is not a weak welfare optimum and in set X_2 , c is not a weak welfare optimum.*

In set X_3 , where the unique choice is c we cannot conclude that it is the only strict welfare optimum. The reason is that since $C(X_4) = \{a\}$ when c is available, so we cannot compare a and c under P^* . Indeed we cannot affect a weak welfare improvement starting from a or c because neither aPc (c is chosen in X_3 when a is available) nor cPa (a is chosen in X_4 when c is available). Since weak improvements are not possible, thus, both a and c are strict welfare optima in the set X_3 although only c is chosen.

Different ancillary conditions may produce conflicting choices, so much so that it becomes difficult or impossible to identify weak or strong unambiguous welfare improvements. Exercise 7 illustrates this problem. On the other hand, the framework potentially solves some empirical puzzles as the next example shows.

Example 22.13 *(Iyengar and Lepper, 2000; Bernheim and Rangel, 2009) Suppose that the potential options are 29 different brands of jams; the 30th option is “choose nothing.” The welfare relevant domain contains all pairs of 30 options and the entire set of 30 options but no other combinations of options. There are no ancillary conditions. In any pairwise comparison, strawberry jam (say option x) is preferred to any other jam. However, when asked to choose among all 30 alternatives in one go, the individual chooses the 30th option, i.e., choose nothing (say, option y). In the Bernheim–Rangel framework this is not problematic. Let us start with x . We cannot find any other option, say, z such that zP^*x . Thus, a strict improvement over x is impossible and it is a weak individual welfare optimum. x is not chosen when all 30 options are presented but option y is chosen. Yet, it is not the case that yP^*x . Nor is it the case that xP^*y (although xP^*z and yP^*z for all other options z). Thus, both x and y are weak individual welfare optimum.*

In Example 22.13, if one restricted the welfare relevant domain to only all pairwise comparisons of the options, but do not allow all options to be presented together, then we do get a unique choice, x . However truncating in this manner can lead to cyclicity of P^* as shown in the next example.

Example 22.14 *Consider the setup of Example 22.9 but restrict the welfare relevant domain to $X_1 = \{a, b\}$, $X_2 = \{b, c\}$, $X_3 = \{a, c\}$, leaving out $X_4 = \{a, b, c\}$. This violates assumption A1 because $G = \{X_1, X_2, X_3\}$ does not contain all finite subsets of the options a , b , and c . Hence, Proposition 22.4 need not apply. Indeed this is the case because P^* cycles: aP^*b (whenever a and b are present in a set, b is never chosen); bP^*c (whenever b and c are present, c is never chosen); cP^*a (whenever a and c are present, a is never chosen). This intransitivity of P^* makes it difficult to figure out what the choice would be (normative or positive) in the set X_4 ; each of a , b , and c is improvable.*

We can relate the binary choice relations P and P^* to traditional measures of welfare improvement such as Pareto optimality in the following *multi-selves interpretation*. Suppose that the welfare relevant domain G is *rectangular*, i.e., $G = \chi \times \Gamma$ where Γ is the set of all ancillary conditions. Suppose that each ancillary condition corresponds to a different self of the same individual and for each ancillary condition $A \in \Gamma$ the individual maximizes a utility function u_A ; thus, preferences are well behaved for each ancillary condition. We now apply the Pareto criteria across the different selves of the individual.

Definition 22.9 (*Multiself Pareto dominance*): Let $y \in X$ for some X in χ .

- (a) x “weakly multiself Pareto dominates” y , written xMy , if $u_A(x) \geq u_A(y)$ for all $A \in \Gamma$.
- (b) x “strongly multiself Pareto dominates” y , written xM^*y , if $u_A(x) > u_A(y)$ for all $A \in \Gamma$.
- (c) $x \in X$ is a weak multiself Pareto optimum if there is no $y \in X$ such that yM^*x .
- (d) $x \in X$ is a strong multiself Pareto optimum if there is no $y \in X$ such that yMx .

The criteria proposed in Definition 22.9 are quite strong. For instance, a typical behavioral finding is that the choice made by an individual often changes with framing effects, which corresponds here to changes in ancillary conditions. However, the multiself Pareto criteria requires that we do not get reversal of rankings when framing changes.

The next proposition establishes the link between multiself Pareto dominance and the relations P and P^* .

Proposition 22.6 (*Bernheim and Rangel, 2009*): Suppose that G is rectangular, and each $A \in \Gamma$ activates a different multiself of the same individual. Assume that for each $A \in \Gamma$, preferences are well behaved, so we can imagine that the self corresponding to $A \in \Gamma$ maximizes a utility function u_A . Then $M^* = P^*$ and $M = P$.

Proposition 22.6 implies that saying $x \in X$ is a weak (strong) multiself Pareto optimum is equivalent to saying that $x \in X$ is a weak (strong) individual welfare optimum.

The main difficulty in operationalizing this choice-based proposal is to specify the welfare relevant domain and to deal with cases where the welfare criterion is not very helpful in narrowing down choice or choice is cyclic (as in Example 22.14). Indeed, one might need to invoke another normative criterion in this case, or use non-choice data such as data from neuroeconomics. Bernheim and Rangel (2009) make other suggestions too. For instance, one might appeal to other principles such as *preponderance* (p. 89); thus, if a decision maker typically chooses x over y but rarely y over x then the rare exceptions should be ignored.

These comments illustrate two things. First, not everyone will find the choice-based approach to be utterly persuasive. Second, there are severe difficulties in making progress with a choice-based approach even when the choice-based approach is stretched to its limits. Indeed, the choice-based approach has been criticized on these grounds and alternatives have been proposed. For instance, Sugden (2013) proposes a contractarian approach (see Section 22.8 below) and Loewenstein and Haisley (2008) advocate welfare criteria based on preferences rather than choice. Cason and Plott (2014) show that subject misconceptions in choice problems provide poor guidance to their underlying preferences, even in relatively simple problems. Choi et al. (2014) find considerable heterogeneity among individuals in their decision making quality/ability and consistency with utility maximization. Relatively poorer decision making quality associated with lower wealth and lower educational attainment, produces choices that have lower consistency with utility maximization.

For an extension of the Bernheim–Rangel framework to an interpersonally comparable concept of well-being and the development of criteria for policy evaluation, see Fleurbaey and Schokkaert (2013). For a survey of alternative measures of GDP in the presence of interpersonal comparisons, see Fleurbaey and Blanchet (2013). Rubinstein and Salant (2008) have independently developed a choice-based framework in which the ancillary conditions in the Bernheim–Rangel framework are called *frames*. They also develop binary relations similar to P and P^* . Manzini and Mariotti (2014) give a useful discussion of the relative merits of the model-free approach, e.g., the Bernheim–Rangel framework, and the model-based approach, e.g., Masatlioglu et al. (2012) (see Section 22.7 below).

Rubinstein and Salant (2012) depart from the Bernheim–Rangel framework by giving up the choice between alternatives based on the Pareto criterion. Their argument is that as the behavioral data grows, the ability of the Pareto criterion to rank alternatives, shrinks. They propose a welfare ranking of any two alternatives even when one alternative does not Pareto dominate the other alternative. Rather than postulate that inconsistent behavior arises by changes in, say, frames, their model supposes that individuals have more than one preference ordering. Inconsistent choices arise because the individual switches between the preference orderings while making different choices.

22.7 Revealed preference under limited attention

So far, we have assumed that individuals pay attention to all alternatives. In contrast, the evidence supports *limited attention* to alternatives in many domains (see Part 7). In this section, we consider the welfare implications of limited attention using the model of Masatlioglu et al. (2012), who also give the following useful taxonomy of limited attention, to which their framework can be applied.

1. *Choose the top N* : Examples include choosing from among the N cheapest suppliers and ignoring the rest; considering only the N most advertised products; and considering only the products advertised on the first page of results from a search engine.
2. *Top on each criteria*: One may sequentially choose among criteria (Manzini and Mariotti, 2007, 2012). For instance, a potential buyer of a car may narrow down his choices by first choosing the safest car, then choosing the most fuel efficient car from the narrower set, and then the cheapest car from the even narrower set.
3. *Most popular category*: A potential buyer of a bike might first check online the shop that offers the largest variety of bikes and then visit it to buy the bike, ignoring all other bike shops.

The proposed framework has three stages. In the first stage, the decision maker chooses to narrow down the set of alternatives to those that he desires to pay attention to, or he may simply be unaware of the existence of some alternatives. In the second stage, he has a complete and transitive preference ordering over the remaining alternatives. In the third stage, we examine the welfare implications of the first two stages.

The Bernheim–Rangel approach described in Section 22.6 is model-free because the choice function is the primitive and any choice procedure that generates the stated choices is consistent with the model. In contrast, the approach under limited attention specifies a particular choice procedure that relies on limited attention, so it is not model-free. In the Bernheim–Rangel approach, x is unambiguously preferred over y when y is never chosen if x is available (Definition 22.6). Under limited attention, by contrast, the decision maker might sometimes not pay

attention to x , resulting in a choice of y . We shall see an example below where the two criteria are in conflict.

We now develop the formal model. Suppose that X is a finite set of alternatives and χ is the set of all non-empty subsets (or feasible sets) of X . Suppose that the decision maker faces the set $S \in \chi$ of alternatives. The decision maker gives attention to a non-empty subset $\Gamma(S)$ of elements in S , known as the *consideration set*.

Definition 22.10 (*Consideration set mapping*): $\Gamma : \chi \rightarrow \chi$ is a consideration set mapping such that for all $S \in \chi$, $\Gamma(S) \neq \emptyset$ and $\Gamma(S) \subset S$.

If the decision maker is in the market for a new car, then S is the set of all models of all cars sold in the country where he lives. Suppose that the decision maker pays attention to a subset $\Gamma(S)$ of the cars. Consider a model of car $x \notin \Gamma(S)$ but $x \in S$. It is quite possible that the decision maker is unaware of the existence of all models in the set $S \setminus \Gamma(S)$. If now the decision maker were to face the set $S \setminus x$ then it is reasonable to assume that his consideration set would not change, so that $\Gamma(S) = \Gamma(S \setminus x)$. In other words, the decision maker is unaware that he is unaware of all the alternatives. This motivates the next definition

Definition 22.11 (*Attention filter*): A consideration set mapping is an attention filter if for any S , if $x \notin \Gamma(S)$ but $x \in S$ then $\Gamma(S) = \Gamma(S \setminus x)$.

We shall assume that the underlying preferences, $\succ$, on X are complete and transitive and the decision maker chooses a unique best element in each consideration set. We denote $\succ$ by P .

Definition 22.12 (*Choice function*): A choice function $c : \chi \rightarrow \chi$ assigns to each element of the feasible set, $S \in \chi$, a unique element $c(S) \in S$.

Definition 22.13 (*Choice with limited attention, CLA*): A choice function c is a choice with limited attention (CLA) if $\exists$ a complete transitive preference $\succ$ over X and an attention filter Γ such that $c(S)$ is the $\succ$ best element in $\Gamma(S)$.

The preferences of the decision maker $\succ$ and the attention filter used by the decision maker are not observable to a third party. Yet, we show below, that from the observed choices we can infer preferences and the attention filter used.

Example 22.15 Let $X = \{x, y, z\}$, so $\chi = \{\{x, y, z\}, \{x, y\}, \{y, z\}, \{x, z\}\}$; we omit the singleton sets that have a trivial choice. Suppose that the choice function is given by

$$c(x, y, z) = x, c(x, y) = x, c(y, z) = y, c(x, z) = z. \quad (22.37)$$

Two possible preferences, $\succ_1$ and $\succ_2$, along with the corresponding attention filters, Γ_1 and Γ_2 , are given in Figure 22.2. The reader is invited to check that Γ_1 and Γ_2 satisfy Definition

Preference		Attention filter			
		$\{x, y, z\}$	$\{x, y\}$	$\{y, z\}$	$\{x, z\}$
$z \succ_1 x \succ_1 y$	Γ_1	xy	xy	y	xz
$x \succ_2 y \succ_2 z$	Γ_2	xyz	xy	yz	z

Figure 22.2 Two possible preferences, $\succ_1$ and $\succ_2$, along with the corresponding attention filters, Γ_1 and Γ_2 .

Source: Masatlioglu et al. (2012) with permission from the American Economic Association.

22.11. Γ_2 gives full attention to all elements of all subsets of χ except $\{x, z\}$ where it ignores the element x . Γ_1 gives full attention to the sets $\{x, y\}$ and $\{x, z\}$ but limited attention to the sets $\{x, y, z\}$ and $\{y, z\}$.

The reader can easily confirm that given the attention filters, Γ_1 and Γ_2 , the preferences, $z \succ_1 x \succ_1 y$ and $x \succ_2 y \succ_2 z$, are entirely consistent with the choices given in (22.37). Yet we cannot observe either the attention filters or the preferences of the individual. However, suppose that we could discover somehow that $\succ_1$ and $\succ_2$ are the only two pairs of preferences that the decision maker could have. Then, it can be shown that the individual prefers x to y on the following grounds. The decision maker gives attention to both x and y under both attention filters, whenever x and y are available in any set in χ . However, x is always chosen when both x and y are available (see (22.37)).

The observations in Example 22.15 give rise to the next definition, which is based on a fairly conservative criterion of unanimity among all pairs of preferences and attention filters. Requiring unanimity has the advantage that the criterion is not controversial, but the disadvantage is that it limits the domain of applicability of the criterion.

Definition 22.14 Suppose that c is a CLA (Definition 22.13) and there are k different pairs of preferences and attention filters that can represent the stated choices, given by $(\Gamma_1, \succ_1)$, $(\Gamma_2, \succ_2), \dots, (\Gamma_k, \succ_k)$.¹¹ Then

- (a) x is revealed preferred to y if $x \succ_i y$ for $i = 1, \dots, k$.
- (b) x is revealed to attract attention at S if $x \in \Gamma_i(S)$ for $i = 1, \dots, k$.
- (c) x is revealed not to attract attention at S if $x \notin \Gamma_i(S)$ for $i = 1, \dots, k$.

Determining revealed preference and revealed attention/inattention can get cumbersome for large k . However, there is a simpler method that we turn to.

Consider Example 22.15 and compare the two sets $S = \{x, y, z\}$ and $S' = \{x, z\}$. From (22.37), the choices given by $c(x, y, z) = x$, and $c(x, z) = z$ reveal a choice reversal. If the decision maker paid attention to x and z in both sets, then we should not expect a choice reversal. A plausible suggestion is that the removal of y from S alters the attention set; thus, the decision maker must have paid attention to y in the set S (revealed attention). If this reasoning is accepted, then the presence of y induces the decision maker to pay attention to x in the set S and the absence of y from the set S' draws attention away from x , which explains the choice $c(x, z) = z$. Since the decision maker pays attention to x and y in the set S yet chooses x we say that x is revealed preferred to y .

More generally, if the choice changes upon removing an alternative, then the originally chosen alternative is preferred to the alternative that is removed. We can formally state the general idea as follows.

Definition 22.15 Let $x, y \in X$ be two distinct elements. Then xPy (x is revealed preferred to y) if there exists a set $S \in \chi$ such that $c(S) = x$ but $x \notin c(S \setminus y)$.

The preference relation $\succ$ on X is transitive. Thus, we if discover that xPy and yPz , then it follows that xPz although x is not directly revealed preferred from the individual's choices. Denote by P_R , the transitive closure of P . The transitive closure of a binary relation P on a set X is the minimal transitive relation P_R on X that contains P . Thus, $x_1 P_R x_n$ if there exist $x_1, \dots, x_n \in X$ and we have $x_j P x_{j+1}$ for $1 \leq j \leq n - 1$. The next proposition directly follows from these observations.

¹¹ For instance, in Example 22.15, $k = 2$.

Proposition 22.7 (Revealed preference; Masatlioglu et al., 2012): Suppose that c is a CLA. For $x, y \in X$, x is revealed preferred to y if and only if xP_{RY} .

In the next example we see how the predictions of this model differ from the Bernheim–Rangel framework.

Example 22.16 Consider a supermarket that displays four products x, y, z, t , each packed in a box. All four products need not be available at all times. The products can be displayed in two aisles, using the following five rules:

- (1) Each aisle can carry no more than two products because the supermarket manager has determined that it would otherwise overload customers' cognitive abilities. Furthermore, none of the aisles contains only one product unless the supermarket runs out of all remaining products.
- (2) x and y come packed in big boxes, which cannot be stored in the same aisle.
- (3) Since the first aisle is more visible to customers, the supermarket fills it first before any products are placed in the second aisle.
- (4) Due to an exclusive agreement with the manufacturers of products y and z , these products are placed in the first aisle whenever they are available.
- (5) The firm deems product t to be the least popular, so it is placed in the first aisle only if there is space remaining in the aisle after displaying the remaining available products.

Suppose that a customer has privately known preferences

$$t \succ x \succ z \succ y. \quad (22.38)$$

His choice is determined as follows: He visits the first aisle and picks his most preferred item; due to limited attention he never visits the second aisle. Let us separately consider the inferences drawn in the Bernheim–Rangel approach and the CLA approach.

I. Bernheim–Rangel approach: Suppose that products x and y are available. From rules 2 and 4, if y is available, then x is never placed in the first aisle. Suppose that x is placed in the second aisle. Since the customer only explores the first aisle due to limited attention, hence, x never gets chosen by the customer. In the terminology of Bernheim–Rangel, yP^*x , yet the individual prefers x to y , i.e., $x \succ y$. Thus, under limited attention, the Bernheim–Rangel criteria is not suitable; indeed it was never designed for limited attention.

II. The CLA approach: The five rules, given above, suggest that the consideration sets are given by

$$\Gamma(xyzt) = \{y, z\}, \Gamma(xzt) = \{x, z\}, \Gamma(xyt) = \{y, t\}, \Gamma(yzt) = \{y, z\}, \Gamma(xyz) = \{y, z\},$$

and when any two products remain we have $\Gamma(ab) = \{a, b\}$ for all $a, b \in \{x, y, z, t\}$. Suppose all four products are available. Then, by rules 2 and 4, y and z are placed in the first aisle and x and t in the second aisle. The individual picks z from the first aisle because $z \succ y$. Once y is unavailable then x is moved to the first aisle; since $x \succ z$, x is now chosen. Suppose that z is sold out. Then t is placed in the first aisle. Given $t \succ x$, the customer then chooses t . In summary the choices are

$$c(xyzt) = z, c(xzt) = x, c(xt) = t.$$

The choice data, if available, correctly identifies the underlying preferences in (22.38).

If removing an option from a set causes a choice reversal then the decision maker must have been paying attention to the removed object (Definition 22.13). It is also possible to determine attention even if no choice reversals take place, as shown in the following example.

Example 22.17 Suppose that a decision maker chooses y from sets S and T . Removing x from T causes a choice reversal, so the decision maker must have been paying attention to x , i.e., $x \in \Gamma(T)$. Suppose that we now consider elements in the set $A = S \cup T \setminus S \cap T$ and suppose that all of these are revealed preferred to y . Then it must be the case that elements in the set A were not under consideration when y was chosen, i.e., did not belong to $\Gamma(S)$ and $\Gamma(T)$. But then removing these elements from S and T will not change the consideration set, so

$$\Gamma(S) = \Gamma(S \cap T) = \Gamma(T). \quad (22.39)$$

Since $x \in \Gamma(T)$, (22.39) implies that $x \in \Gamma(S)$. Thus, we can infer which elements belong to $\Gamma(S)$ without actually looking for choice reversals from the set S . The next proposition formalizes these ideas about revealed inattention (recall that P_R is the transitive closure of P).

Proposition 22.8 (Revealed inattention; Masatlioglu et al., 2012) Suppose that c is a CLA, then

- (a) x is revealed not to attract attention at a set S if and only if $xP_{RC}(S)$,
- (b) x is revealed to attract attention at a set S if and only if there exists a set T such that $c(T) \neq c(T \setminus x)$, and the following two conditions hold:
 - (bi) $yP_{RC}(S)$ for all $y \in S \setminus T$
 - (bii) $zP_{RC}(T)$ for all $z \in T \setminus S$.

Part (a) is obvious. If x is revealed preferred to all elements actually chosen then it must be the case that the decision maker does not pay attention to x . Part (b) is exemplified in Example 22.17.

Propositions 22.7 and 22.8 require that c is a CLA. We now explore how we can characterize a CLA. We first define the analog of the weak axiom of revealed preference (WARP) under limited attention. Under full attention, WARP implies that every set S has a best alternative, x^* , such that if the choice from some set T lies in S then that choice must be x^* . Under limited attention we must, in addition, ensure that the decision maker pays attention to x^* .

Definition 22.16 The weak axiom of revealed preference with limited attention (WARP(LA)) requires that for a non-empty set S there exists $x^* \in S$ such that if $x^* \in T$ and,

$$\text{if (i) } c(T) \in S \text{ and (ii) } c(T) \neq c(T \setminus x^*) \text{ then } c(T) = x^*.$$

The requirement $c(T) \neq c(T \setminus x^*)$ ensures that the decision maker gives attention to x^* ; this is the only component in WARP(LP) that differentiates it from WARP.

Proposition 22.9 (Characterization of CLA; Masatlioglu et al., 2012): The choice function c satisfies WARP(LA) if and only if c is a CLA.

Proposition 22.9 shows that the characterization of CLA is simple and depends on just one behavioral axiom, WARP(LA).

The basic idea that in choosing an element from a set S , the decision maker only considers a subset $T \subset S$ plays a role in several different models. The reader might wonder how these alternative models relate to the CLA approach. For instance, Cherepanov et al. (2013) propose a model in which decision makers evaluate alternatives based on their ability to *rationalize* them.

There can be several *rationales* and each rationale is a transitive binary relation, R_i . In particular, R_i need not be complete, so R_i may not be able to compare two distinct alternatives, x and y . The set of rationalizable alternatives in S , denoted by $\hat{\Gamma}(S)$, comprises alternatives that dominate all others based on at least one rationale. Thus,

$$\hat{\Gamma}(S) = \{x \in S : \text{For some } R_i, xR_i y \text{ for all } y \in S\}. \quad (22.40)$$

It can be shown that $\hat{\Gamma}$ is not an attention filter. Furthermore, there are rationales that do not imply the CLA model and there are attention filters that do not satisfy $\hat{\Gamma}$. Hence, neither CLA implies rationalizability nor is it implied by it; an exercise invites the reader to explore this for an example.

Manzini and Mariotti (2007) propose the application of two rationales applied in a sequential and fixed manner, irrespective of the set of alternatives. The available choices are pruned by the first rationale (shortlisting) to enable the second rationale to select the final outcome. This is termed as the Rational Shortlist Method.¹² Masatlioglu et al. (2012) state that most models in this class satisfy the *Weak WARP axiom*, which states that if x is chosen from the pair of alternatives $\{x, y\}$ and from a set with a larger number of alternatives, then y cannot be chosen from a set with an intermediate number of alternatives.

Definition 22.17 (*Weak WARP; Masatlioglu et al., 2012*): Suppose $\{x, y\} \subset T \subset S$. If $c(xy) = c(S) = x$, then $y \notin c(T)$.

It is not hard to construct examples where the choice function satisfies WARP(LA) but does not satisfy Weak WARP; an exercise asks you to show this. The converse can also be shown, namely, that choice patterns that satisfy Weak WARP need not satisfy WARP(LA); see Example 3 in Masatlioglu et al. (2012).

22.8 The contractarian approach

In neoclassical economics, and in the soft paternalism approach, one typically advises a choice architect, a social planner, the government, or the policymaker. In the contractarian approach, by contrast, one advises directly the individual who suffers from behavioral biases. Sugden (2013) outlines the *contractarian approach* to normative economics that is based on Buchanan (1968, 1975, 1986); we consider this below.

The contractarian recommendation to any set of individuals is addressed to each individual in the set, not by appeal to the common interest, but by stressing the advantage to each individual. Appeals in the common interest may involve winners and losers, yet the losers may agree to participate voluntarily, perhaps motivated by the common good. However, this is not part of the contractarian framework. If the contractarian recommendations lead to harm to some parties, the proposal may include compensating mechanisms. However, a contractarian recommendation cannot impose net losses on anyone, say, on the grounds that the recommendation imparts high benefits to others.

A contractarian's role is similar to that of a mediator who makes suggestions that are mutually beneficial to different parties in a conflict situation. The contractarian does not advise any par-

¹² For a generalization of the model to accommodate more general menu dependence, see Manzini and Mariotti (2012).

ticular party to strategically out-think the others. Rather he is advising all individuals to reach a mutually beneficial settlement, although some individuals may gain relatively more than others. Since the aim is to achieve a mutually beneficial outcome for all parties, one begins from some baseline position or the status quo. For instance, consider several buyers and a seller of an object. The baseline position is that the seller has the object and the buyer has the money and both parties expect to trade voluntarily without any incurring losses. The contractarian might now recommend a second price auction to all parties as a trading mechanism to realize gains from trade.

Those who formulate contractarian policies are required to have incentives to make the necessary recommendations to individuals. Thus, the underlying framework needs to be broad enough to capture the incentives of the relevant actors, which might include political actors or policymakers who make the recommendations.

Example 22.18 *Consider the recommendation to motorists approaching a roundabout to “give way to traffic from the right.” This is, for instance, enshrined in the traffic laws in the UK. This rule is mutually beneficial to drivers at the roundabout by giving rise to common expectations. In any particular trip, a driver who has to wait for the vehicle from the right loses some time while the other party gains. However, on average, as one makes many car trips, the average gains and losses counterbalance each other, and drivers benefit from a smooth and less stressful flow of traffic, so all drivers benefit.*

Sugden (2013, pp. 530–1) raises an important issue about the relevant *addressee* in normative economics and in the contractarian approach: “The literary convention of addressing normative economics to a public decision-maker seems rather out of place when what are being discussed are (supposed) mistakes in decisions that are made by private individuals and that do not affect anyone else. Advising individuals on how to pursue their own interests in their private lives is a natural counterpart to advising them about how to pursue common interests through agreement. In other words, it is a natural counterpart to the contractarian approach.” The next example illustrates this point further.

Example 22.19 *Suppose that an epidemiologist discovers a link between some human actions, say, eating a particular food and some human disease or illness. The contractarian approach would take the form of direct information dissemination of the findings to the public. Indeed, in the case of smoking and alcohol consumption, this has been the approach in many countries (although belatedly in the case of smoking). So while normative economics is largely addressed to a hypothetical social planner, in actual practice it is not unusual that public policy takes the form of directly informing people about their biases.*

As these examples show, the contractarian approach takes the form of recommendations made directly to individuals, once it is discovered that they exhibit some form of bias. No paternalism is allowed in the contractarian approach. In particular, the contractarian cannot choose to nudge an individual who chooses not to be nudged, no matter how much the contractarian deems the nudge to be in the individual’s interest. This stands in contrast to the libertarian-paternalism approach.

Nudges recommended under soft paternalism are viewed to be paternalistic in the contractarian approach. The reason for disallowing paternalism under the contractarian approach is not because paternalism might unduly intrude into individual liberty. Rather, the reason stems from a practical concern, namely, that *paternalism lacks a valid addressee*. Sugden (2013, p. 537) writes:

“Unless individuals themselves wish to license others to act as their guardians, there is no common interest in paternalism.”

The contractarian approach is not without its limitations. Providing information in the contractarian approach may also be considered by some as a form of nudging. How does one know if individuals wish to be nudged, i.e., be provided with the relevant information? Since issues of the framing of information can be critical, who decides how the relevant information is to be framed? How does one determine if the same information will not be interpreted by different people in a different manner? Perhaps these concerns apply with less force in some examples rather than others, but clearly there are no simple answers to these vexed questions.

22.9 Behavioral public finance and welfare

In Part 7, we noted the effect of limited attention on the demand for a single good under salient and non-salient taxes (Chetty et al., 2009); we assume familiarity with the material on limited attention in Part 7 in this section. When taxes are made more salient, individuals reduce their demand for the good. In this section, we first extend this framework to consider the tax incidence and excess burden under limited attention. Then, we consider some reduced-form frameworks that are suitable to model the welfare implications of alternative policies.

22.9.1 Tax incidence under limited attention

Suppose that a consumer consumes two goods, x and y , and the utility function is additively separable

$$u(x) + v(y). \quad (22.41)$$

The consumer has income $I > 0$. Good y is the numeraire good, whose price is normalized to 1, and it is not taxed. Let p denote the pre-tax unit price of good x that is posted on the price stickers and saliently observable to all buyers. The post-tax price of the good is $q = p + \tau$, where τ is a specific consumption tax. Under full attention, denote the solution to the consumer's optimal demand for x by $x^*(p, \tau, I)$ and for y by $y^*(p, \tau, I)$; we assume that demands are continuously differentiable in the parameters p, τ, I . All feasible choices for the levels of demand must satisfy the consumer's budget constraint

$$(p + \tau) x^*(p, \tau, I) + y^*(p, \tau, I) = I. \quad (22.42)$$

Under classical public finance theory, the consumer takes account of the full post-tax price, q , so the sales tax, whether posted on price stickers or imposed at the sales register, is fully salient, so $x^*(p, \tau, I) = x^*((1 + \tau)p, 0, I)$. Thus, there is no need to separately observe the sales tax if the consumer already takes account of the post-tax price. Under full attention, an increase in the post-tax price, q , on account of an increase in τ , or an increase in p , has identical effects on the demand for x , thus, $\frac{\partial x^*}{\partial q} = \frac{\partial x^*}{\partial p} = \frac{\partial x^*}{\partial \tau}$.

Now introduce the possibility of limited attention towards the sales tax. Denote the optimal consumption bundles under limited attention by $x(p, \tau, I)$ and $y(p, \tau, I)$. In this case, whether the sales tax is displayed on the price stickers, or imposed at the sales register, has an important effect on demand, and empirical evidence indicates that $\frac{\partial x}{\partial p} \neq \frac{\partial x}{\partial \tau}$ (see Part 7 for the evidence).

Following Chetty et al. (2009), let us conduct a partial equilibrium analysis below. Our main focus will be on the demand for good x ; let us write $x(p, \tau, I) \equiv D(p, \tau, I)$ to make the demand connotation salient. Let $\epsilon_{D,p} = -\frac{\partial D}{\partial p} \frac{p}{D}$ and $\epsilon_{D,\tau} = -\frac{\partial D}{\partial \tau} \frac{\tau}{D}$ denote, respectively, the elasticity of demand for $x \equiv D$ with respect to p and τ ; we assume that both p and τ influence demand through their effect on $q = p + \tau$, so we avoid the more cumbersome but accurate notation for these elasticities: $\epsilon_{D,q|p}$ and $\epsilon_{D,q|\tau}$.

Under classical public finance theory, we should, by definition, observe that $\epsilon_{D,p} = \epsilon_{D,\tau}$; but this is no longer guaranteed under limited attention. One way of representing limited attention to taxes that are not displayed on price stickers, but rather added at the point of sale, is to write $D(p, \tau, I)$ in a log-linear form (let us keep I fixed).

$$\log D(p, \tau, I) = \alpha + \beta \log p + \theta \beta \log \tau. \quad (22.43)$$

In (22.43), the coefficients β and $\theta\beta$, respectively, give the two elasticities $\epsilon_{D,p}$ and $\epsilon_{D,\tau}$. Thus,

$$\theta = \left(\frac{\partial \log D}{\partial \log \tau} \middle/ \frac{\partial \log D}{\partial \log p} \right) = \frac{\epsilon_{D,\tau}}{\epsilon_{D,p}} = \left(\frac{\partial D}{\partial \tau} \middle/ \frac{\partial D}{\partial p} \right). \quad (22.44)$$

Under classical public finance, $\theta = 1$ (unlimited attention). However the empirical evidence suggests that $\theta < 1$ because demand is less responsive to less salient taxes, relative to changes in the price of the good, which is salient. Thus, the magnitude of θ may be taken to be a measure of inattention. More generally, $\theta < 1$ may capture other errors in optimization caused by cognitive limitations that are unrelated to inattention. While $\theta < 1$ is in agreement with the empirical evidence on consumption taxes, for other taxes, such as estate taxes, the evidence appears consistent with $\theta > 1$ (tax rates are overestimated).

From (22.44), we get

$$\epsilon_{D,\tau} = \theta \epsilon_{D,p}. \quad (22.45)$$

The problem of *tax incidence* essentially involves figuring out the relative shares of the tax burden borne by producers and consumers of an increase in the tax rate. Let us introduce producers in a simple manner. Suppose that identical competitive firms produce good x . The cost of production faced by a representative firm is $c(S)$, where $S = 1, 2, \dots$ is the number of units of the good produced by a firm, and $c' > 0$, $c'' > 0$. The profit level of the representative firm is given by $\pi = pS - c(S)$. Profit maximizing firms produce at the point where $p = c'(S(p))$; $S(p)$ is the optimal supply of the representative firm as a function of the price of the good. Denote the elasticity of supply by $\epsilon_{S,p} = \frac{\partial S}{\partial p} \frac{p}{S}$.

In a partial equilibrium analysis, we are interested in market clearing in the market for good x , so

$$D(p, \tau, I) = S(p). \quad (22.46)$$

Implicit differentiation of (22.46) gives: $\left(\frac{\partial D}{\partial p} - \frac{\partial S}{\partial p} \right) dp + \frac{\partial D}{\partial \tau} d\tau = 0$. Simplifying, and using (22.45), we get

$$\frac{dp}{d\tau} = \frac{\frac{\partial D}{\partial \tau}}{\frac{\partial S}{\partial p} - \frac{\partial D}{\partial p}} = -\frac{\epsilon_{D,\tau}}{\frac{q}{p}\epsilon_{S,p} + \epsilon_{D,p}} = -\frac{\theta \epsilon_{D,p}}{\frac{q}{p}\epsilon_{S,p} + \epsilon_{D,p}}. \quad (22.47)$$

The calculation $\frac{dp}{d\tau}$ in (22.47), gives the incidence of the tax on producers. Using the relation $q = p + \tau$, we can find the incidence of the tax on consumers as $\frac{dq}{d\tau} = 1 + \frac{dp}{d\tau}$; using (22.47) we can rewrite this as

$$\frac{dq}{d\tau} = \frac{\frac{q}{p}\epsilon_{S,p} + (1 - \theta)\epsilon_{D,p}}{\frac{q}{p}\epsilon_{S,p} + \epsilon_{D,p}}. \quad (22.48)$$

Figure 22.3 shows the effect of tax incidence under limited attention; the pretax price is measured on the vertical axis and the quantities demanded and supplied of good x are measured on the horizontal axis. The original equilibrium at a zero tax rate is shown at point 1. The corresponding pre-tax equilibrium price is p_0 and the equilibrium quantity is x_0 ; since the tax rate is zero, so the pre-tax and the post-tax prices coincide, $p_0 = q_0$. Consider now an increase in the tax rate to $\tau > 0$. The increase in the tax rate shifts the demand curve inwards by $\frac{\partial D}{\partial \tau} \tau$. At the existing equilibrium price, p_0 , there is an excess supply of the good, equal to $\frac{\partial D}{\partial \tau} \tau$; $\frac{\partial D}{\partial \tau}$ is evaluated at $p = p_0$. In order to clear the market, competition among producers ensures that the equilibrium price falls to $p = p_1$ and the equilibrium quantity falls to x_1 ; the new equilibrium point is labeled 3. The post-tax price, $q_1 = p_1 + \tau$ is also shown in the figure and τ is shown as the vertical distance between points 3 and 4. The total tax revenue collected by the government is τx_1 .

Clearly, the change in the price $dp = p_0 - p_1 < \tau$. Thus, producers bear a part of the burden of an increase in the tax burden, shown by the area $(p_0 - p_1) x_1$. The remaining tax burden, shown as the area $dq = (q_1 - p_0) x_1$, is borne by the consumers. Thus, $\tau x_1 = (p_0 - p_1) x_1 + (q_1 - p_0) x_1 \equiv x_1 dp + x_1 dq$ gives the split of the increased tax revenues between that paid by firms and consumers, although the tax is levied only on the consumers. Under full attention, we have $\theta = 1$, so $\frac{\partial D}{\partial \tau} = \frac{\partial D}{\partial p}$. Thus, in Figure 22.3, we could have shown the leftward shift in demand as $\frac{\partial D}{\partial p} \tau$, which is not the case under limited attention ($\theta < 1$); this is the only difference in Figure 22.3 relative to the standard model in public finance.

From (22.47), $\frac{dp}{d\tau}$ is directly proportional to the size of θ . In the extreme case of no attention, $\theta = 0$, we have $\frac{dp}{d\tau} = 0$, so producers do not bear any burden of the tax increase; consumers bear the entire tax burden. As θ increases, the relative tax burden borne by the producer increases, and correspondingly, the tax burden on the consumer falls. It is tempting to conclude that if

Figure 22.3 Tax incidence under limited attention.

consumers pay less than full attention to an increase in the tax rate, it is as if their demand is inelastic, hence, producers can pass a greater amount of the tax rate to final consumers. From (22.45) we know that $\epsilon_{D,\tau} = \theta \epsilon_{D,p}$, so a change in θ or a change in $\epsilon_{D,p}$ have similar effects on $\epsilon_{D,\tau}$, yet their effect on tax incidence is different.

To see this, suppose we have two economies, A and B , with identical supply elasticities $\epsilon_{S,p}^A = \epsilon_{S,p}^B = 0.1$. In economy A , all consumers are neoclassical and display perfect attention ($\theta^A = 1$), but in economy B they display limited attention ($\theta^B = 0.3 < 1$). Demand in economy A is inelastic ($\epsilon_{D,p}^A = 0.3$) while in economy B it is more elastic ($\epsilon_{D,p}^B = 1$). Thus, in each case we have $\epsilon_{D,\tau}^A = \epsilon_{D,\tau}^B = 0.3$. However, using (22.47), we have $\left(\frac{dp}{d\tau}\right)_A = -0.75$ and $\left(\frac{dp}{d\tau}\right)_B = -0.27$. Producers in economy A bear a larger share of the tax despite full attention; in contrast the limited attention in economy B allows its producers to shift a greater share of the tax to its consumers. Following an increase in the tax rate, inattention only shifts down the demand curve (as in Figure 22.3). In contrast, a lower elasticity of demand reduces the inward shift in demand and also requires a larger price cut (size of $p_0 - p_1$ in Figure 22.3) to establish the new equilibrium where demand equals supply.

From (22.47), if we hold fixed the tax elasticity of demand, $\epsilon_{D,\tau}$, a larger value of price elasticity $\epsilon_{D,p}$ increases $\frac{dp}{d\tau}$, or reduces the absolute value of the change $\left|\frac{dp}{d\tau}\right|$ needed to equilibrate markets. However, it is possible that the degree of attention given may also depend on the price elasticity, in which case one would need to model the covariance between θ and $\epsilon_{D,p}$.

22.9.2 Excess burden under limited attention

Let us now use the setup in Section 22.9.1 to calculate the excess burden of taxation, but revert back to $x(p, \tau, I)$ instead of $D(p, \tau, I)$. Assume that initially, the commodity tax rate is zero ($\tau = 0$). Suppose that there are constant returns to scale in production and firms are perfectly competitive, so each firm makes zero profits. Thus, welfare measurements can be equated purely with consumer welfare.

Substituting $x(p, \tau, I)$ and $y(p, \tau, I)$ in the utility function (22.41), we get the indirect utility function

$$V(p, \tau, I) = u(x(p, \tau, I)) + v(y(p, \tau, I)). \quad (22.49)$$

Let the expenditure function be denoted by $e(p, \tau_1, I)$; it is the minimum expenditure required to achieve the level of utility $V(p, \tau_1, I)$ (corresponding to a tax rate of τ_1) when the price is p and the tax rate is τ_2 . We denote government revenue by $R = \tau x(p, \tau, I)$. From (22.42), we have

$$px(p, \tau, I) + y(p, \tau, I) = I - \tau x(p, \tau, I) \equiv I - R(p, \tau, I). \quad (22.50)$$

The LHS of (22.50) is the total expenditure on consumption goods, and the RHS is the total disposable income.

We now use these concepts to define the excess burden, or deadweight loss, of a consumption tax by

$$EB(\tau) = I - R(p, \tau, I) - e(p, 0, V(p, \tau, I)). \quad (22.51)$$

$I - R(p, \tau, I)$ is the disposable income when the distortionary consumption tax rate is τ , and the corresponding indirect utility is $V(p, \tau, I)$. Suppose that we ask what expenditure is needed to achieve a utility of $V(p, \tau, I)$ when we remove the distortionary tax and replace it by a lump-sum tax, L ? The budget constraint with a lump-sum tax is $px(p, 0, I) + y(p, 0, I) = I - L$. Since there are no distortions associated with a lump-sum tax, hence, the same level of utility can be achieved with a lower expenditure, $e(p, 0, V(p, \tau, I))$. Thus, the RHS of (22.51) measures the extra expenditure required under a distortionary tax to achieve the same level of utility as a lump-sum tax; in other words, it is the deadweight loss associated with the tax.

An issue in most behavioral welfare analyses where people do not strictly optimize is to compute the indirect utility $V(p, \tau, I)$. The indirect utility function is obtained by substituting the optimal choices into the utility function. Suppose, as an extreme example, that an individual pays no attention to tax rates ($\theta = 0$). Then, as the tax rate changes, the individual does not choose the optimizing bundles of x, y , thus making it difficult to define an indirect utility function. In order to deal with this problem, consider two assumptions.

- A1: Taxes do not directly affect the utility function. Rather, taxes only affect the utility function indirectly through changes in the demands $x(p, \tau, I)$ and $y(p, \tau, I)$. In other words, the indirect utility function is as given in (22.49).
- A2: Recall that $x^*(p, \tau, I)$ and $x(p, \tau, I)$ are the optimal consumption bundles under, respectively, full attention and limited attention, and that our initial tax rate is $\tau = 0$. We require that

$$x(p, 0, I) = x^*(p, 0, I) = \arg \max u(x(p, 0, I)) + v(I - px(p, 0, I)). \quad (22.52)$$

The implication of (22.52) is that under limited attention, we can discover the underlying preferences of a decision maker who exhibits limited attention, if $\tau = 0$; when $\tau = 0$, there are no issues of inattention.

It is best to examine conditions under which these assumptions are violated in order to understand them better.

Assumption A1 is not likely to hold if taxes directly influence individual utility. This may happen, for instance, (1) if individuals are troubled by the fairness of the fiscal system (e.g., those individuals who feel that the tax system is unfair may evade more taxes), or (2) if individuals must expend costly cognitive effort to give more attention to taxes. In these cases, instead of (22.49), the indirect utility function may have to be written as $\tilde{V}(p, \tau, I) = u(x(p, \tau, I), \tau) + v(y(p, \tau, I), \tau)$. Assumption A2 can be violated even when in the absence of taxes, individuals do not choose the optimal consumption bundles; for instance, under *shrouded attributes* (see Part 7).

Thus, our strategy is to first use (22.52) to compute the individual's underlying preferences, and then use the Marshallian demand functions under limited attention, $x(p, \tau, I)$ and $y(p, \tau, I)$, to compute the indirect utility function in (22.49).

Denote by $h = h(p, \tau, V)$ the Hicksian or compensated demand for good x , under limited attention. Then assumption A2, and the Slutsky equation implies

$$\frac{\partial h}{\partial p} = \frac{\partial x}{\partial p} + x \frac{\partial x}{\partial I}. \quad (22.53)$$

Demands, Hicksian or Marshallian, optimally respond to prices, so we have the usual condition $\frac{\partial h}{\partial p} < 0$. However, due to limited attention, there is no presumption that demands respond optimally to changes in the tax rate, τ . So if we define

presence of income effects we would have to consider Hicksian demands in Figure 22.4. In the absence of income effects, we can also replace θ^c by θ in (22.55).

Two kinds of demand curves are shown in Figure 22.4. $x(p, 0)$ is the demand curve when $\tau = 0$, and it shows how optimal demand varies under limited attention when the price alone varies. The initial commodity price of good x is p_0 , and $\epsilon_{s,p} = \infty$, so the supply curve is horizontal at p_0 . The demand curve $x(p_0, \tau)$ shows the variation in optimal demand when price is fixed at p_0 , but the tax rate, τ , varies. In the figure, we have shown $x(p_0, \tau)$ to be steeper relative to $x(p, 0)$; this is consistent with the empirical evidence that consumers respond less to taxes that are less salient.

The equilibrium when $\tau = 0$ is shown at point J and the consumer demands x_0 units at a price p_0 per unit. Now suppose that we impose a commodity tax $\tau > 0$ on x so that the post-tax price of x is $p_0 + \tau$. In response to an increase in the tax, the consumer reduces demand from x_0 to x_1 . However, at a level of demand x_1 , the marginal willingness to pay is given by the demand curve $x(p, 0)$, i.e., the vertical distance FM , which is lower than the actual price paid, $p_0 + \tau$. Suppose that we use as our measure of welfare, the sum of consumer surplus and government tax revenues. Before the imposition of the tax, tax revenues are zero and consumer surplus is AGJ , so initial total welfare is AGJ . After the imposition of the tax, consumer surplus is $AKMF - BKMD = ABC - CDF$. Total government tax revenues equal $BGIFC + CDF$. Thus, total welfare after the imposition of the tax is $ABC + BGIFC$. The difference in the levels of welfare in the two cases is $AGJ - (ABC + BGIFC) = FIJ$; this is the excess burden of the tax and is shown as the shaded area in Figure 22.4.

As noted above, in the absence of income effects, $\frac{\partial x}{\partial I} = 0$ (e.g., underlying utility function is quasilinear), so we may write $EB(\tau) \simeq \frac{1}{2}(\tau\theta)^2 x(p, \tau, I) \frac{\epsilon_{x,p}}{p+\tau}$. Thus, if $\theta = 0$ (tax changes are ignored, so extreme limited attention), then $EB(\tau) \simeq 0$. The reason is that starting from a zero tax rate, if the imposition of a positive tax rate is ignored by the individual, then there are no substitution effects, only income effects, hence there is no deadweight loss either. When $\theta = 0$, the budget constraint of the consumer must nevertheless be respected on imposition of the tax. Thus, the distortionary tax under extreme limited attention ($\theta = 0$) becomes just a lump-sum tax, that leads to a choice of the first best consumption bundle, x^* . On the other hand, if $0 < \theta < 1$ then the excess burden increases with the square of θ , just as it does for the tax rate, τ . Thus, limited attention reduces the excess burden of taxation, which is welfare improving. In classical public finance theory, it does not matter if taxes are imposed on consumers or producers. However, under limited attention, the two taxes may lead to different effects. The reason is that taxes on producers are often included in the posted price of the good, hence, they are more salient (higher θ); thus the excess burden arising from these taxes is relatively greater.

Going back to Figure 22.4, where we assumed $\frac{\partial x}{\partial I} = 0$, suppose that the curve $x(p, 0)$ becomes steeper (price elasticity reduces), then the area FIJ expands, so the excess burden increases.

If there are income effects $\frac{\partial x}{\partial I} > 0$, then limited attention may increase the excess burden of taxation; this result arises even if $\theta = 0$, so the consumer pays no attention to tax, $\frac{\partial x}{\partial \tau} = 0$ (see (22.44)). When $\frac{\partial x}{\partial \tau} = 0$, we get from (22.54) that $\frac{\partial h}{\partial \tau} = x \frac{\partial x}{\partial I}$. Substitute this, and $\theta^c = \left(\frac{\partial h}{\partial \tau} / \frac{\partial h}{\partial p} \right)$, into the first line of (22.55), to get

$$EB(\tau) \simeq \frac{-1}{2} (\tau x)^2 \left(\frac{\partial x}{\partial I} / \frac{\partial h}{\partial p} \right) \frac{\partial x}{\partial I} > 0. \quad (22.56)$$

The sign in (22.56) follows because $\frac{\partial h}{\partial p} < 0$. Thus, under complete inattention, we can get a positive excess burden of taxation when there are income effects.

To see this, consider an example in which x is the number of visits to the theater and y is food. Suppose that the government levies tax, $\tau > 0$, on theater visits and the consumer is completely inattentive to these taxes ($\theta = 0$). The budget constraint of the consumer is given by $(p + \tau)x(p, \tau, I) + y(p, \tau, I) = I$. Differentiate both sides with respect to τ to get

$$\frac{\partial x}{\partial \tau} + \frac{\partial y}{\partial \tau} = -x.$$

Thus, one method by which the budget may be balanced is that the individual ignores the effect of tax on x , i.e., sets $\frac{\partial x}{\partial \tau} = 0$. In this case, as the consumer's income goes down after paying the tax, the full effect is felt as a decrease in the consumption of food, y . Thus, the new income level, net of taxes, is not allocated efficiently between theater visits and food, which creates a deadweight loss from taxation, hence, the excess burden is positive.

Finally, note from Proposition 22.10, when tax increases are imposed on pre existing positive tax rates, then the tax increases can have first order effects (as in the term $\tau_0 \Delta \tau$), although these effects are weakened by inattention (low values of θ^c).

22.9.3 A note on reduced-form approaches to behavioral public finance

A departure in behavior from the neoclassical benchmark can sometimes be explained by several competing behavioral explanations. Consider, for instance, the finding that individuals might buy energy inefficient lightbulbs and cause carbon externalities on others (Hausman, 1979; Allcott et al., 2014). Do individuals engage in this decision because they are present-biased (lightbulbs impose current costs, but future benefits; see Part 3 of the book), or simply because they possess limited attention (insufficient attention to future benefits; see Part 7 of the book)? Competing behavioral explanations of the same phenomenon are viewed by some as a drawback of behavioral economics. This is a mistake. There are almost always competing explanations of a phenomenon in any science; even in neoclassical economics one can often explain the same phenomenon by simply invoking some form of asymmetric information or other auxiliary assumptions. It is the role of empirical evidence to help us sift through these alternative explanations and pin down the empirically correct explanation.

Reduced-form approaches to behavioral public finance seek to provide a framework that is robust to alternative behavioral explanations, within some subset of explanations. Mullainathan et al. (2012) propose a reduced-form approach that nests competing behavioral explanations that draw on the distinction between experienced utility and decision utility (see Parts 6 and 7 of the book). We now consider the basic model.

Suppose that there are n individuals indexed by $i = 1, \dots, n$. Individual i can take a binary action $a_i \in \{0, 1\}$, for instance, buy or not buy an energy efficient product; 0 denotes *inaction*, while 1 denotes taking the *action*. The action costs p (price and other costs associated with the action). The benefit to individual i from the action, in income equivalent units, is b_i ; benefits have a distribution function F in the population. By taking the action, an individual imposes an externality e on all individuals (e.g., higher carbon emissions for all when an individual buys a more polluting car). So if $m \leq n$ individuals choose to take the action, then the externality on any individual is me .

The government levies a tax t on the action taken by an individual. Hence, the post-tax price paid by an individual who chooses to take the action is $q(t)$; for instance, in the case of a specific

consumption tax, $q(t) = p + t$. The government also transfers an amount T to each individual, so the government budget constraint can be written as $G(t, T) = 0$.

The initial income of each individual is Y , and each individual has an increasing and concave utility function, U , that is defined as follows.

$$U = \begin{cases} U(Y + T + (b - q(t)) - me) & \text{if } a_i = 1 \\ U(Y + T - me) & \text{if } a_i = 0 \end{cases} . \quad (22.57)$$

It follows that $a_i = 1$ is strictly preferred to $a_i = 0$ by a neoclassical consumer, if

$$b > q(t). \quad (22.58)$$

We can also find that $m = 1 - F(q(t))$. In contrast to (22.58), behavioral consumers, in this reduced-form approach, chose $a_i = 1$ over $a_i = 0$, if

$$b + d(b, t) > q(t), \quad (22.59)$$

where $d(b, t) \geq 0$ is a non-stochastic distortion term that reflects behavioral factors, and is increasing in b . We may describe the decision rule (22.59) as reflecting *decision utility* and the decision rule (22.58) as reflecting *experienced utility*. This framework applies to any situation where there is a wedge between experienced and decision utility. Clearly this does not apply to many kinds of behavioral factors such as social preferences or to the presence of reference points, where no such meaningful distinction between the two notions of utility is required.

Example 22.20 (Laibson, 1997; O'Donoghue and Rabin, 1999): Suppose that the individual takes some action that involves current benefits and future costs (e.g., buying consumer durables on credit; see Part 3 for several examples). Let $b = v - c$, where v is the current benefit and c is the future cost. Suppose that $t = T = 0$ and the price $p = p_0 + p_1$, where p_0 is the price paid now and p_1 is the price paid in the future. Suppose that $\beta \in (0, 1)$, then present-biased individuals choose to take the action if $v - \beta c - (p_0 + \beta p_1) > 0$, or

$$v - c + (1 - \beta)(c + p_1) > p_0 + p_1.$$

Setting $d(b, t) = (1 - \beta)(c + p_1)$ and $q = p_0 + p_1$, we get the decision rule in (22.59).

Example 22.21 (Nudges, Thaler, and Sunstein, 2009): Suppose that there are $j = 1, 2, \dots, k$ possible nudges. Then, we may index $d(b, t)$ in (22.59) by j , so that the decision rule under nudges is $b + d_j(b, t) > q(t)$.

The main insight offered by this reduced-form approach is to show that the identity of the marginal individuals on which policy applies in the presence and in the absence of behavioral factors is different. Suppose, for instance, that the government increases the tax rate from t to $t + \Delta t$. Prior to the tax increase, the individuals who took the action satisfied the condition

$$b > p + t - d,$$

while after the tax increase, the individuals who take the action satisfy the condition

$$b > p + t + \Delta t - d.$$

The marginal behavioral individual for small changes, $\Delta t \rightarrow 0$, is one whose benefit from the action is $b \approx p + t - d$. In neoclassical economics, the marginal individual has benefits $b \approx p + t$, which reflect the true marginal cost of taking the action. Suppose that $d > 0$ (e.g., sin goods; see Part 3 for a framework of analysis), then for a behavioral individual, the marginal benefit, b , of the good is below the marginal cost, $p + t$. The extra tax could then dissuade this individual from undertaking the activity, which is welfare improving. In Part 3, we report evidence, based on Canadian data, that cigarette smokers welcome an increase in the tax rate. As Mullainathan et al., (2014, p. 17.9) put it: “For many policy problems, the feature of the behavioral bias that matters most is how it affects who is marginal. This change is at the heart of our entire approach.”

Farhi and Gabaix (2015) propose an ambitious research program in which they model limited attention by using the sparse max operator (see Part 7 for the details) and develop the theory of optimal taxation with behavioral agents. They derive optimal tax formulae under these conditions for commodity taxes (the analogue of Ramsey taxes), income taxes (the analog of the Mirrlees approach to non-linear income taxation), and corrective taxes in the presence of externalities (the analog of the Pigouvian framework in classical public finance). The optimal taxes in classical public finance are often too complex relative to real-world taxes that are relatively simple. The authors exploit insights from limited attention to show that taxpayers may give even lower salience to complex tax systems, driving an even greater wedge between the private marginal cost and the private marginal benefit of a decision, making it welfare improving to design simpler tax systems.

Exercises for Part 8

1. (Camerer et al., 2003) (a) Evidence shows that people are ambiguity averse (see Part 1) and have social preferences (see Part 2). Do these findings create a need for paternalism?
 (b) Use asymmetric paternalism in order to evaluate the following policy proposal. A policy that requires patients to get a second opinion before undergoing surgery.
 (c) Can one use asymmetric paternalism to rationalize the existing licensing regulations in many countries for physicians (and car drivers) that bar entry into the profession if one does not have the appropriate license?
 (d) How can *cooling-off periods* for consumers, advocated under soft paternalism, influence the behavior of sellers?
2. (Camerer et al., 2003) Suicide is currently illegal, which is a form of *heavy-handed paternalism*. How might you deal with the problem of suicide using soft paternalism?
3. (Camerer et al., 2003) How might one use asymmetric paternalism in order to address the problems indicated in the following empirical findings?
 (a) Enron's 401(k) plan was heavily invested in the company's own stock with the result that when Enron collapsed, so did the pension plans of the employees.
 (b) Evidence indicates that people vastly overestimate the chances of winning lotteries, which might account for the large participation rates in lotteries.
 (c) "Rent to own" establishments lease consumer durables and furniture, typically to low-income consumers. Most US states treat these contracts as rental agreements even though 70% of the consumers buy the products they rent. This frees up firms from the regulations that cap interest rates. Consumers end up paying high interest rates.
 (d) People often run up high credit card debts because they fail to fully appreciate the difference between simple and compound interest rates.
4. Derive the analog of Proposition 22.1 under Type 2 asymmetric information (Definition 22.3b).
5. (Dalton and Ghosal, 2011) Consider the framework developed in Section 22.2. Suppose that the action set is $A = \{a_1, a_2, a_3\}$ and the set of psychological states is given by $\Theta = \{\theta_1, \theta_2, \theta_3\}$. The decision maker faces payoff relevant uncertainty. There are two equally likely states of the world in which the payoffs corresponding to each action–psychological state pair are given in Tables 8.E1 (for state 1) and 8.E2 (for state 2).
 (a) Suppose that the decision maker must choose his action before uncertainty about the state of the world resolves and that he is an expected utility maximizer. What is the unique solution to the behavioral decision problem (BDP) and the corresponding payoff of the decision maker? Would the decision maker be better off if he had known the state of the world with certainty?
 (b) Consider the payoff matrix in Table 8.E3.

Table 8.E1 Payoffs in state 1.

	θ_1	θ_2	θ_3
a_1	−1	0	0
a_2	0	3	0.5
a_3	1	4	1

Source: Dalton and Ghosal, 2011.

Table 8.E2 Payoffs in state 2.

	θ_1	θ_2	θ_3
a_1	1	4	1
a_2	0.5	3	0
a_3	0	0	−1

Source: Dalton and Ghosal, 2011.

Table 8.E3 Payoffs for each pair of actions and psychological states.

	θ_1	θ_2	θ_3
a_1	−1	0	0
a_2	0	3	0.5
a_3	1	4	1

Source: Dalton and Ghosal, 2011.

Suppose first that $A = \{a_1, a_2\}$ and $\Theta = \{\theta_1, \theta_2\}$, so the relevant payoff matrix is the 2×2 payoff submatrix in Table 8.E3. Now expand the set of actions and psychological states such that $A = \{a_1, a_2, a_3\}$ and $\Theta = \{\theta_1, \theta_2, \theta_3\}$; the payoff matrix is given by the entire 3×3 payoff matrix in Table 8.E3. Find the unique BDP solution in each case. Is the decision maker better off or worse off following an increase in the set of actions?

6. Consider the Bernheim and Rangel (2009) framework developed in Section 22.6. Consider the setup in Example 22.9 but replace (22.25) by the following choices

$$C(X_1) = \{a\}, C(X_2) = \{b\}, C(X_3) = \{c\}, C(X_4) = \{c\}.$$

Show that the binary relation R^* is intransitive.

7. (Bernheim and Rangel, 2009) Consider the Bernheim–Rangel framework in Section 22.6. Let $X_1 = \{a, b\}$, $X_2 = \{b, c\}$, $X_3 = \{a, c\}$, $X_4 = \{a, b, c\}$, and $\chi = \{X_1, X_2, X_3, X_4\}$. Suppose that we have two possible ancillary conditions A and A' . The welfare relevant GCSs are given by $G = \chi \times \{A, A'\}$. Under the ancillary condition A , b is never chosen when a is available and c is never chosen. Under the ancillary condition A' , b is never chosen when c is available and a is never chosen.
- (a) Are any of the alternatives, a, b, c , comparable under P or P^* ?
- (b) What conclusions can you draw about the set of weak and strict individual optima (see Definition 22.8).
8. (Masatlioglu et al., 2012) Consider the CLA method in Section 22.7. Show that the complete and transitive relation P in this model is acyclic if and only if the choice function c satisfies WARP(LA) given in Definition 22.16.
9. (Masatlioglu et al., 2012; Cherepanov et al., 2013) Consider the Rationalization model in Section 22.7 and the associated set of rationalizable alternatives, $\hat{\Gamma}$, given in (22.40). Construct examples to show the following.
- (a) Show using an example with 3 alternatives and 2 rationales that $\hat{\Gamma}$ is not an attention filter (Definition 22.11).

(b) Show that for any rationalization, R_i , and some set S of alternatives

$$x \in \hat{\Gamma}(S) \Rightarrow x \in \hat{\Gamma}(T) \text{ for all } x \in T \subset S.$$

Does this property hold in the CLA model?

(c) What relationship can you conclude between the CLA model and the Rationalization model from your answers to (a) and (b)?

(d) Show that the Rationalization model is a special case of the CLA model if the rationales, R_i , were transitive and complete for all i (Note: in the Rationalization model R_i is incomplete).

10. (Masatlioglu et al., 2012) Consider the model of CLA in Section 22.7. Suppose that there are four alternatives x, y, a, b . The alternatives a and b are never chosen (unless there is no other alternative) but they alter the attention of the decision maker. The decision maker's preference is given by $y \succ x \succ a \succ b$ and she picks the best alternative using these preferences. She considers y only when either a or b is feasible, but not both, and always considers all other alternatives. Show that her consideration set mapping satisfies WARP(LA) (Definition 22.16) but it does not satisfy Weak WARP (Definition 22.17).
11. (Sugden, 2013) Thaler and Sunstein (2009), in their libertarian paternalism approach, give the example of the operation of a cash machine. The machine returns the card first, which if taken out first, triggers the delivery of cash. This prevents individuals from forgetting their card in the cash machine. Consider now the contractarian approach outlined in Section 22.8. Suppose that we are back in time when machines returned cash before the card. How would a contractarian design the appropriate intervention if it were found that people sometimes forget cards in the machine? In your answer, consider two different cases. (i) The cash machine is owned by a private firm. (ii) The cash machine is owned by a public agency that finances its operations through general taxation.
12. (Mullainathan et al., 2012) Consider the reduced-form model in Section 22.9.3. In each of the two examples below, show that the decision rule for the individual can be stated in terms of the decision utility interpretation in (22.59) and find an explicit formula for $d(b, t)$.
 - (a) Inattention to salient components of price (Gabaix and Laibson, 2006; Chetty et al., 2009; DellaVigna, 2009) Suppose that individuals decide to take some action for which benefits are salient. However, the individual pays limited attention to sales taxes. Inattentive individuals discount non-salient costs by the factor $\theta \in (0, 1)$. Thus, inattentive consumers think that they are paying a price $p + \theta t$, where p is the retail price per unit and t is a sales tax.
 - (b) False beliefs and overconfidence (Sandroni and Squintani 2007, Spinnewijn 2015) Suppose that agents misestimate or have false beliefs about the benefits from an action. For instance, the unemployed could be too overconfident of their ability to find a job, hence, searching suboptimally for a new job. Conversely, people may overweigh the benefits to taking an action, for example, when buying an inefficacious herbal medicine. Instead of taking the action when $b > q(t)$, such people take the action when $\hat{b} > q(t)$.

PART 9

Neuroeconomics

INTRODUCTION TO PART 9

Part 9 offers a brief, selective, and incomplete introduction to the rapidly growing field of *neuroeconomics*. We make no attempt to be comprehensive; the treatment here is best thought of as a brief taster course in neuroeconomics. The aim of neuroeconomics is not only to identify the brain regions that are activated during economic choices, but also to uncover the neural circuits that may suggest new economic theories, and enable new predictions. The hope is that, in due course, economic models can successfully make joint predictions about choice behavior and the relevant neural circuitry. Most of the behavioral theories discussed in this book have not required neural foundations. Whether neural foundations will successfully underpin behavioral theories in the near future cannot be answered with certainty at the moment.

Neuroeconomics is a relatively new field in economics that is also one of the fastest growing. While our understanding of the neural underpinnings of behavior continues to improve, there is still much disagreement about the neural foundations of behavior. Indeed some readers may even object to the inclusion of such a chapter in a book that has the word “Foundations” in its title. However, it would be a mistake to ignore this field, yet at the same time, it must be realized that many of the results are tentative and speculative at the moment. Given the rapid progress in the field, this state of affairs can change in the future.

We introduce the reader to the major brain areas that are of interest to neuroeconomists and give a brief outline of the two main kinds of methods in neuroeconomics: *Measurement techniques* and *manipulation techniques*. Measurement techniques measure some aspect of brain activity; examples are single-neuron recordings, positron emission tomography, and functional magnetic resonance imaging. Manipulation techniques can alter activity in specific areas of the brain, allowing for an observation of the associated behavioral change; examples include transcranial magnetic stimulation, transcranial direct current stimulation, and brain lesion studies. Each of the techniques has advantages and disadvantages, hence, data from several complementary techniques helps us to build a better picture of the neural correlates of behavior. Some of the most interesting results come from attempts to predict the direction of causality.

We only focus on the neural underpinnings of some aspects of human behavior outlined in the first four parts of the book: behavioral decision theory with a focus on prospect theory; social preferences with a focus on inequity aversion, social trust, and punishment; time preferences with a focus on two alternative models, the β - δ model, and the planner-doer model; and strategic interaction with a focus on the neural underpinnings of equilibrium and non-equilibrium reasoning, as embodied in level- k and CH models. Finally, we briefly comment on pharmacoeconomics, which studies the change in human behavior when one interferes with the neuromodulator system, with a focus on the effects of oxytocin.

CHAPTER 23

Neuroeconomics

23.1 Introduction

It is useful to begin with a definition of neuroeconomics. Camerer et al. (2015) define neuroeconomics as follows.

Neuroeconomics is the study of the biological microfoundations of economic cognition and economic behavior. Biological microfoundations are neurochemical mechanisms and pathways, like brain regions, neurons, genes, and neurotransmitters.¹ Economic cognition includes memory, preferences, emotions, mental representations, expectations, anticipation, learning, perception, information processing, inference, simulation, valuation, and the subjective experience of reward. In general, neuroeconomic research seeks to identify and test biologically microfounded models that link cognitive building blocks to economic behavior.

Neuroeconomic insights have, so far, not been critical to the development of behavioral economics, but they have already begun to enrich it, and may do so even more, in due course. For instance, the work of Kahneman and Tversky that laid the seeds of behavioral economics, and much subsequent work, did not need neural foundations. The System 1 and System 2 distinction (see Part 7) that Kahneman (2011) uses to motivate judgment heuristics is just a useful metaphor to organize behavioral insights; there is no presumption that distinct brain regions correspond to these systems.

The advocates of neuroeconomics suggest several potential benefits of their research, many of which are necessarily speculative at this early stage (Glimcher et al., 2009; Glimcher and Fehr, 2014; Camerer et al., 2005; Camerer et al., 2015). The most ambitious hope is that, in due course, economic models will make joint predictions about the choices made (based on observables), and the neural mechanisms that give rise to these choices. Such models can then be tested using either traditional methods in economics or neuroeconomic methods, or both. Furthermore, such theories may make novel predictions that theories based on choice behavior alone might not be able to make.

Other ambitious hopes from neuroeconomic research include direct measurements of human welfare, and the use of neuroeconomic data to spur the development of newer models in economics. The common perception is that neuroeconomics tries to identify particular brain areas for each task. However, as Camerer et al. (2015) note, the main thrust of neuroeconomics is the

¹ Neurotransmitters are molecules that carry neurochemical signals from one neuron to another.

hope that “common patterns of [brain] circuitry will emerge which will inform debates about the computations that are performed, and suggest new theories of behavior and new predictions.”

The literature on neuroeconomics, and the neuroscience that it draws on, is already quite vast. This chapter gives a brief account of a few selected topics from this literature. We make no pretense at being complete, comprehensive, or balanced. One justification for this brevity is that several excellent accounts written by the leaders in the field are already available (Glimcher et al., 2009; Glimcher, 2011; Glimcher and Fehr, 2014; Camerer, 2013; Camerer et al., 2015). We choose to focus only on a few studies that explore the neural foundations of some of the human behavior outlined in the first four parts of the book: behavioral decision theory, social preferences, time preferences, and strategic behavior. The hope is to give the readers a flavor of the methods and results, so as to stimulate their interest in a fuller exploration of the issues.

We omit a range of standard topics in neuroeconomics that can be more fully pursued in the references. These include estimation techniques and computational methods in neuroeconomics, and the neuroeconomics of learning and emotions. We also omit a discussion of the debate between those who argue that economics should only consider choice data and others who argue for a broader view of economics; the thrust of these issues has already been considered in Part 8. In the most restrictive view of economics, all non-choice data is inadmissible, particularly neuroeconomic data; this position is most starkly outlined in Gul and Pesendorfer (2008). For a view offering strong support for a broader view of economics, particularly encompassing neuroeconomic data, see Camerer (2008).² Several key arguments offered by Camerer such as the ability of neuroeconomic data to predict human choice and estimate behavioral parameters of interest are illustrated in this chapter.

The first two sections give an introduction to the basics. Section 23.2 gives a brief introduction to brain areas and regions of interest to neuroeconomists. Section 23.3 gives an introduction to alternative methods of measuring brain activity and identifying neural circuitry responsible for economic decisions. Each method has its own advantages and disadvantages, hence, a more complete picture typically emerges by comparing the results from different complementary techniques. We separate the techniques into two classes: *Measurement techniques* and *manipulation techniques*, and evaluate them on the following three criteria. *Temporal resolution* (time frequency of recording of brain activity), *spatial resolution* (precision with which one can narrow down brain activity to a particular area), and the *degree of invasiveness*.

Measurement techniques typically establish correlations between economic behavior and brain activity. This can take the form of single unit recording of neuronal activity, or forming 2D or 3D images of brain activity. We mainly discuss *single-neuron recording*, *electroencephalography* and *magnetoencephalography*, *positron emission tomography* (PET), and *functional magnetic resonance imaging* (fMRI). Manipulation techniques alter (either increase or inhibit) activity in a part of the brain and then study the resulting change in human behavior. The three main manipulation techniques that we describe are: *repeated transcranial magnetic stimulation* (rTMS), *transcranial direct current stimulation* (tDCS), and studies of *brain lesion patients*.

Section 23.4 considers the neuroeconomics of risky decisions with a focus on prospect theory. We begin in Section 23.4.1, with a brief discussion of the neural correlates of value and probability (Glimcher, 2011; Fehr and Rangel, 2011). We ask if the brain computes something like a utility from simple outcomes that is decisive in choosing among the outcomes? The bulk of the studies that answer this question have been performed using simple food items or simple tasks such as judging the quality of an item. It is not always clear if these results will carry over to more

² See also Bernheim (2008) who offers a constructive view on the role of neuroeconomics.

complex economic decisions such as portfolio choice (Camerer, 2013). The distinction that we drew in Part 7 between *decision utility* and *experienced utility* turns out to be of critical importance in these experiments and is shown to have a good neural basis. Decision utility appears to be associated with the ventromedial prefrontal cortex while experienced utility is associated with the orbitofrontal cortex and the nucleus accumbens (these and other brain regions are described in more detail in Section 23.2). We also comment very briefly on the neural basis of mean variance utility, and the axiomatic approach to modeling brain activity.

Section 23.4.2 considers reference dependence. The amygdala has been implicated in fMRI studies of framing effects that are consistent with reference dependence (De Martino et al., 2006; Roiser et al., 2009). However, contrary to these claims, amygdala lesioned patients also exhibit framing effects (Talmi et al., 2010). In another implication of reference dependence—the WTA/WTP disparity—the neural correlates of WTA and WTP lie, respectively, in the ventromedial prefrontal cortex and the lateral orbitofrontal region (Knutson et al., 2008; De Martino et al., 2009). Section 23.4.3 considers loss aversion. Tom et al., (2007) find that in mixed lottery experiments, there is increased activity in the ventromedial prefrontal cortex, medial orbitofrontal cortex, and the anterior cingulate cortex when subjects face increased gains. However, when they face increased losses there is simply reduced activity in the same brain areas, that is greater in absolute value compared to gains; this is a form of *neural loss aversion*.

In particular, risky losses do not induce activity in the expected brain areas such as the amygdala and the insula, which are associated with fear, anxiety, and emotions. However, contrary to these results, patients with brain lesions in the amygdala show no loss aversion (De Martino et al., 2010). Several reasons may account for this difference, which include the range of losses used in the experiments, and the role of the amygdala as an intermediate output area (Jenison et al., 2011). Finally, Section 23.4.4 considers non-linear probability weighting. Prominent brain regions that appear to be associated with non-linear probabilities are the striatum and the cingulate gyrus (Paulus and Frank, 2006; Berns et al., 2008; Hsu et al., 2009).

Section 23.5, the longest section in this chapter, considers the neural foundations of social preferences. Section 23.5.1 considers the neural circuitry associated with social rewards. There appears to be a common neural activation for private and social rewards (Izuma et al., 2008; Smith et al., 2010). Based on identical underlying tasks, in private and social rewards treatments, areas of ventromedial prefrontal cortex and the ventral striatum, encode signals for both kinds of rewards (Lin et al., 2012). Section 23.5.2 shows that inequity averse preferences have strong neural foundations (Tricomi et al., 2010). Indeed the *neural strength* of these preferences appears to be greater than the *behaviorally observed* inequity averse preferences. The ventral striatum and the ventromedial prefrontal cortex are important brain areas that appear to encode these preferences. Neural data can also differentiate between inequity averse preferences that arise from cases where the income distribution is generated from endogenous or exogenous effort (Cappelen et al., 2014).

Section 23.5.3 considers the neural basis of social punishment and trust. In a trust game with punishment that varied intentions and punishment costs, brain activity in the caudate nucleus under free punishment predicted the level of punishment when it was costly (De Quervain et al., 2004). Furthermore, the punishment decision involved a trade-off between reduction in personal rewards and the satisfaction arising from punishing. Hence, it activated the median orbitofrontal cortex, which has been implicated in similar trade-offs. These results speak to an important puzzle in classical game theory that arises from the empirical results from public goods games with punishment: Why do people punish when bygones are bygones? The neural answer is simply that people derive satisfaction from the act of punishing norm offenders; such punishment activates the brain's reward circuits, hence, punishment confers hedonic benefits. Players who are treated

unfairly in ultimatum games show increased activation of the emotional regions of the brain such as the anterior insula (Sanfey et al., 2003). Thus, unfair offers appear to elicit an emotional or affective response.

The differing neural responses in punishing ingroup and outgroup members provide a neural basis for *parochial altruism* (Baumgartner et al., 2012). In punishing outgroup members there is activation in the right orbitofrontal gyrus, right lateral prefrontal cortex, and the right dorsal caudatus. However, in punishing ingroup members, subjects must generate rationales for mitigating punishments. The neural circuitry that is activated in this case is the temporoparietal junction that is often implicated in neural research on the *theory of the mind*, i.e., mentalizing about the motives, strategies, and beliefs about others. Brain manipulation techniques show that disrupting the right lateral prefrontal cortex reduces rates of rejection in ultimatum games (Knoch et al., 2009). Individuals with lesions in the ventromedial prefrontal cortex exhibit different social preferences relative to non-lesioned subjects (Koenigs and Tranel, 2007; Krajbich et al., 2009). The amygdala has also been implicated in the evaluation of fairness in ultimatum games (Koscik and Tranel, 2011; Gispic et al., 2011). The size of the amygdala is also correlated with the size of one's social network (Bickart et al., 2011).

Section 23.5.4 considers the neural basis of selected human virtues. Neural activity in deceptive and honest players is markedly different when they play the same game. Activity in the anterior cingulate cortex and the right interior frontal gyrus in an anticipation task can successfully predict the extent of deception that an individual will engage in (Baumgartner et al., 2009). Section 23.5.5 shows that there is a neural basis to some of the constructs used in psychological game theory, such as the feeling of *guilt* in trust games when receivers return low amounts to trustors (Chang et al., 2011).

Section 23.6 considers the neuroeconomics of time preferences. Support is found for two different models of time discounting considered in Part 3, (β, δ) quasi-hyperbolic discounting (Laibson, 1997), and the planner–doer models (Thaler and Shefrin, 1981; Fudenberg and Levine, 2006). Separate areas of the brain are activated when subjects express a preference for immediate rewards (β -areas), relative to delayed rewards (δ -areas). β -areas include nucleus accumbens, subgenual cingulate cortex, and medial orbitofrontal cortex, while δ -areas include posterior cingulate cortex, posterior parietal cortex, and the insula (McClure et al., 2004, 2007). However, these results have been questioned by contrary empirical evidence (Glimcher et al., 2007; Kable and Glimcher, 2007). In the planner–doer models, fMRI evidence indicates that the dorsolateral prefrontal cortex plays the role of a patient long-run planner (Hare et al., 2009). Temporary disruption of the dorsolateral prefrontal cortex using brain manipulation techniques leads subjects to choose more immediate rewards, which is consistent with the planner–doer approach (Figner et al., 2010).

Section 23.7 considers the neuroeconomics of strategic interaction. A major thrust of this literature is to uncover neural activity that illuminates how players develop and use a theory of the mind. In other words, how do players infer the likely strategies, beliefs, and mental models of others? One method of revealing a theory of the mind is to check for the contrast when humans play against human opponents and against computers. Different neural circuits appear to be engaged in the human–human and human–computer pairings (Gallagher et al., 2002; McCabe et al., 2001; Coricelli and Nagel, 2009).

Another issue is the differing neural activity of “equilibrium types” who play in accordance with classical equilibrium strategies, and the behavioral types who play non-equilibrium strategies (e.g., level- k players). Since beliefs and choices are aligned for equilibrium subjects, as hypothesized their brain activity occurred in largely similar areas, but for non-equilibrium subjects, brain activity was much more dispersed (Bhatt and Camerer, 2005). Within level- k subjects,

differing neural activity has been found among high and low level reasoners in a p-beauty game; decisions of high level reasoners were associated with relatively greater activity in the medial prefrontal cortex (Coricelli and Nagel, 2009). Two brain areas were particularly highlighted for high level reasoners; one is associated with taking a third person perspective while the other is involved in thinking about the strategies of like-minded other people. However, results from other studies have not always supported these conclusions (Kuo et al., 2009). Finally, we consider the neural basis of deception that is of critical importance in game theory. Emerging evidence supports level- k reasoning in simple, two-player, buyer–seller bargaining experiments where deception is possible (Bhatt et al., 2010, Bhatt et al., 2012).

Finally, in Section 23.8, we briefly touch upon the expanding literature on the pharmacology of economic and social decision making. The main aim of this research is to interfere with the body's *neuromodulator systems* by altering the levels of neuromodulators (dopamine, serotonin, norepinephrine), or hormones such as testosterone and oxytocin. We focus exclusive attention on the role of oxytocin as an illustration of this line of research. Readers interested in an authoritative and accessible survey can consult Crockett and Fehr (2014). Oxytocin has been shown to increase the level of trust that trustors place in trustees in trust games. However, the effect of oxytocin is very selective in influencing only the trust level of trustors; it does not alter the general level of optimism, risk perception, moods, or social trust (Kosfeld et al., 2005). Subsequent studies have enriched our understanding of oxytocin by examining the effects of interpersonal relations, generosity, cooperation, perceptions of trustworthiness, attractiveness, approachability, attachment, and socio-emotional responses such as envy and social aversion (Bartz et al., 2011). In the trust game, it is payoff improving for both parties if the trustor trusts more, hence, oxytocin plays a positive role. However, in other contexts, oxytocin may reduce the ability to recognize deceptive behavior and reduce one's payoffs (Israel et al., 2014).

23.2 A brief introduction to the brain

In this section, we briefly review some features of the human brain that are useful in the study of neuroeconomics; for an authoritative source for economists, see Glimcher and Fehr (2014). *Modularity* refers to the idea that the brain is composed of discrete parts that perform their own specific computations and then pass on the results to other brain areas for further processing and analysis (Gazzaniga, 2009). *Plasticity* refers to the ability of the brain to evolve and learn as the environment changes. *Automaticity* refers to the idea that we engage in certain behaviors/deliberations without being consciously aware that we are doing so.

We might often be unaware of the cause of our own behavior on account of automaticity. As Camerer et al. (2004) put it: “the human brain is like a monkey brain with a press secretary, which puts a coherent spin, and sometimes a wrong one, on what the monkey brain did.” The brain is sometimes “too good” for its own good at *sense making*. Experimental evidence, reviewed elsewhere in the book, indicates that people claim to spot regularity in completely random patterns such as stock market prices. Elsewhere, hot hands in basketball, the gambler's fallacy, the hindsight bias, and regression to the mean may also, perhaps, be guided by a similar desire for sense making even when the underlying data does not support these inferences based on classical statistics (see Part 7).

The flip side of these features is that the brain allocates attention selectively, which protects capacity limits in perception and cognition by biasing/prioritizing salient or relevant representations over others; recall, for instance, the phenomenon of confirmation bias discussed in Part 7.

In an interesting paper by Simons and Chabris (1999) with the title “Gorillas in our midst: Sustained inattention blindness for dynamic events”, subjects watch a video of six individuals playing basketball. The experimental task is to count the number of passes made by each team that wears a different jersey color. Within a minute, a gorilla walks into the center of the game and stays there for 9 seconds. At the end of the experiment, half the subjects in the experiment have no recollection of seeing a gorilla in the video clip.

When humans departed from their nearest primate relatives (about 6 million years ago), the human brain was not redesigned from scratch. Evolution, because it is inherently conservative and cautious, added neural regions imparting significant cognitive ability to humans, such as the prefrontal cortex, on top of the existing brain structures. Going back even further into evolutionary history, at the core of the human brain is a primitive mammalian brain, the limbic system, that controls emotions such as fear, anger, disgust, etc. Thus, experiments conducted on other mammals are of potential value for an understanding of the human brain, particularly those conducted on our nearest primate relatives. For instance, rats become addicted to almost all the substances that humans become addicted to (Camerer, 2007). Wrapped around this primitive mammalian brain is the neocortex (also called the cerebral cortex, which corresponds to people’s perception of “gray matter”) that accounts for about 5/6 of the human brain. The neocortex is responsible for human cognition, language, and speech. For instance, it allows humans, unlike other animals, to think about the longer-term consequences of their actions.

With this brief introductory background, let us consider the various brain regions that are important in neuroeconomics.³ The four main regions of the brain are shown in Figure 23.1. Each of the four lobes is responsible for functions that are either independent or overlapping. The *frontal lobe* is associated with cognition and logic. The *parietal lobe* is associated with recognition and movement; the *occipital lobe* with the processing of visual information; and the *temporal*

Figure 23.1 A classification of the brain into four lobes: frontal, parietal, occipital, and temporal.

³ For textbook treatments see Breedlove et al. (2014) and Bear et al. (2007). For a brief and clear introduction, see Glimcher and Fehr (2014). © Shutterstock

lobe with memory and auditory stimuli. Neuropsychological studies of aphasia (a term used for a collection of speech disorders) suggest that speech production and comprehension might be attributed to distinct frontal and temporal substrates. The lobes come in pairs, one on each side of the brain; language is associated with a left hemisphere function. The lobes are connected by neurons that enable the brain to simultaneously engage its various parts to generate a composite response to external stimuli.

Example 23.1 (Camerer et al., 2004): “When an automated insurance broker calls and says, ‘Don’t you want earthquake insurance? Press 1 for more information’ the occipital lobe ‘pictures’ your house collapsing; the temporal lobe feels a negative emotion; and the frontal lobe receives the emotional signal and weighs it against the likely cost of insurance. If the frontal lobe ‘decides’ you should find out more, the parietal lobe sends signals to your finger to press 1 on your phone.”

The following terminology is useful in identifying various brain regions; see Figure 23.2. We quote the following description from Zak (2004, p. 1739): “Terms for locations of brain regions include: dorsal (top, from the Latin for back); ventral (bottom facing the central axis, from the Latin for belly) or basal; rostral (front, from the Latin for beak) or anterior; caudal (back, from the Latin for tail) or posterior; superior (towards the top); inferior (towards the bottom);

Figure 23.2 A convenient classification of brain regions. © Shutterstock

medial/mesial (middle); lateral (away from midline); and orbital (above the eyes, from the Latin orbital meaning eye sockets).” In evolutionary terms, ventral brain regions are typically phylogenetically older in comparison to dorsal and rostral regions.

It is sometimes helpful to separate the brain into three divisions. These are the forebrain or *telencephalon*, midbrain or *mesencephalon*, and the hindbrain or *brainstem*; see Figure 23.3. The main focus in neuroeconomic research has been on the telencephalon. In turn, the telencephalon is typically divided into three main regions. These are the *cerebral cortex*, *basal ganglia*, and the *thalamus*; see Figures 23.3, 23.4. Our main focus will be on the cerebral cortex and the basal ganglia. Of these, in evolutionary terms, the cerebral cortex is the most recently evolved structure, while the basal ganglia, shown in Figure 23.4, is the oldest (recall that the more ventral structures are typically phylogenetically older).

The two regions in the basal ganglia, *caudate* and *putamen*, together comprise the *striatum*, an important brain region in neuroeconomics. The striatum, an input area of the basal ganglia, receives inputs from the frontal cortex and mainly sends its inputs to the output areas in the basal ganglia, the *globus pallidus* and the *substantia nigra pars reticula*. Another area in the basal ganglia that plays an important role in neuroeconomics is the dopaminergic system that is comprised of neurons that release dopamine in the *ventral tegmental area* and the *substantia nigra pars compacta*.

The brain is covered with an outer layer of neural tissue called the *cerebral cortex*; in common usage this is also referred to as *gray matter*. Dense axons under the gray matter are sometimes known as *white matter*. The most recent evolutionary part of the cerebral cortex is the neocortex, which is a six layered structure shown in Figure 23.5. Each layer can have different kinds of neurons, and has its own functional specialization, but overall the neocortex is fairly uniform. For instance, layer 4 (the internal granular layer) is typically an input region in the cortex and layer 5 comprises mainly the pyramidal neurons that connect, through their axons, with other regions in the cortex. The phylogenetically more ancient part of the cerebral cortex is the hippocampus, which is a three layered structure. In order to increase surface area within the confines of the

THE LIMBIC SYSTEM

Figure 23.6 The limbic system of the brain. © Shutterstock

skull, the cerebral cortex is folded; ridges are known as gyri (singular gyrus) and grooves are known as sulci (singular sulcus).

Figure 23.6 shows a sketch of the limbic system, which is a part of the forebrain; some of the important limbic structures for neuroeconomic research are the hippocampus, amygdala, fornix, mammillary body, and cingulate gyrus. The amygdala is a part of the telencephalon, yet it is not considered to be a part of the basal ganglia or of the cerebral cortex. The amygdala is activated when individuals experience fear or a perceived threat; it receives inputs from several sensory areas and feeds into the hypothalamus. The hippocampus, a three layered structure, is a part of the ancient cortex; it is associated with long-term memory and plays a central role in neuroeconomic studies of learning and memory.

Korbinian Brodmann classified the brain into distinct, numbered, regions based on the differences in neuronal architecture between these regions. This classification, published originally in 1909, is shown in Figure 23.7 (Brodmann, 1909). The Brodmann areas typically perform well-defined and discrete tasks. Some Brodmann regions receive inputs from the eyes and ears, so they are referred to as *sensory areas*, while others are associated with the control of movement, so they are known as *motor areas*. We can use the Brodmann areas to identify an important region of interest for neuroeconomists, the *prefrontal cortex*, abbreviated as PFC; this is neither a sensory, nor a motor, area and is sometimes referred to as an *association area*. The PFC comprises of the following three regions. *Dorsolateral prefrontal cortex* abbreviated as dlPFC (areas 9, 46); *ventromedial prefrontal cortex*, abbreviated as vmPFC (area 45); *orbitofrontal cortex* OFC (area 10).

Different parts of the brain communicate with each other through special cells called *neurons* or *nerve cells*. There are many kinds of neurons in the human body. For instance, the motor neurons receive information from the spinal cord and are responsible for muscle contractions. The sensory neurons respond to the senses, e.g., touch, and transmit signals to the spinal cord. Figure 23.8 shows two neurons and the basic structure of a neuron; multiple arrows represent the direction of the flow of information.

Figure 23.7 Brodmann areas of the human brain.

Figure 23.8 The structure of a neuron. © Shutterstock

The bulbous cell body, or *soma*, encloses the nucleus; different structures inside the cell body process sugars and oxygen to provide the energy that powers the neuron. Several thin structures that can branch several times, called *dendrites*, emanate from the soma; these are the input structures of the neuron and receive information from other neurons. A single, thin, output structure, the *axon*, originates from each cell body of a neuron. It transmits electrochemical information to a neighboring neuron through special structures called *synapses* that come into contact with the dendrites of other neurons. Axons can be quite long, and in rare cases, up to a meter long. Unlike dendrites, each neuron has a single axon, which nevertheless can branch several times.

Signals between neurons are sometimes known as *action potentials* or simply *spikes*. Neurons are surrounded, like all cells, by a thin *membrane* impermeable to water-based chemicals that is perforated by tiny tubes or *channels*. These tubes, also known as ion channels, allow for the exchange of sodium ions (relatively abundant outside the membrane) and potassium ions (relatively abundant inside the soma). *Neurotransmitters* that move from the synapse of one axon onto the dendrite of another axon regulate the opening and closing of the ion channels. Neurons have an electric resting potential of about -70 microvolts. This means that when the neuron is not sending any signals, the inside of the neuron is 70 microvolts less than the outside and there are relatively more sodium ions outside the neuron but relatively more potassium ions inside. Action potentials occur if the voltage in a neuron exceeds a certain threshold, typically around -50 microvolts caused by inputs from other neurons. This allows the ion channels in the membranes of neurons to be activated. Depending on the type of the neuron, the baseline firing rates vary from a few spikes per second to about a hundred spikes per second.

We shall sometimes report activity in an area of the brain by its (x, y, z) coordinates; most software packages use the Montreal Neurological Institute (MNI) coordinates. Camerer et al. (2015) succinctly explain these coordinates: “A higher positive value of y is further forward, or more anterior, in the brain; more negative values are more posterior toward the back of the brain. Similarly, x values range from the left side (most negative) to the right side (most positive), and z -values range from most negative (the inferior part or bottom of the brain) to the most positive (the superior part or top of the brain).”

23.3 An introduction to neuroeconomic techniques

Neuroeconomics uses a range of methods to gather evidence and form inferences.⁴ Many methods of neuroeconomic measurement aim to measure the flow of electrochemical information between neurons. Different techniques measure different aspects of neural activity with varying degrees of accuracy and precision. It might help to distinguish between two categories of techniques.

Measurement techniques measure some form of brain activity using, say, neuronal firing rates, or metabolic activity, when subjects in experiments engage in some relevant economic choice. Such techniques typically establish correlation but not causation between brain activity and human decisions. *Manipulation techniques*, on the other hand, alter some aspect of brain function temporarily or permanently and observe the causal effect on human decisions. It is possible to alter the neuronal firing rates in a selected region of the brain, or to alter the neurotransmitter levels in a transient manner. In animal studies, it is possible to permanently damage brain tissue and then observe which aspects of animal behavior change. Human subjects may have *brain*

⁴ For an excellent and concise introduction, see Ruff and Huettel (2014) that we draw upon below.

lesions caused by infections or by accidents that are also used in manipulation techniques. There is a degree of complementarity between the two techniques because measurement techniques may identify brain areas that can be manipulated later to establish causality.

23.3.1 *Criteria for evaluating neuroeconomic measurement techniques*

Alternative methods of measuring brain activity have their pros and cons. Hence, alternative techniques play a complementary role in building a richer picture of the relation between brain activity and economic decisions. Neuroeconomic methods of measurement may be evaluated on the following three main criteria.

(1) *Temporal resolution* is the frequency with which brain activity is recorded. The best techniques that measure neuronal activity directly, by measuring the flow of ions in brain tissue (electrophysiological measurements), achieve millisecond precision. Indirect measures of neuronal activity, such as measuring changes in blood oxygen levels in the brain, have intermediate temporal resolution that ranges from seconds to minutes. Brain manipulation techniques, say, drug induced temporary damage to brain tissue, have the lowest precision that ranges from minutes to days (the exception is event-related transcranial magnetic stimulation).

(2) *Spatial resolution* is the precision with which one can narrow down brain activity to a particular region of the brain. Naturally, techniques that place electrode sensors directly in the brain, typically in animals, achieve the highest spatial resolution and may measure activity directly for a particular neuron. Functional neuroimaging techniques that are extremely popular (see below) achieve spatial resolution of millimeters to centimeters. Finally, techniques that measure electrical signals of brain activity non-invasively, say, by measurements taken on the skull, achieve the poorest spatial resolution that ranges from centimeters to the entire brain.

(3) *Degree of invasiveness* refers to the extent to which one may have to interfere with brain processes in order to measure brain activity. Examples include knocking-out areas of the brain temporarily or permanently; the latter is typically possible only with animals. In humans, invasive techniques may be used prior to neurosurgery.

Our focus is not on the estimation and computation techniques of neuroeconomics. The interested reader can begin with Busemeyer and Diederich (2014) and follow the references therein.

The older methods measure *psychophysical* activity, i.e., the involuntary reaction to stimuli. These methods include, for instance, pupil dilation, skin conductance, and the heart rate. We now focus on some of the modern methods of measurement.

23.3.2 *Single unit recording*

Using fairly invasive methods, one can measure the electrical activity in a single targeted neuron. An electrode, typically a very thin insulated wire, is inserted in the neural tissue surrounding a single neuron; this is able to measure the neuron's electrical activity. Such techniques are quite invasive because they involve the opening of the skull, hence, they are typically used only on animals. However, they are also sometimes used on humans, who for some medical reasons, e.g., epilepsy, need to have an electrode inserted in their brain. Since animals share the affective rather than the deliberative faculties of the brain with humans, this evidence speaks more to the emotional rather than cognitive aspects of behavior. The advantage of these techniques is that they can target their location very precisely.

Most neurons are extremely small, so it might not always be possible to distinguish the firing rate of a neuron from other neurons in close proximity. However, improvements in techniques

have reduced this problem. Single unit recording has very high temporal and spatial resolution, hence, it has enabled the identification of some of the core brain functions. Since the method is highly targeted at specific neurons, and neurons differ in their firing rates and their responses to different inputs, it helps to build a picture of brain functions that is unmatched in comparison to the other methods. The main drawback of the technique is the degree of invasiveness, and the rate of data collection is very slow because data is collected for a single neuron at a time. Animal colonies for experimental purposes are costly to maintain, so the technique is relatively expensive. Finally, the technique is also not very suitable when analyzing complex brain functions that involve interactions among several parts of the brain or neural coding at the population level.

23.3.3 *Electroencephalography and magnetoencephalography*

The *electroencephalogram* (EEG) measures brain activity, externally, say, by electrodes positioned on the scalp, or positioned internally, while subjects make some decisions. EEG at the scalp measures changes in the polarity of synchronously firing populations of neurons. The advantages of this technique are as follows. (i) It measures brain activity directly, rather than using some proxy such as blood flow or the level of metabolism. (ii) It has a high temporal resolution that allows one to study dynamic processes in the brain. (iii) It is relatively inexpensive in terms of equipment, say, relative to the cost of an MRI scanner (although the set-up time to position the electrodes correctly on the scalp is high). The disadvantage is that it has low spatial resolution, i.e., it measures aggregate brain activity in some region of the brain and cannot always localize the source of that activity.

An alternative to measuring electrical activity is to measure the magnetic fields associated with electrical activity in the neurons; this technique is known as *magnetoencephalography*. It has similarly high temporal resolution as electroencephalography but does not suffer from the problem of weakening of the electrical signal on passing through the skull, which is the case with electroencephalography. However, the magnetic fields are relatively weak and the equipment is relatively expensive, hence, not many studies in neuroeconomics have used it.

23.3.4 *Positron Emission Tomography*

Positron Emission Tomography (PET) relies on early work done in the 1950s and falls within the ambit of *functional neuroimaging*, i.e., producing 2D or 3D maps of brain activity. The method is to inject a weak, short-lived, radioactive isotope into the body of a subject in the experiment. Once enough time has been given for the solution to permeate the tissue of interest, the radioactive solution decays and emits positrons. The emitted positrons collide with electrons within a short distance and emit gamma rays. A *PET scanner* records the gamma rays and assigns to them a likely region of origin in the brain; this gives rise to a *PET image*.

The disadvantages of this technique are that it is invasive, relatively expensive, and its temporal resolution is relatively low (it shows average brain activity over an entire experiment), while its spatial resolution is intermediate. However, there are some advantages over other functional neuroimaging techniques such as fMRI, which relies on blood flow to correlate with neural activity. For instance, PET provides a more direct indicator of neural activity and, by creating customized molecules that are attached to radioactive isotopes, it can provide fairly precise chemical information.

23.3.5 *Functional magnetic resonance imaging*

Magnetic resonance imaging (MRI) is a body imaging technique that is about 35 years old. It can provide detailed information about any part of the human body in any plane. The idea is to expose the body to a powerful magnetic field so that the protons in human cells line up with the direction of the magnetic field. A second electromagnetic field is then switched on which enables the protons to absorb the energy of this field. When this secondary electromagnetic field is switched off, the protons emit the energy that they have absorbed. MRI contrasts are then created based on the speed with which protons realign with the magnetic field once the radio frequency pulse offsets. Protons from different tissues in the body emit energy in different ways, allowing the researcher to form detailed internal images of the body.

A newer version of the MRI is the *functional magnetic resonance imaging* technique (fMRI) that has been developed since the early 1990s and is very popular.⁵ Electrical activity in the brain requires the firing of neurons. However, neurons do not have their own internal source of energy. Hence, when neurons need to fire, they absorb oxygen from the surrounding blood stream. This increases the blood flow towards those neurons (a process called as *hemodynamics*) after a delay of between 1–5 seconds. The response of oxygenated blood to a magnetic field is different from that of deoxygenated blood; this is known as the blood-oxygenation-level-dependent (BOLD) contrast. The BOLD contrast allows a magnetic field to pick out the neurons that are firing (say, in response to some stimuli). The fMRI interface modifies the MRI technique by installing an MR-compatible monitor or a head mounted display, which subjects use to register their choices and decisions by using a joystick or pressing buttons. Arguably the biggest distinction between fMRI and MRI is that fMRI measures changes in the BOLD signals while MRI produces high resolution structural images of the brain's morphology.

The advantage of the fMRI technique is that it is non-invasive (like the EEG) and it has good spatial resolution (3–6 millimeters). The disadvantage, relative to the EEG, is that it has poorer temporal resolution (several seconds), although it is still relatively good. This is because, while the EEG measures electrical activity, fMRI measures the differential response of oxygenated and deoxygenated blood. Other shortcomings are that (1) it is relatively expensive, (2) subjects face many repeated trials to uncover the underlying brain processes, even for essentially static games, and (3) the MRI scanner is loud and it presents a confined environment. The unit of measurement in fMRI trials is typically a *voxel* that localizes brain activity using three-dimensional coordinates. The typical fMRI voxels are 27 mm^3 , i.e., a cube whose sides are of 3 mm length. Each voxel can have more than a million brain cells.

The fMRI technique allows one to correlate an external stimulus with hemodynamic activity in a certain part of the brain. It does not directly establish causality, although it can do so indirectly by running more than one treatment. One can use observations on neural activity from some treatment, and then make predictions of neural activity that will arise in another treatment, also known as “out of treatment forecasting.” Fehr and Camerer (2007) give the following examples (p. 423): “For example, individual differences in caudate nucleus activation when punishment is costless for the punisher can be used to predict how much individuals actually pay for punishment when it is not costless. Likewise, individual differences in striatal activity in the condition in which donations are forced can be used to predict subjects’ willingness to donate money to charities in the condition in which donations are voluntary.”

⁵ For a textbook treatment of the technique, see Huettel et al. (2009).

23.3.6 Manipulation techniques

The techniques discussed above, establish correlation between human decisions and activity in specific regions of the brain. This does not establish causality (unless one uses out of treatment forecasting). We now move into the category of *manipulation techniques* that either temporarily or permanently disable a brain area or heighten activity in that area, and then study the resulting behavioral implications. Brain lesions and neuropharmacological interventions provide an opportunity to apply these techniques in humans. The basic principles have been understood for a long time, initially by using invasive studies for animals (Fritsch and Hitzig, 1870) and humans (Penfield and Rasmussen, 1950).

Most studies nowadays use non-invasive methods; the two most popular methods are *transcranial magnetic stimulation* and *transcranial direct current stimulation*. These studies take a step towards establishing causality but none of the methods, on their own, can conclusively establish causality. A great difficulty in establishing causality in neuroeconomic studies is that the same brain region is typically activated in a range of economic situations. Given the current state of knowledge in neuroeconomics, it is very difficult to establish causality from an activation of a brain region (Poldrack, 2006). One typically uses other supporting evidence to increase faith in the degree of causality; this includes moods, skin conductance measures, and response times; see Hutzler (2014) for a view that is more sympathetic to the ability of neuroscience data to establish causality.

TRANSCRANIAL MAGNETIC STIMULATION

Transcranial magnetic stimulation (TMS) is a non-invasive manipulation method.⁶ As noted above, neurons have an electric resting potential of -70 microvolts. TMS takes the form of stimulating areas in the brain by using the principle of electromagnetic induction. A weak electrical current is induced in the neurons belonging to a selected part of the brain by rapidly changing magnetic fields. This is achieved by placing a looped copper coil on the part of the scalp directly over the brain region that is intended to be stimulated; not all locations in the brain are equally easy to stimulate.

Modern studies typically use repetitive TMS (rTMS) pulses separated by only a few milliseconds to achieve high temporal resolution. One may apply rTMS pulses in one of two ways: in an *online fashion* or in an *offline fashion*. When applied in the offline fashion, rTMS is applied at low temporal frequency for several minutes just prior to subjects' participation in the actual experimental task. This induces lowered cortical excitability in a particular brain region that lasts for 10–30 minutes. When applied in the online fashion, rTMS pulses serve to heighten cortical activity. If part X of the brain is thought to perform some task T, then TMS can be used to momentarily enhance or knock out part X. If this affects performance on task T, then it is suggestive of the causality of brain region X for task T.

A major advantage of the TMS technique is that it is non-invasive and has high spatial and temporal resolution. A disadvantage is that it is more difficult to be precise in targeting a specific brain area, particularly the deeper brain areas. In the offline studies, it is not always clear how long the rTMS pulse should be applied, prior to the experiment. Furthermore, some subjects might find the procedure noisy and uncomfortable.

⁶ See Wassermann et al. (2008) for a book length treatment.

TRANSCRANIAL DIRECT CURRENT STIMULATION

Under *transcranial direct current stimulation* (tDCS), two electrodes are placed on the scalp and an electric current is passed through them. This affects the voltage in the membranes of the neurons along the path of the current and, thus, their firing rates, which can be measured. One of the electrodes is positively charged (anodal) and the other is negatively charged (cathodal).

There are two main types of tDCS simulations. Under *anodal* tDCS, the neurons are upregulated, or stimulated, while under *cathodal* tDCS, they are downregulated. A third kind of simulation, *sham simulation*, applies only a momentary current for the same length of time as the other two simulations; subjects are not told that they are in a sham simulation treatment, hence, this acts as a placebo treatment.

The advantages of tDCS are that it is relatively inexpensive, not noisy, and unlike TMS, it does not have unpleasant tactile sensations. One can run tDCS experiments simultaneously with a group of subjects (not possible under many other methods, such as fMRI). This feature is very useful in running a wider range of experiments, particularly those that involve social preferences.

BRAIN LESION STUDIES

One may study individuals who exhibit behavioral deficits following damage to some area of the brain (brain lesions); this is part of the subject matter of *neuropsychology*. The classic study is based on a grievous accident suffered by a Vermont Railway worker, Phineas Gage, in 1848.⁷ In an injury caused by a dynamite explosion, a tamping iron rod went through the side of his face, through the back of his left eye and broke the top of his skull; see Figure 23.9.

Figure 23.9 A drawing showing the skull of Phineas Gage, after a tamping iron went through it. © Everett Collection Historical/Alamy Stock Photo

⁷ An excellent account of the incident can be found on the wikipedia page: http://en.wikipedia.org/wiki/Phineas_Gage. © Everett Collection Historical / Alamy Stock Photo

Phineas Gage survived the accident but the destruction to his left prefrontal cortex significantly altered his behavior. Post-accident, he exhibited lack of foresight, fickle changes of mind, bad temper, impulsiveness, and several kinds of emotion deficits that were previously absent in his behavior (Harlow, 1868).⁸ A case study of this accident contributed significantly to an understanding of the causal role of the prefrontal cortex.

Brain lesions can occur in many ways, for instance, surgical removal of tumors, brain infections such as meningitis or encephalitis, and exposure to neurotoxins such as excessive alcohol. The challenge is to pinpoint, as accurately as possible, the exact location of the brain lesion. In *double dissociation studies*, one establishes that two groups of patients with different brain lesions perform differently in two distinct tasks. This is an important component in establishing causality. Brain lesion studies are subject to two disadvantages. First, one typically does not have data on patients prior to their brain lesions. Second, as the brain reorganizes in the period following the brain lesion, as it appears to have done in the later years of Phineas Gage's life, one needs to separate two different effects: Those arising from the original brain lesion and those arising from brain reorganization. In animals, brain lesion studies involve more direct and invasive intervention in which the targeted brain tissue is either permanently or temporarily disabled. In a control group, an identical surgery is performed but the relevant brain areas are not disabled; clearly this is not possible with human subjects.

23.4 The neuroeconomics of risky decisions

Part 1 considered alternative theories of risk, uncertainty, and ambiguity. The behavioral evidence indicates that among the available behavioral theories, prospect theory is currently the most satisfactory alternative. For this reason, this section focuses mainly on the neural evidence for prospect theory.

23.4.1 Neural basis of value and risk

There is a large literature on the neural encoding of value for simple binary tasks that differ in the quantity or quality of a reward. For instance, choosing between a higher and lower quantity of apples, or choosing between a more or less tasty variety of apple. The aim is to show that the brain computes something like the utility of an outcome. While there is substantial merit in understanding the correlates of neural activity for simple choice tasks, it is not clear if the insights gained from this analysis carry over to more complex tasks such as deciding among complex portfolios of stocks, or among alternative pension plans (Camerer, 2013). For this

⁸ Here is the full quote from Harlow (1868, pp. 13–14), who was the doctor who treated him using pioneering methods: "The equilibrium or balance, so to speak, between his intellectual faculties and animal propensities, seems to have been destroyed. He is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires, at times pertinaciously obstinate, yet capricious and vacillating, devising many plans of future operations, which are no sooner arranged than they are abandoned in turn for others appearing more feasible. A child in his intellectual capacity and manifestations, he has the animal passions of a strong man. Previous to his injury, although untrained in the schools, he possessed a well-balanced mind, and was looked upon by those who knew him as a shrewd, smart business man, very energetic and persistent in executing all his plans of operation. In this regard his mind was radically changed, so decidedly that his friends and acquaintances said he was 'no longer Gage'."

reason, our discussion will be brief. The interested reader can consult several references for more details.⁹

A typical experiment in this literature proceeds as follows. The subjective value assigned by subjects to an object is elicited, using standard behavioral economics experiments. For instance, subjects might be asked to bid for an item under institutional rules such as second price auctions, which predict that bids and valuations for the item will be identical. While placing the bids, the brain activity of subjects is measured, say, using fMRI techniques, or single neuron recordings. One could then ask, which brain regions are particularly active, or what brain circuitry is implicated when individuals choose high value items? The items used in the analysis are typically simple food items such as snacks (Plassmann et al., 2007). The main result from these experiments indicates that value is encoded in the vmPFC. Experiments using gambles, charitable contributions, and delayed monetary rewards also support this result (Levy et al., 2010; Kable and Glimcher, 2007; Hare et al., 2009).

An important insight in this literature is to address the observed choice between options by individuals; a choice that appears apparently stochastic. For instance when individuals are repeatedly asked to make a choice between two close options, A and B, or we use a between-subjects design to study the choice between these two options, there is an element of stochasticity to the choices. One way of modeling stochasticity in choices is to use random utility models (see the introductory chapter and Part I). An alternative, and intriguing, possibility is that this stochasticity reflects noise in underlying cognitive processing (Glimcher, 2011; Woodford, 2014).¹⁰ Thinking of options A and B as two external stimuli, the choice made by an individual depends on the number of spikes produced by different populations of neurons, each tuned to respond differentially to the two stimuli. The number of spikes, in turn, is drawn from an underlying probability distribution that could be common to the two options. For binary choice data, Clithero and Rangel (2013) show that when response times are taken into account, the out of sample predictions based on such a model (the drift-diffusion model) outperform the predictions from the standard logistic model.

Recall the distinction between *decision utility* and *experienced utility* that we made in Part 7; the evidence indicates that this distinction has a neural basis. A quick summary of the literature is as follows.

(1) *Decision utility*, or *subjective expected value*, arises at the time of making choices. Different choice options give rise to different *stimulus values* (SV), which are compared to determine the option with the highest SV (Wallis, 2007; Kable and Glimcher, 2009; Rangel et al., 2008; Rangel and Hare, 2010; Rushworth et al., 2009). Furthermore, fMRI evidence shows that SV signals have been found in the vmPFC (Chib et al., 2009; Hare et al., 2008, 2009; Kable and Glimcher, 2007; Padoa-Schioppa, 2009; Plassmann et al., 2007; Plassmann et al., 2010; Tom et al., 2007). The vmPFC also appears to encode value from *appetitive goals* (e.g., tempting food when hungry) and *aversive goals* (e.g., an electric shock) (Litt et al., 2010; Plassmann et al., 2010). Single neuron studies in monkeys show that decision value signals exhibit *range adaptation*, i.e., the neuronal activity range does not depend on the range of values given (Padoa-Schioppa, 2009; Padoa-Schioppa and Assad, 2006). If these findings apply to humans, they could violate the standard assumption of independence of irrelevant alternatives.

⁹ For a book length treatment, see Glimcher (2011); for a survey for economists, see Fehr and Rangel (2011); and for a critical and insightful commentary on this literature, see Camerer (2013).

¹⁰ For a recent theoretical exploration of the relation between the two approaches, see Webb (2015).

(2) *Experienced utility* is the *experienced subjective value* (R) at the time of consumption. While the vmPFC is activated in the case of decision utility, as described above, experienced utility appears to be associated instead with the orbitofrontal cortex and the nucleus accumbens (Blood and Zatorre, 2001; de Araujo et al., 2003; McClure et al., 2004). The initial price of a product may signal the quality of a product, hence, it could also influence the experienced utility from the product. Plassmann et al. (2008) varied the original price for an identical wine after which subjects received sprints of the wine inside a fMRI scanner. They found that experienced utilities were positively influenced by the initial price and higher experienced utility was associated with greater activity in the orbitofrontal cortex.

(3) *Prediction error* (PE) is the difference between decision utility and experienced utility. PE is used to update stimulus values in models of reinforcement learning. The main brain region associated with PE in human fMRI studies is the ventral striatum (Delgado et al., 2000; Berns et al., 2001; Yacubian et al., 2006; Hare et al., 2008).

Many models in finance use mean-variance utility analysis. Evidence suggests that different brain areas encode the mean and variance of rewards. Mean rewards are correlated with activity in the striatum (Preusschoff et al., 2006) while variance of rewards, since it reflects risk, activates the insula (Mohr et al., 2010). The greater activation of the insula when presented with higher risks suggests that there is an *affective response* to risk that is consistent with the *risk as feelings* hypothesis of Loewenstein et al. (2001) (see Part 6). tDCS studies show that stimulation of the right dlPFC increases risk aversion (Fecteau et al., 2007) and disrupting the dlPFC increases risk seeking (Knoch et al., 2006).

An alternative approach to studying neural activity is to propose axioms related to the neural encoding of rewards and prediction errors (differences between decision and experience utilities). This approach has been used, for instance, to test the *dopaminergic reward prediction error hypothesis* (DRPE) (Caplin and Dean, 2008; Caplin et al., 2010). The DRPE hypothesis relates to the responsiveness of dopamine release (a neurotransmitter) from dopamine neurons as various external stimuli, such as rewards or probabilities are manipulated. An advantage of the axiomatic approach is that it makes very precise and testable predictions. The axiomatic approach also allows for a more direct and stringent test of the DRPE hypothesis because one can dispense with auxiliary assumptions based on reinforcement learning that alternative approaches have relied upon. Camerer (2013, Section 4.1) critically evaluates the axiomatic approach relative to the alternative approach of fitting ever improving functional forms as the understanding of a phenomenon improves. Camerer's (2013, p. 1167) own assessment of the axiomatic approach, at this relatively early stage, is that: "I agree that there is an added dimension of 'rigour' . . . but there is not a big leap in knowledge."

23.4.2 Reference dependence

One implication of reference dependence is the identification of differences in behavioral patterns in the domains of gains and losses. De Martino et al. (2006) exploit this implication to study the neurobiological basis of reference dependence. Twenty subjects initially received an endowment of £50 and were then asked to choose between risky options of the form $(x, p; -y, 1 - p)$ and a sure option $(z, 1)$, where x, y, z are monetary amounts and $p > 0$ is a probability. The sure outcome, z , was either framed as a gain or as a loss. For instance, in the *gain frame*, the sure option could take the form "keep £20 of the £50." In the *loss frame*, the equivalent sure option is described as "lose £30 of the £50." Subjects chose the risky option in 42.9% of the cases in the gain frame and 61.6% of the cases in the loss frame; these proportions are different from 50% at the 5% significance

Figure 23.10 fMRI results for the gain and loss frames.

Source: From De Martino, B., Kumaran, D., Seymour, B., and Dolan, B. J. (2006). "Frames, biases, and rational decision-making in the human brain. *Science* 313: 684–7. Reprinted with permission from AAAS.

level. Thus, as expected, under prospect theory, decision makers are risk averse in the gain frame and risk seeking in the loss frame (the authors do not check for the *fourfold classification of risk* under prospect theory; see Part 1).

Decisions between lotteries were made inside an fMRI scanner. Thus, brain activity was monitored when in the gains frame subjects chose the sure option (G_{sure}) or the risky option (G_{gamble}). Likewise in the loss domain they were monitored when they chose either the sure option (L_{sure}) or the risky option (L_{gamble}). The main contrast was between activation in brain areas when subjects chose in accordance with their predominant behavioral tendency ($G_{sure} + L_{gamble}$) or against it ($G_{gamble} + L_{sure}$).

The main results are shown in Figure 23.10. Panel A shows activation in the amygdala when subjects choose according to their predominant behavioral tendencies (sure outcome in gains and risky outcome in losses). Panel B shows the percentage signal change for peaks in the right amygdala; a positive change is observed when choosing according to their behavioral tendencies and a negative change when they do not choose according to it. When subjects choose contrary to their behavioral tendencies (risky outcome in gains and sure outcomes in losses) the fMRI scan in Panel C shows activation mainly in the ACC and to a lesser extent in the dlPFC. In Panel D, one can observe relatively increased activation in the ACC when subjects make choices contrary to their behavioral tendencies.

Subjects who resisted framing effects (gains and losses are the two frames) showed relatively greater activation in the orbitomedial prefrontal cortex (omPFC). The authors interpret

activation in the amygdala when subjects are susceptible to framing effects as driven by an affect heuristic (p. 686). Furthermore, they argue (p. 687) that “As such, our findings support a model in which the omPFC evaluates and integrates emotional and cognitive information, thus underpinning more rational (i.e., description-invariant) behavior.”

These results were replicated in the study by Roiser et al. (2009) who showed that subjects who had a specific genetic neurotransmitter variant were more influenced by framing effects. But when this genetic variant was absent, subjects appeared to show no framing effects. However, Talmi et al. (2010) found that amygdala lesioned subjects continued to exhibit framing effects of the sort studied in De Martino et al. (2006). This makes it difficult to implicate the amygdala conclusively in framing effects. In related neuroeconomic studies of the disparity between WTP and WTA (for which reference dependence is a necessary condition) a correlation has been found between (i) WTP and activation in the vmPFC, and (ii) WTA and activation in the lateral orbitofrontal region (Knutson et al., 2008; De Martino et al., 2009).¹¹

23.4.3 *Loss aversion*

Tom et al. (2007) examine the neural correlates of loss aversion. They presented subjects with a range of choices between accepting or rejecting lotteries of the form $(x, p; -y, 1 - p)$, where $x > 0$ and $y > 0$. In order to ensure that subjects would never be out of pocket, they were given an endowment of money larger than the maximum loss that they could incur. Subjects were asked to rate the strength of their acceptance or rejection on a four point scale.

The median loss aversion was found to be 1.93. Other things fixed, as the size of gains increased, there was increased activation in dorsal and ventral striatum, vmPFC, vlPFC, ACC, OFC, and dopaminergic midbrain regions. There are two competing hypotheses about brain activation when subjects are presented with increased potential losses. One hypothesis is that loss aversion may be driven by a fear response that is caused by activation of brain regions such as the amygdala and anterior insula. An alternative hypothesis is that gains and losses are mediated by a single system. In this study, support is found for the second hypothesis. No brain region is found to be additionally activated when the size of potential loss in gambles increased. The same brain areas involved in the computation of expected rewards for gains showed decreased activity when potential losses are increased; these areas are the striatum, vmPFC, ventral ACC, and medial OFC. In particular, there was hardly any activity in the amygdala and the insula. Thus, it appears that there is a single brain system involved in the computation of gains and losses. Increased activity in the striatum that is associated with gains and decreased activity in the striatum associated with losses is consistent with the findings from some other studies (Breiter et al., 2001; Delgado et al., 2003). Replications of these findings also showed up decreased activity in the vmPFC when losses are increased (Cunningham et al., 2009; Plassmann et al., 2010).

So how do these results compare with other studies that find activation in the amygdala and the insula in the evaluation of lotteries with losses (Kahn et al., 2002; Kuhnen and Knutson, 2005)? Tom et al. (2007) conjecture that their experiments focused on decision utility, while the other studies might have been picking up the effects of prediction errors. De Martino et al. (2006) find a correlation in activity in the amygdala and an increase in risk. However, risk and loss aversion are different concepts. Furthermore, Tom et al. (2007) identify a form of *neural loss aversion*. The positive slope which reflects the increase in activity in the striatum and the vmPFC for gains is found to be smaller than the absolute value of the negative slope that

¹¹ For more details, the interested reader can pursue Louie and De Martino (2014).

measures a decrease in activity for losses in the same brain areas. Thus, these results provide support for a core component of prospect theory—loss aversion—a feature that humans share with close primate relatives such as capuchin monkeys (see Part 1 for the details on the empirical evidence).

Yacubian et al. (2006) consider the neural correlates of positive and negative expected values of lotteries using fMRI data. Let $x < 0 < y$, and consider choices over lotteries of the form $(x, p; y, 1 - p)$. Then the expected value EV can be written as $EV = EV^+ + EV^-$, where $EV^+ = y(1 - p)$ and $EV^- = xp$. The prediction error is given by $PE = R - EV$, where R is the actual outcome, x or y . EV^+ was found to be correlated with activity in the ventral striatum; in particular, the bilateral ventral striatum was activated as the reward magnitude or its probability increased. EV^- was correlated with activity in the bilateral amygdala.

An alternative method of discovering brain areas associated with loss aversion is to study patients with brain lesions. De Martino et al. (2010) study the behavior of two subjects with lesions in the amygdala. Subject SM, a 43 year old woman, had lesions in the entire amygdala region, while subject AM's lesions were confined to 50% of the amygdala. Both subjects were endowed with \$50 cash and then asked to accept or reject a series of mixed gambles in which gains ranged from \$20 to \$50 and losses ranged from $-\$20$ to $-\$50$. The decisions of each subject were compared to a set of six subjects, comparable in terms of education, age, income, and gender; these subjects played the role of control subjects.

Both lesioned subjects exhibit no loss aversion relative to their respective control groups; this finding echoes the spirit of studies with other primates in which amygdala lesioned monkeys approach stimuli that are rejected by non-lesioned monkeys (Mason et al., 2006). In contrast, the loss aversion parameter found in the control group in each case is close to the previous findings. However, both lesioned patients satisfy a basic consistency requirement by preferring larger gains and smaller losses; these results are consistent with evidence from other primate studies (Murray et al., 1996). The more lesioned patient, SM, exhibited a slight loss seeking behavior while the less lesioned patient, AM, was loss-neutral.

Clearly, these results on the role of the amygdala differ from those in the fMRI study by Tom et al. (2007). One possible reason is that the De Martino et al. (2010) study uses a larger range of losses. For smaller losses, the BOLD signal in the amygdala might not be detectable using existing fMRI techniques. A second possibility is that in the evaluation of mixed lotteries, the amygdala might contribute vital inputs to other brain regions (e.g., the striatum) involved with the processing of synaptic processing that is picked up by the BOLD signal. This possibility is confirmed in Jenison et al. (2011) who recorded 16 amygdala neurons whose spike is particularly associated with a WTP task for three subjects. Of these 16 neurons, 9 showed a negative correlation with the WTP and 7 showed a positive correlation. Thus, it is quite likely that in fMRI studies, the neuronal signals from the amygdala cancel out, yet the amygdala may play an important role in providing inputs during mixed lottery decision tasks.

De Martino et al. (2010) were able to distinguish between risk aversion and loss aversion. Loss aversion implies an aversion to mixed gambles because losses are weighted more heavily than gains. In contrast, in gambles with all gains or all losses, loss aversion does not have bite. For such gambles, the spread of outcomes can be varied to test for risk aversion. It turns out that the risk aversion of amygdala lesioned patients is no different from the respective control groups. Thus, amygdala damage seems to lower loss aversion while keeping fixed the level of risk aversion; indeed separate neural systems could be responsible for loss aversion and risk aversion.

The behavioral evidence shows that loss aversion can be reduced in some cases by asking subjects to think like traders and combine gains and losses (Sokol-Hessner, Delgado, et al., 2009).

The neural correlates of such manipulation have been shown to be a reduction in activity in the amygdala and increased activity in the dlPFC (Sokol-Hessner, Hsu, et al., 2009).

23.4.4 Non-linear probability weighting

Under expected utility theory, probabilities enter into the objective function in a linear manner. In contrast, in the main behavioral alternatives such as rank dependent utility and prospect theory, individuals weight objective or subjective probabilities in a non-linear manner. In particular, inverse S-shaped probability weighting is the most common empirical finding, at least for probabilities bounded away from the endpoints of the probability interval $[0, 1]$; see Part I for the details on these assertions. There are many alternative probability weighting functions, but the most satisfactory is the Prelec (1998) function; it is axiomatically founded, and consistent with the empirical evidence.¹² The one parameter form of the Prelec function is $w(p) = e^{-(\ln p)^\alpha}$, where $\alpha > 0$ is the single parameter, $p \in [0, 1]$ is the probability, and w is the probability weight.

Most probability weighting functions are relatively flat in the middle range of probabilities. Hence, in order to detect non-linear probability weighting, one needs to use lotteries with probabilities that are dispersed over the range $[0, 1]$. Neural responses to probabilities have been found in the striatum and the cingulate gyrus (Paulus and Frank, 2006; Berns et al., 2008). A PET study by Takahashi et al. (2010) found a negative correlation between dopamine D_1 receptor binding in the striatum and the degree of non-linear probability weighting (relative to the benchmark of linear weighting).

Hsu et al. (2009) allow for a suitably large range of probabilities; we consider their work, next. In their experiments, on the first screen, subjects observed a lottery $L_1 = (x_1, p_1)$ (x_1 is an outcome and p_1 is a probability) without the confounding influence of a comparison between two lotteries. On the second screen, subjects were asked a question to test their understanding of the lottery (x_1, p_1) (e.g., is the probability lower than or greater than p ?). On the third, and final, screen, subjects were asked to choose between two lotteries, $L_1 = (x_1, p_1)$ and $L_2 = (x_2, p_2)$, where (x_2, p_2) is another outcome–probability pair. The first experiment (first two screens) revealed the brain areas involved in *reward anticipation*, while the second experiment (third screen) revealed brain areas involved in *choice*. Probabilities were chosen from the set $\{0.01, 0.1, 0.3, 0.5, 0.8, 0.95\}$ and outcomes, all positive, were chosen from the set $\{10, 20, 50, 100\}$.

In order to separate the objective function into a linear and a non-linear component, the objective function under prospect theory for lottery $L = (x, p)$ can be written as $PT(L) = \pi(p, \alpha)v(x)$, where $\pi(p, \alpha)$ is the decision weight under prospect theory (α is the parameter of the one-parameter Prelec function) and $v(x)$ is the utility function under prospect theory (see Part I for the details). We can rewrite the objective function as

$$PT(L) = \pi(p, \alpha)v(x) = pv(x) + \Delta(p, \alpha)v(x), \text{ where } \Delta(p, \alpha) = \pi(p, \alpha) - p. \quad (23.1)$$

In the parametric estimation, v is assumed to take the power form $v(x) = x^\gamma$, $\gamma > 0$.¹³

¹² For three different axiomatic foundations, see Prelec (1998), Luce (2001), and al-Nowaihi and Dhami (2006). For empirical support for the Prelec function, see Stott (2006).

¹³ The power form of utility is supported by the evidence (Kahneman and Tversky, 1979; Tversky and Kahneman, 1992; Stott, 2006). For an axiomatization of the power form of utility under prospect theory, see al-Nowaihi et al. (2008).

In the first experiment that involved reward anticipation, the BOLD signal in the brain is regressed on the two terms on the RHS of (23.1), $p\nu(x)$ and $\Delta(p, \alpha)\nu(x)$. If humans only take account of linear probability weighting, as under expected utility, then the BOLD signal should not be correlated with the non-linear term $\Delta(p, \alpha)\nu(x)$; in constructing $\Delta(p, \alpha)$ the group mean value of $\alpha = 0.77$ was used.

A non-parametric method was also employed to correlate brain activity with the behavioral shape of the Prelec function.¹⁴ Each of the probabilities is assigned a dummy variable, $d(p)$ (e.g., $d(0.5) = 1$ and $d(p') = 0$ for any $p' \neq 0.5$). Letting z be the BOLD response in the brain, captured by the fMRI evidence, the relation

$$z = a + \beta d(p)\nu(x) + \varepsilon \quad (23.2)$$

was estimated; ε is a noise term and a, b are the parameters to be estimated.

The results are as follows. In the parametric model, the brain regions that correlated with the linear term ($p\nu(x)$) in the first experiment (anticipated reward case) are the striatum, cerebellum, motor areas, and the median prefrontal cortex. These results are consistent with the identification of similar areas in related tasks. Activation in the following regions was correlated with the non-linear term ($\Delta(p, \alpha)\nu(x)$): striatum, cingulate gyrus, motor cortex, and the cerebellum. The areas of the brain that were equally activated by the linear and non-linear terms are striatum, motor cortex, and the cerebellum. The activation of the striatum for the reward anticipation task is consistent with the results from other studies on reward anticipation/reward processing (Knutson et al., 2000; O'Doherty et al., 2004). This region has also been found responsive to a multiplicative combination of probabilities and reward magnitudes (Tobler et al., 2007).

The coefficient β in the non-parametric model (23.2) is shown for various probabilities as the dots in Figure 23.11 for the left and right striatum, separately. The BOLD signal activation

Figure 23.11 The coefficient β in (23.2) (shown as the dots) for the left striatum (left panel) and the right striatum (right panel) for different probabilities. The behavioral Prelec function for the group average value of $\alpha = 0.77$ is shown as the continuous curve.

Source: Hsu et al. (2009).

¹⁴ Note that the inverse S-shape of the Prelec function arises for $\alpha < 1$ but not for $\alpha > 1$, which is also admissible under the axioms that lead to the Prelec function; see al-Nowaihi and Dhami (2006).

is non-linear in probabilities; it is overweighted relative to the behavioral Prelec function for low probabilities and underweighted for high probabilities.

23.5 The neuroeconomics of social preferences

The long-overdue incorporation of social preferences into economics has led to a huge increase in our understanding of a wide range of phenomena. Part 2 of this book, one of the longest, is devoted to a study of social preferences. In this section, we study the neural basis of some aspects of human sociality.

23.5.1 *Computation of social rewards in the brain*

Most of the studies mentioned in Section 23.4.1 on the neural correlates of private rewards, use non-social rewards such as juice, food, or money. In this section, we ask the question: Which are the neural correlates of social rewards? Are the same regions and neural processes that are involved in private rewards, also implicated in the processing of social rewards? Izuma et al. (2008) found that acquiring a good reputation (a social reward) activates the same brain areas as in the case of monetary rewards. They conclude that there is a common neural currency for private and social rewards, which is supported by other neuroeconomic evidence (Zink et al., 2008; Smith et al., 2010).

We focus now on Lin et al. (2012) who consider identical tasks that can lead to either private or social rewards. The task is shown in Figure 23.12. In the private/monetary and social rewards conditions, individuals chose between two slot machines, each of which produced three possible outcomes, positive (\$1), neutral (\$0), and negative (−\$1); subjects had to learn the probability distribution over outcomes produced by each of the slot machines. In each stage, the choice was between a neutral slot machine (represented by six circular dots) which had a uniform distribution over the three outcomes, and one of two other slot machines (see top two machines in Panel B in Figure 23.12).

If the outcome is positive, then (i) under social rewards, individuals see a smiley face and hear emotionally matched words such as excellent, bravo, and fantastic, and (ii) under monetary rewards subjects simply received \$1. If a negative outcome arises, then (i) under social rewards, subjects see an angry face and hear words such as stupid, moron, and wrong, and (ii) under monetary rewards, \$1 was subtracted from their endowments. Finally, in the case of a neutral outcome, (i) under social rewards, subjects see a neutral face and hear neutral words such as desk and paper, and (ii) under monetary rewards they receive \$0.

As one would expect in such a simple task, participants learnt to choose the positively valenced slot machine after a few trials (the machine in the middle row in Panel B); see Panels C and D in Figure 23.12. The fMRI data for subjective value (SV), reward magnitude (R), and prediction error (PE) for the social, monetary, and a combined condition are shown for various regions of the brain in Figure 23.13. In the monetary and social conditions, the SV on the slot machines was correlated with the vmPFC and additionally with the mid-cingulum, superior frontal gyrus, and angular gyrus. Thus, the neural circuitry for computing SV is similar in the monetary and social rewards tasks. In the monetary condition, activation in the caudate and putamen was correlated with PE, while there were no statistically significant correlations, at the chosen threshold, in the social task. Finally, reward magnitudes (R) are correlated with activation in the vmPFC for social and monetary conditions; in the monetary condition there was also activation in the insula, occipital

Figure 23.12 Panel A: Each choice involved choosing from a neutral or valenced slot machine. The decision and rewards time intervals are shown. Panel B: Probability distributions over rewards of the three slot machines, each represented by a different pattern. Panels C and D: Choices of subjects by disaggregated and aggregated treatment effects.

Source: Lin et al. (2012).

cortex, cingulate gyrus, and the superior frontal gyrus. The authors conclude (p. 280): “Together with other recent findings . . . our results provide increasing support that overlapping areas of vmPFC and ventral striatum encode value signals for both types of rewards.”

23.5.2 The neural basis of inequity averse preferences

We have discussed *models of inequity aversion* in Part 2 (Fehr and Schmidt, 1999; Bolton and Ockenfels, 2000). However, several explanations that were traditionally based on inequity aversion were sought to be supplanted later by concerns for social image (Andreoni and Bernheim, 2009) as well as reciprocity considerations (Falk et al., 2008; Rabin, 1993). In this section, we report neural evidence, based on fMRI tests, that establishes neural networks in the brain, which encode inequity averse preferences in a simple model.

Figure 23.14 The behavioral evidence. Vertical bars denote standard errors of the mean.

Source: Reprinted by permission from Macmillan Publishers Ltd. *Nature* 463: 1089–91 (25 February 2010). "Neural evidence for inequality-averse social preferences," Elizabeth Tricomi, Antonio Ranger, Colin F. Camerer and John P. O'Doherty.

In Tricomi et al. (2010), the data is based on 20 pairs of unacquainted males who were given a baseline pay of \$30. Half were then randomly selected and given \$50 (high-pay group), while the other half was given nothing extra (low-pay group). Individuals in both groups then had to rate an incremental transfer between \$0 and \$50 to themselves and to their partner in the group by assigning a number from a ratings set $\{-5, -4, \dots, 0, \dots, 5\}$.

Figure 23.14 shows the regression coefficient obtained by regressing ratings on the amount transferred to themselves and to others. Both groups rated own-transfers positively. Now consider transfers to the partners. Members of the high-pay group rated transfers to the low-pay

partner positively (advantageous inequity), because such transfers narrowed the income gap. By contrast, members of the low-pay group rated transfers to the high-pay partner negatively (disadvantageous inequity), because such transfers widened the income gap. Thus, the behavioral data is consistent with the Fehr–Schmidt (1999) model of inequity aversion.

fMRI data shows that in the case of own-transfers, there was a statistically significant correlation in the activation of the vmPFC and ventral striatum with the magnitude of transfers. This is not surprising. The same areas are known to be activated in the case of private rewards; see Section 23.4.1.

The authors next considered a statistic, which is the contrast of the fMRI response for own-transfers relative to partner-transfers for both groups. Figure 23.15 shows the resulting effects on the ventral striatum while Figure 23.16 shows the corresponding effects on the vmPFC. For each of the two groups, there is activation in both the regions and the contrast statistic is significantly higher for the low-pay group. For the low-pay group, the activation of both regions is greater for own-transfers as compared to partner-transfers. For the high-pay group, we get the opposite

Figure 23.15 The fMRI evidence on activation of the ventral striatum for the contrast between own-transfers relative to partner-transfers for both groups. (a) Activation in the ventral striatum (circled); contrast was significantly higher for low-pay group. (b) Contrast values for both groups. Vertical bars denote standard errors of the mean.

result, i.e., relatively more activation for partner-transfers relative to own-transfers. The results hold even when wealth effects and prediction errors are controlled for.

Comparing Figure 23.14 with Figures 23.15 and 23.16 for the high-pay group, one notices a discrepancy between the behavioral and the neural results. In the behavioral results, one rates an own-transfer relatively higher than a partner-transfer while the reverse is true for the neural data. The authors note (p. 1090): “basic reward structures in the brain may reflect even stronger equity considerations than is necessarily expressed or acted on at the behavioral level. These findings raise the possibility that even when basic reward responses reflect strong equity considerations, in some cases additional factors may intercede to moderate the influence of such equity judgements on behavior, such as strategizing . . . or the engagement of self-serving biases such as judgements of deservingness or need.” This is an example where neural data enriches understanding of human behavior relative to a consideration of behavioral data alone.

Cappelen et al. (2014) study the neural correlates of inequity aversion when individuals evaluate different income distributions that are generated by an input of endogenous effort. The behavioral data suggests a preference for income distributions in which incomes are proportional to effort. Thus, individuals are less inequity-averse when inequity arises from the input of endogenous effort. There was a significant activation in the striatum whenever the income distribution deviated from the one where incomes are proportional to effort. In competitive environments, such as tournaments between competing agents, workers, or athletes, winning is considered more personally rewarding. In such environments, winning is correlated with increased activity in the vmPFC and the striatum, which are also activated in the case of private rewards (Bault et al., 2011).

23.5.3 Neural basis of social punishment and trust

Classical game theory predicts that bygones are bygones, so we should not observe players imposing costly punishments on others. Yet, the empirical findings of costly punishment in a range of games, precisely when bygones should be bygones, is puzzling. A prominent example is the data from public goods games with punishment (Fehr and Gächter, 2002; see Part 2 for details). In other contexts, one observes costly punishment meted out to others, including third parties, for violating social norms; this is sometimes known as *altruistic punishment* or *indirect reciprocity*. Indeed, such reciprocal behavior appears to have been critical to the survival of traditional societies, prior to the establishment of a formal state, and it has evolutionary foundations.¹⁵ In this section, we consider the neurobiological foundations of such behavior.

De Quervain et al. (2004) consider a *trust game* between player A (the trustor) and player B (the trustee) that allows for punishment of the trustee for betrayal of trust. Players A and B are endowed with 10 MUs (experimental unit of currency). Player A sends an amount, x MUs, to B that the experimenter quadruples and passes on to B. Player B then has an opportunity to repay this trust by choosing to send back one of two amounts: 0 MUs or $\frac{1}{2}(10 + 4x)$ MUs. On observing the amount sent back by B, player A is given 1 minute to deliberate and then decide on the level of punishment to impose on B. Different treatments vary the cost of punishment on both players. During the 1 minute that player A deliberates, his brain is scanned using positron emission tomography (PET). In order to reduce the exposure of radioactive substances, the authors scan in only those cases where player B sends back nothing; we report these results below.

¹⁵ See Part 2 for the details. Several excellent references are available. These include Boyd et al. (2003), Bowles and Gintis (2004, 2011), Fehr and Gächter (2002), Fehr et al. (2002), and Fehr and Fischbacher (2003).

Four different treatment conditions were considered, depending on the cost of punishment; these are IC, IF, IS, and NC. The first letter in any name of treatment captures the intentionality (I) or non-intentionality (N) of the decision made by B. Under N, a random device makes the decision on behalf of player B, while under I, player B directly makes the decision. The second letter of the treatment name determines if the punishment is costly (C), free (F), or purely symbolic (S). Under C, player A gives up 1 MU to reduce the payoff of player B by 2 MUs, while under F, there is no cost to player A. Under S, there is no cost to either of the players.

The four treatments provide the necessary contrasts to evaluate the relevant hypotheses. Player A should have an incentive to punish player B whenever B intentionally chooses the action of sending back nothing (the only case considered below). When punishment is symbolic, player A has the intention to punish but not the means to do so, hence, he might not get any satisfaction in this case. The contrast IF–IS captures the satisfying aspect of punishment. If punishment is satisfactory in the treatment IF, then provided punishment is not too costly, we expect players to also punish in the IC treatment, although the punishment might be reduced. Indeed, brain areas that are involved in the calculation of such trade-offs may come into play.

One might expect that subjects with the greatest activation in the reward areas in the brain in the IF treatment might engage in the greatest punishment in the IC treatment. If so, then this would contribute to the ability of neuroeconomics to make successful predictions. When the decision by player B is non-intentional, then player A should not derive any pleasure from punishing player B. The combined contrast (IC + IF) – (IS + NC) is also useful. In the treatments IC and IF, there is a desire and opportunity to punish while in treatment IS there is no opportunity to punish and in treatment NC there is no desire to punish.

Player A is asked to rank the perceived unfairness of player B and the desire to punish player B on a seven-point *Likert scale* from –3 to +3. A Likert scale is a bipolar scale in which subjects indicate a positive and a negative response, with 0 denoting indifference. The behavioral results are shown in Figure 23.17 for each of the four treatments. Maximal perceived fairness is indicated by –3 and maximum perceived unfairness by +3. The maximal desire to punish is indicated by +3 and the maximal desire to reward by –3.

Mean perceptions $\pm$ standard errors are shown in Panels A, B in Figure 23.17. When the choices of B are unintentional (treatment NC) there is no perceived unfairness (panel A), desire to punish

Figure 23.17 Mean responses by player A when player B returns 0 MUs, and the actual payoff reduction of player B in various treatments.

Source: "The neural basis of altruistic punishment." Dominique J.-F. de Quervain, Urs Fischbacher, Valerie Treyer, Melanie Schellhammer, Ulrich Schnyder, Alfred Buck, and Ernst Fehr, *Science* (27 August 2004) 305 (5688): 1254–8. Reprinted with permission from AAAS.

is very small (panel B), and the payoff of player B is reduced very little through punishment, possibly on account of inequity-aversion (panel C). In the other three treatments, the intentional choices of B are perceived as unfair, there is desire to punish, and actual punishment takes place. The highest punishment takes place when it is free (treatment IF).

Consider the contrasts $(IC + IF) - (IS + NC)$, $IF - IS$, $IC - IS$, $IF - NC$, $IC - NC$. In these contrasts, the PET results show that the highest activation is achieved in the caudate nucleus and this activation is particularly significant in the contrasts $(IC + IF) - (IS + NC)$ and $IF - IS$. The MNI coordinates of this brain area are [6, 22, 4]. A secondary area that was activated in these contrasts is the thalamus.

Figure 23.18 shows the peak blood-flow increase in the caudate nucleus in each treatment, relative to the average level of activation. The greatest activation was in the IC and IF treatments where there is a desire and an opportunity to punish, relative to the other two cases. The caudate nucleus has been found to be associated with the brain's reward circuits in brain lesion studies in rats, single neuron studies in non-human primates (Hollerman et al., 1998) and neuroimaging studies in humans (Knutson et al., 2001; Delgado et al., 2000). The thalamus too has been implicated in the processing of rewards in neuroimaging studies in humans (Delgado et al., 2000). Thus, it appears that the act of punishing an unfair act by player B is hedonically rewarding to player A.

An important step is taken in establishing causality by first identifying the 16 subjects in their roles as player A who exhibit the highest caudate activation in the IF condition when they punish player B. These players are also the ones who punish maximally in the IC condition when punishment is costly. Thus, the PET study appears to clearly identify those players who derive the greatest pleasure from punishing norm violation by player B; these players behave exactly as predicted in the IC condition. Costly punishments involve a trade-off. On the one hand, punishment is satisfying, but on the other hand, punishment imposes a personal cost. In this case, the PET data shows activation also in the mOFC, which is typically engaged in making difficult choices.

Empathy allows individuals to share the emotions, pain, and suffering of others. Neural evidence shows that similar brain regions are highlighted when one experiences painful events or suffering, or observes others experiencing these events with whom one has empathy. These brain areas are typically the anterior insula (AI), front-insular cortex (FI), and the anterior cingulate cortex (ACC) (Wicker et al., 2003; Keysers et al., 2004; Singer et al., 2004; Morrison et al., 2004).

Figure 23.18 Peak activation in the caudate nucleus relative to the mean level in all four treatments.

Source: de Quervain et al. (2004).

One might wonder how empathy towards others varies, depending on how favorably one views them. This question is addressed by Singer et al. (2006) and is the one that we consider next.

They play a modified trust game that they call a sequential prisoner's dilemma. Subjects in their roles as first movers could send an amount of money to a second player who then chooses to either send back a low, seemingly unfair, amount or a high, seemingly fair, amount. The second player is a confederate of the experimenter in the sense that he/she chooses a fair or an unfair amount in accordance with the experimenter's instructions. First movers were then asked to rate the fairness, agreeableness, or likeability of the second player; they rated the second player positively on these traits if they sent a fair amount, and negatively otherwise.

Once first movers had rated the second players, fMRI was used to monitor their empathetic responses when a painful stimulus was applied to them (self-condition) and to the other players who were fair or unfair (others-condition). Consistent with the earlier literature on empathy, in the self-condition, the activated brain areas were AI and ACC, extending into the FI and brain-stem. There was also a high correlation between empathy scores in behavioral tasks and activation of the relevant brain areas associated with empathy. The others-condition gives rise to two main results. First, less brain empathy is generated, measured by the activation of the relevant brain areas in fMRI data, when the partner is unfair, relative to being fair. Second, there is a significant gender difference. Measured by peak brain activity, there was little or no empathetic response in the fMRI data of men when the partner was unfair. In contrast, women still showed a significant empathetic brain response to unfair partners, although lower as compared to fair partners.

In an early study, Sanfey et al. (2003) showed that players who were treated unfairly in ultimatum games (offered a low amount by the proposer) exhibited activation in the emotional regions of the brain, such as the anterior insula. Thus, rejection of unfair offers may be associated with a negative emotional response. Tabibnia et al. (2008) argue that it is not clear if the brain responds to a lower monetary offer or a lower perceived fairness of the offer. They disentangle these two effects in which all players, in their roles as responders, play two ultimatum games. There were no proposers in the game, although the responders were told that proposers had already made offers that they were to respond to and actual payments would be made to the hypothetical proposers, whose pictures were shown to them.¹⁶

Consider, for instance, the offers in ultimatum games shown in Figure 23.19. An offer of \$7 out of \$15 may be deemed as fair but so is an offer of \$0.50 out of \$1. Hence, one may vary the monetary amount but maintain the same degree of fairness. Similarly, the last row of Figure 23.19 shows that depending on the base amounts, two different monetary payoffs, one higher than the other, may be deemed to be unfair.

In the behavioral results, self-reported happiness of proposers is significantly higher for fairer offers and self-reported contempt was significantly higher for unfair offers. The main areas of brain activity revealed by fMRI data that were activated in the fair versus unfair offers contrast were vmPFC, ventral striatum, and the amygdala. The activation of the amygdala is interesting because one typically associates it with a fear response. However, it has also been implicated in reward processing in other studies also.¹⁷ One potential limitation of this study is that the authors only included matched pairs of data in which the same amount was rejected in one case and accepted in the other (see p. 342). Hence, as Fehr and Krajbich (2014, p. 206) note, the "high > low fairness contrast is essentially the same as contrasting accepted > rejected offers."

¹⁶ Experimenters in economics often argue strongly for eliminating deception from experiments (Houser and McCabe, 2014, p. 27). The experiments reported here could possibly be construed as borderline deception.

¹⁷ The interested reader can look up the references in Tabibnia et al. (2008).

		Material payoffs	
		High	Low
Fairness	High	\$7 out of \$15	\$0.50 out of \$1
	Low	\$7 out of \$23	\$0.50 out of \$10

Baumgartner et al. (2012) explore the neural basis of *parochial altruism*, which is a form of altruism that is particularly directed at ingroup members only; see Chapter 7 for issues of social identity. The authors give a very clear definition (p. 1453): “Parochial altruism constitutes a persuasive psychological phenomenon which is qualified by a preference for altruistic behavior towards the members of one’s ethnic, racial, or any other social group, combined with a tendency for indifference, mistrust, or even hostility toward outgroup members.” Parochial altruism has played a critical role in norm compliance not only over human evolution but also in modern times; see Parts 2 and 5 of this book for details. Such norm compliance often takes the form of third party punishment of norm violators. Third parties are typically not harmed by observed opportunistic behavior between other parties, yet they are willing to engage in costly punishments that do not give them any direct benefits. The authors conjecture that such behavior, which is the product of human evolution, might also have given rise to specialized neural structures that support it.

The setting for the social identity experiments used by the authors has already been outlined in Chapter 7 (Goette et al., 2006). Swiss army recruits are randomly assigned to platoons over a four week training course. The behavioral results are consistent with the social identity view that own-platoon members are considered as ingroups relative to other-platoon members. A simultaneous move prisoner’s dilemma is conducted with two players A and B in the third or fourth week of training. A and B are given 20 points; the points can be exchanged for money with the experimenter at a known exchange rate. Under cooperation, C, the players can simultaneously transfer 20 points to the other player, which the experimenter doubles before transferring to the other player. So if both players transferred their entire endowments to the other player, each gets 40 points. The players can also choose not to transfer (defection, D) and simply exchange their endowment for money with the experimenter at the end of the game. Since decisions are made simultaneously, the four outcomes or *conditions* are CC, CD, DC, and DD. Thus, for instance, in condition DC, player A plays the strategy defect (D) and player B plays the strategy cooperate (C).

A third player, player C (not to be confused with the strategy C) observes the results of these experiments within five days and must decide on the level of punishment. He can only punish one of the two players. The identities of the players are so arranged that player C can only punish player A, who could be a ingroup or an outgroup member. Punishment costs 1 point but allows for a deduction of 3 points from the target. While engaging in punishment, fMRI data was collected from player C, whose behavior will be our main focus of attention.

There are three main groups/constellations, each with three players. In group ABC, all three players are from the same platoon; in group AC, players A and C are from the same platoon, but B belongs to another platoon; in group BC, players B and C are from the same platoon, but A belongs to another platoon. To summarize:

{ 2 player Conditions/Strategy profiles chosen by players A, B:	{CC, CD, DC, DD}
{ 3 player Groups/Constellations listing ingroup members only:	{ABC, AC, BC}

Consider the condition DC in which player A defects and player B cooperates. In the constellation BC, player A is an outgroup member, while in the constellation AC, A is an ingroup member. Parochial altruism arises if player C punishes A more in the constellation BC (where A is an outgroup member) as compared to the constellation AC (where A is an ingroup member).

In the case of two-player punishment games, the brain regions involved in the punishment of norm violators are the right lateral prefrontal cortex (rLPFC) (Knoch et al. 2006, 2008; Sanfey et al. 2003), and the dorsal caudatus (de Quervain et al. 2004; Seymour et al. 2007). The calculations in third party punishment games are similar to the case of two-player punishment games. One has to trade off the loss in personal material payoff with the desire to punish norm violators; indeed such punishment offers personal satisfaction (de Quervain et al., 2004). Hence, we might expect similar brain regions to be activated in third party punishment.

However, the introduction of third party punishment in a social identity experiment introduces other issues. Third parties will need to engage *mentalizing processes* that justify why punishment meted out to ingroup members should be lower as compared to outgroup members for the same norm violation? Such mentalizing might take the form of mitigating factors to justify norm violations of ingroup members. Neural evidence indicates that the brain regions associated with this type of mentalizing are the dorsomedial prefrontal cortex (dmPFC) and the bilateral temporoparietal junction (TPJ). A range of studies have implicated the TPJ in suggesting *a theory of the mind*, i.e., the ability of an individual to take on the perspective of another person (Decety and Lamm, 2007; Frith and Frith, 2007; Van Overwalle, 2009).

The main condition of interest that we now focus on is DC (because in the conditions CC, CD, and DD, player A behaves no worse than player B so there would appear to be no desire to punish). Two main brain contrasts were used in the condition DC. (1) Constellation BC (player A belongs to the outgroup) minus the constellations (AC + ABC) (player A belongs to the ingroup). (2) The constellation (AC + ABC) minus the constellation BC. The first contrast allows us to examine if there is increased brain activity when one punishes an outgroup norm violator. The second contrast allows one to test if there is increased activity in the mentalizing network when one reduces punishment of ingroup norm violators.

A special software (MarsBaR) is used to identify the *regions of interest* (ROI analysis) during fMRI imaging.¹⁸ This is based on maximum observed voxel activity in these regions during third party punishment. Furthermore, Physio-Physiological Interaction (PPI) analysis was used to determine interaction between brain regions that goes towards establishing causality of one brain region in modulating activity in other brain regions.

The behavioral results confirm the classical results in social identity theory. There is punishment of norm violators, which arises most starkly in the condition DC (relative to the conditions CC, CD, and DD). Furthermore, there is a statistically strong effect of group membership on

¹⁸ Other programs can also be used to define ROI on the basis of anatomical or functional criteria, e.g., SPM and MRICro.

punishment; outgroup members belonging to other platoons are punished much more strongly than ingroup members for the same norm violation.

The fMRI results are as follows. Consider first the outgroup effects as captured by the contrast between the constellation BC and the constellations (AC + ABC); see Figure 23.20 for the results. Here the third party punishes outgroup members who violate norms against ingroup members who follow norms. The expected brain areas involved in punishment decisions showed increased activity in this case. These included the right orbitofrontal gyrus (rOFG), rLPFC and the right dorsal caudatus (rdCau). In order to establish the connectivity across these brain regions, a PPI analysis reveals that greater activity in rOFC is associated with greater connectivity of neural activity between rLPFC and the right caudatus. This suggests that the three regions are part of a functionally connected neural network that determines punishment behavior.

The results for the second brain contrast, the constellation (AC + ABC) minus the constellation BC, that captures ingroup effects is shown in Figure 23.21. The main brain activity in the contrast took place in those regions of the brain that have already been implicated in the mentalizing network; these regions are dmPFC and the temporoparietal junction (TPJ) (Gallagher and Frith, 2003; Rilling et al., 2004a). In Figure 23.21, the ROI analysis revealed the left and right parts of the TPJ, respectively lTPJ and rTPJ, as being active in this contrast. Interestingly, the stronger the interaction between these two regions of the mentalizing network, the lower is the punishment of ingroup members for defecting. A PPI analysis showed that activity in the lTPJ modulates the connectivity between dmPFC and areas in the OFC and rLPFC. These areas, thus, appear to form a mentalizing network that shades punishment of ingroup members.

Neural findings suggest that disrupting the right dlPFC through repeated transcranial magnetic stimulation (rTMS) reduces the rejection rates of subjects (often called deviant subjects) in

Figure 23.20 Outgroup effects captured by third party punishment of outgroup members who play opportunistically against ingroup members who cooperate. All data shown is for the condition DC. The first row shows activation in the three main brain regions of interest using fMRI data. The second row shows the contrast estimates, relative to a baseline, in the three brain regions, for three different constellations BC, AC, and ABC. Bars denote standard errors of mean.

ultimatum games. Such disruption does not influence the ability of the deviant subjects to judge the fairness of offers (Knoch et al., 2006; Knoch et al., 2008; Wout et al., 2005). However, when rTMS is applied to the left dlPFC, it produces no differences in rejection rates relative to a sham treatment.

Baumgartner et al. (2011) combine fMRI methods with rTMS in order to reduce the limitations of these methods when they are applied separately. In their experiments, subjects play an ultimatum game. The proposer has an endowment of CHF 20 and he proposes a split to the responder. The offers are restricted to the set {4, 6, 8, 10}, so 4 is the most unfair offer and 10 the most fair because it results in an equal share of the pie for both players. Low frequency, 1Hz, rTMS is applied for 15 minutes to the right or left dlPFC of responders, prior to their decision to reject or accept offers (offline rTMS). This disrupts the functioning of the dlPFC; deviant subjects whose right dlPFC is disrupted are expected to reject unfair offers less frequently.

The results are shown in Figure 23.22. The rejection rates increase when the proposers make smaller offers. Disruption of the right dlPFC by rTMS leads to a much lower rate of rejection, which is consistent with the earlier results. Overall, the percentage rejection rates for offers of 4, 6, 8, and 10 were, respectively, 62, 25, 1, and 1. The percentage rejection rates for the unfair offers of 4 and 6, under right rTMS, were 45 and 13, while the corresponding figures for left rTMS were 79 and 35. The differences are statistically significant.

Several empirical studies report the following findings. (1) In the processing of unfair offers, two main brain regions, the anterior insula and the dACC, are reported to be activated (Sanfey et al., 2003; Tabibnia et al., 2008). (2) These brain regions are also known to be involved in the processing of negative emotions and in modulating conflict between cognitive and behavioral tasks (Baumgartner et al., 2009; Herwig et al., 2007).

Figure 23.22 Mean rejection rates $\pm$ s.e.m. for different treatment groups and for different offers.

Source: Reprinted by permission from Macmillan Publishers Ltd. *Nature Neuroscience* 14: 1468–74. Baumgartner, T., Knoch, D., Hotz, P., Eisenegger, C., and Fehr, E. (2011). "Dorsolateral and ventromedial prefrontal cortex orchestrate normative choice."

The empirical evidence shows that disrupting the left dlPFC does not reduce rejection rates but disrupting the right dlPFC does reduce rejection rates; see Figure 23.22. So the regions listed in (1) and (2) above, are expected to be activated in the contrast between these two disruption treatments when evaluating fair and unfair offers. However, no differential activation of these regions is found in the two treatments. The only brain region that is differentially activated in the two treatments in the fair/unfair contrast is the posterior vmPFC, a region typically associated with positive stimuli. However, unfair offers are negative stimuli. This suggests that distinct areas in the vmPFC are associated with the processing of positive and negative stimuli, a result that is confirmed by the authors.

Knoch et al. (2009) examine if disruption of the right lateral prefrontal cortex (rlPFC) by rTMS alters behavior in a 15 period repeated trust game in two treatment conditions. Trustees could either transfer back nothing, or transfer a quarter, or equalize payoffs by their back transfer. In the anonymous condition, the trustor does not learn of the trustee's past behavior. However, in the reputation condition, he can observe their behavior in the last three periods. The results are shown in Figure 23.23 for the following three cases. (i) Disruption of right dlPFC. (ii) Disruption of left dlPFC. (iii) A sham condition.

In the anonymous condition, there are no differences in the back transfers by the trustee in the three cases because there is no incentive to build a reputation. However, in the reputation condition, disruption to the right dlPFC causes lower back transfers relative to the other two cases. Such disruption appears to increase the temptation to reap current rewards relative to investing in one's reputation. It turns out that trustees who engaged in reputation building ended up with relatively higher payoffs. For instance, trustees who always chose to equalize payoffs, faced a 71% chance of getting a 10 point investment from the trustor, while the corresponding probability for

Figure 23.23 Relative back transfers in the two treatment conditions with varying degrees of brain function disruption.

Source: Knoch, D., Schneider, F., Schunk, D., Hohmann, M., and Fehr, E. (2009). "Disrupting the prefrontal cortex diminishes the human ability to build a good reputation." *Proceedings of the National Academy of Sciences* 106: 20895–9.

those who returned nothing was less than 6%. It is important to note that disruption to the right dlPFC did not alter the fairness judgments of subjects. This was inferred from questions that subjects were asked immediately after the experiment to judge the fairness of alternative levels of back transfers.

Individuals with lesions to the vmPFC have been found to be more sensitive to fairness concerns because they are more likely to reject unfair offers in ultimatum games (Koenigs and Tranel, 2007). However, when asked to respond to hypothetical unfair offers, their answers are very

similar to normal individuals without lesions (Leland and Grafman, 2005; Krajbich et al., 2009). Individuals with lesions in the vmPFC also exhibit diminished social preferences in their roles as proposers in dictator games, and trustees in trust games (Krajbich et al., 2009). The difference in hypothetical and actual choices indicate that the vmPFC is not involved in the detection of fairness, but it is involved in the expression of social preferences.

The amygdala has also been implicated in social preferences. For instance, individuals who have lesions in the amygdala react less to untrustworthy behavior (Koscik and Tranel, 2011). The amygdala also plays a role in determining punishments for different crimes (Buckholtz et al., 2008). In an ultimatum game, administration of a benzodiazepine that lowers amygdala activity also reduced the rejection rates (Gospic et al., 2011).

The size of the amygdala has been found to be associated with the size of one's social network and social behavior in nonhuman primates (Lewis and Barton, 2006). Bickart et al. (2011) conduct a similar analysis for humans. The regression results are shown in Figure 23.24, using two alternative but highly correlated measures of social networks. These are the number of people in the social network and the number of embedded networks (the number of distinct groups of contacts). Amygdala volume is measured using MRI data. Since the amygdala volume decreases with age, it is controlled for in the empirical analysis. Linear regression lines for both measures of social networks are plotted in Figure 23.24, and the regression coefficient is shown as the number B . A significantly positive relation between amygdala volume and social networks was found using both measures. Bickart et al. (2014) show that different parts of the amygdala are responsible for different aspects of social behavior.

Altruistic behavior has been observed in a wide range of other human activities. For instance, one may be slightly more altruistic when being observed by others. There is some evidence that there is increased activity in the left ventral striatum when one's charitable donations are observed by others (Izuma et al., 2010). Hsu et al. (2008) consider trade-offs between equity and efficiency. They find that a brain area, the putamen, responds to efficiency considerations while the insula

Figure 23.24 Two different measures of social networks plotted against amygdala size for two age groups: young participants (black circles) and older participants (gray triangles).

Source: Reprinted by permission from Macmillan Publishers Ltd. *Nature Neuroscience* 14: 163–4 (2011), "Amygdala volume and social network size in humans," Kevin C. Bickart, Christopher I. Wright, Rebecca J. Dautoff, Bradford C. Dickerson, and Lisa Feldman Barrett.

responds to inequity considerations. Zaki and Mitchell (2011) also provide behavioral and neural support to efficiency considerations. They implicated the OFC in efficiency choices. The activation of the insula in equity considerations, which is also found in several other studies, indicates that fairness in behavior has a basis in emotional processing. Indeed, the very first fMRI study of ultimatum games found increased activity in the anterior insula and the ACC in the fair/unfair offers contrast (Sanfey et al., 2003). In redistribution of wealth from rich to poor individuals, increased activity was observed in the lateral frontal gyrus and the anterior insula (Dawes et al., 2012). However, when expressing egalitarian preferences, only the insular cortex activations were observed.

23.5.4 Human virtues and the brain

Chapter 7 is devoted to the study of human virtues. Is there a neural basis for human virtues? Consider, for instance, the act of making a promise and keeping it, even at a cost in terms of material payoffs. This is considered to be a virtuous act in most cultures, yet it is at odds with a model based purely on self-regarding preferences. Indeed, oral and non-binding promises might have been the precursor of modern legally enforceable contracts that underpin economic exchange. However, the presence of enforceable contracts has not diminished the importance of promises in creating favorable expectations, and a great deal of modern commerce and exchange is possibly based on oral promises. In repeated games, promises can be motivated by reputational concerns. However, we know from Chapter 7 that promises and other human virtues can also be motivated by intrinsic considerations (Charness and Dufwenberg, 2006; Vanberg, 2008); we explore the neural basis of some of these considerations now.

Baumgartner et al. (2009) consider a modified two-player trust game in which the trustor (player A) can send any or part of an endowment of 2 MUs to a trustee (player B); B has no endowment. The experimenter multiplies the amount sent by A by a factor of 5 and passes it on to player B. Player B then sequentially decides to send back either half of the MUs to A, or nothing. Each set of players play three consecutive trust games. In one set of trials, player B cannot make an upfront promise on his back transfers (before A makes his decision). In another set of trials, B can choose the *strength of his promise*, i.e., promise upfront that he will send back half the MUs to A *always*, *mostly*, *sometimes*, or *never*. Almost all players choose their promise with the maximum strength, i.e., “always.”

The data revealed two clusters of players among those who had originally promised to send back a transfer. The first cluster does not send back any MUs (dishonest subjects), while the second cluster keeps its promise of sending back half the MUs (honest subjects). These clusters behaved in an identical manner, irrespective of whether the trials allowed a promise to be made or not. Thus, honest player Bs returned half their MUs to A, irrespective of having made a promise or not, while the dishonest player Bs never returned any MUs to A. An additional feature of these experiments relative to the earlier literature on deception in neuroscience studies is the introduction of an anticipation stage.¹⁹

Once player B has made a promise, there is a time interval of a few seconds that creates an anticipation in the mind of player B if player A will trust him. During the anticipation period, useful brain data can be gathered. Player Bs who intend to break their promise are likely to exhibit different brain activity relative to those who make a sincere promise that they intend to keep. This

¹⁹ For a survey of earlier neuroscience studies of deception that do not allow for promises made under free will or issues of anticipation, see Spence et al. (2004) and Sip et al. (2008).

is because dishonest players may face emotional conflict from making a promise that they do not intend to keep.

An important aim of this study is to be able to predict whether player Bs will subsequently honor their promise by looking at their brain activity at the time of making their decision. In other studies, such emotional conflict has led to increased activity in the anterior cingulate cortex (ACC) and the amygdala (Botvinick et al., 1999; Phillips et al., 2003; Sanfey et al., 2003). Furthermore, is the anticipation period for dishonest player Bs more uncertain and stressful as revealed by their fMRI scans? Finally, when dishonest player Bs break their promise, they may fear the negative consequences if their dishonesty is discovered. In previous studies, such deception has led to increased activation of the ACC.²⁰

These anticipated results are largely confirmed. In the anticipation stage, dishonest player Bs exhibited relatively greater brain activity in the right anterior insula and right inferior frontal gyrus (IFG), as compared to a baseline condition. In the decision stage, when player A makes his decision, dishonest player Bs exhibited relatively greater brain activity in the ACC as compared to a baseline condition. In another decision stage just prior to the decision of player Bs to honor their promise, when they are reminded of their original promise, dishonest player Bs show relatively greater activity in the left amygdala.²¹ Using brain activity at the time of making a promise, activation in the anterior insula, ACC, and IFG, can successfully predict if player B intends to break his promise subsequently.

23.5.5 Neural interplay of guilt and social preferences

Prosocial behavior may be caused by feelings of *guilt* that arise from antisocial behavior. We have considered issues of guilt in Part 4 of the book, in the section on psychological game theory. Here, we consider the neural correlates of guilt by describing the experiments of Chang et al. (2011), who collect fMRI data from individuals who play the trust game. They give a useful definition of guilt (p. 560): “Guilt can be conceptualized as a negative emotional state associated with the violation of a personal moral rule or a social standard (Haidt, 2003) and is particularly salient when one believes they have inflicted harm, loss, or distress on a relationship partner, for example when one fails to live up to the expectations of others (Baumeister et al., 1994).”

Using the notation of Part 4, let b_A^1 be the first order beliefs of the trustor (player A) about the amount of money that the trustee (player B) will return to him. The trustee’s second order beliefs about b_A^1 are denoted by b_B^2 and his payoff is given by

$$\pi_B = \begin{cases} m_B - \theta (b_B^2 - r) & \text{if } r \leq b_B^2 \\ m_B & \text{if } r > b_B^2 \end{cases},$$

where m_B is the final monetary amount in the ownership of player B at the end of the game, r is the amount returned by B to A, and $\theta > 0$ is a guilt-aversion parameter. Notice that guilt arises if B’s action (r) falls short of the second order beliefs of B about the action (b_B^2). Player B chooses r in order to maximize his utility. Furthermore, the beliefs are endogenous and, in

²⁰ For a focus on the neural systems underlying the trustors’ behavior in trust games see Delgado et al. (2005), King-Casas et al. (2005) and Krueger et al. (2007). van den Bos et al. (2009) show that player Bs who abuse the trust of player As in trust games, typically show enhanced activity in the vmPFC and the posterior cingulate cortex (PCC).

²¹ In this and the previous sentence, the word “relatively” captures statistical significance either at the 5% or the 1% level, based on the treatments.

equilibrium, they must concur with the actions. If the guilt-aversion parameter is high enough, in the sense that $\theta > 1$ and $r < b_B^2$, then by making an extra unit of back transfer relative to keeping it, the trustee increases his own payoff. Hence, guilt aversion may enhance prosocial behavior. On the other hand, if guilt aversion is low ($\theta < 1$) the trustee does not send back anything.

Participants in the experiments played the one-shot trust game multiple times. The first and second order beliefs of players were also elicited before they made their respective decisions. The trustees underwent fMRI scans while they made their decisions. The behavioral results are in line with the typical trust game experiments. Some amount of money was always sent by the trustors. The trustees were typically able to predict the expectations of the trustors fairly accurately. The actual amounts returned by them, r , were close to these expectations, which is consistent with the guilt-aversion hypothesis.

The fMRI results are as follows. The main contrast is between two groups of trustees for whom $r = b_B^2$ and $r < b_B^2$, respectively. When $r = b_B^2$, there is increased activity in the insula, supplementary motor area (SMA), dorsal anterior cingulate (dACC), dorsolateral prefrontal cortex (DLPFC), and the temporal parietal junction (TPJ). In contrast when $r < b_B^2$, there is increased activity in the ventromedial prefrontal cortex vmPFC, bilateral nucleus accumbens (NAcc), and dorsomedial prefrontal cortex (dmPFC).²² The individual differences between the players also give interesting insights. Trustees who reported that they would have felt guilty if they had returned less money showed more activity in the insula and in the SMA when they contributed the expected amount ($r = b_B^2$). By comparison, participants who said that they would not feel guilty by returning less than the expected amount, showed increased activity in the NAcc when they contributed lower amounts ($r < b_B^2$). Thus, activity in the insula appears to be correlated with fairer choices.

23.6 The neuroeconomics of time preferences

Animals, even primates, who are most closely related, find it difficult to delay gratification (unless the animal is pre-programmed to do so, e.g., seasonal food storage among squirrels). As Loewenstein et al. (2008) describe: “Even after long periods of training, our nearest evolutionary relatives have measured discount functions that fall in value to nearly zero after a delay of about one minute. For example, Stevens et al. (2005) report that cotton-top tamarin monkeys are unable to wait more than eight seconds to triple the value of an immediately available food reward.” In humans, individuals whose prefrontal cortex is damaged, say, by accident or surgery, are influenced more by the availability of immediate reward (Lhermitte et al., 1986). In particular, damage to the mPFC and the extent of the damage are both positively correlated with the choice of immediate over later rewards (Sellitto et al., 2010). These observations provide clues to the potential neural basis of intertemporal choice.

Let $c_0 = (c_0, c_1, \dots, c_T)$ denote the *temporal consumption profile* of the individual at time $t = 0$. Under the (β, δ) form of hyperbolic discounting, or quasi-hyperbolic discounting (see Part 3), the temporal stream $(c_0, c_1, \dots, c_T)$ is evaluated in the following manner (Laibson, 1997):

$$U^0(c_0, c_1, \dots, c_T) = u(c_0) + \beta \sum_{t=1}^T \delta^t u(c_t), \quad 0 < \beta < 1, \delta > 0. \quad (23.3)$$

²² Trustees in trust games who abuse trust show greater activity in the vmPFC and in the posterior cingulate region; see van den Bos et al. (2009).

By a multiplicative scaling, (23.3) can be written as

$$V^0 = \left(\frac{1}{\beta} - 1 \right) u(c_0) + \sum_{t=0}^T \delta^t u(c_t). \quad (23.4)$$

The first and the second terms in (23.4) can be thought of as describing, respectively, the β system and the δ system.

McClure et al. (2004) measure brain activity when participants in their experiments make a set of intertemporal choices between a smaller–earlier reward (\$ s with a time delay d) and a larger–later reward (\$ L with a time delay D); $L > s$ and $D > d$. Values of $d = 0$ (immediate gratification) and $d > 0$ were considered, while the rewards ranged from \$5 to \$40. The authors hypothesize that the limbic system is driven relatively by immediate rewards rather than future rewards while the anterior and dorsolateral regions of the prefrontal cortex are driven relatively more by future rewards.

In terms of the (β, δ) preferences of quasi-hyperbolic discounting, McClure et al. (2004) hypothesized that β is controlled by the limbic system, while δ is controlled by the prefrontal cortex. It turned out that when the choice (s, d) was made, parts of the limbic system, which the authors call β -areas, the ventral striatum, orbitofrontal cortex and the medial prefrontal cortex, were disproportionately activated. In contrast, when difficult choices are given, the δ -areas, such as the prefrontal and parietal cortex are disproportionately activated. This is because difficult choices are evaluated using the cognitive system. The δ -areas were also disproportionately activated when individuals chose the (L, D) option. The frontal and parietal cortex is activated for all (s, d) and (L, D) options; these are regions responsible for abstract planning and cognition.

In the McClure et al. (2004) experiments, the rewards were gift certificates, so one potential drawback of the approach was that gift certificates did not necessarily represent immediate rewards. This criticism was addressed in a later study by McClure et al. (2007) that we now describe. Subjects in their experiments abstained from drinks for 3 hours prior to the experiment. A choice between dated rewards was offered; the rewards being squirts of juice or water. The typical choice was of the following form. Choose (x, D) or (x', D') , where x and x' are both either squirts of juice or squirts of water and D, D' were, respectively, time delays expressed in minutes. In the experiments, the values of (x, x') used were (1, 2), (1, 3), and (2, 3) while the values of (D, D') used were (0, 1), (0, 5), (10, 11), (10, 15), (20, 21), (20, 25).

The behavioral data is shown in Figure 23.25, where the vertical axis is the probability of choosing the earlier reward, x , and D is the earlier time. The probability of choosing the earlier reward is always higher when the early time, D , is closer to the present; these results are consistent with models of present-biased preferences such as hyperbolic discounting. In the right hand side panel in Figure 23.25, it is clear that the results are mainly driven by the cases where the time delay difference $D' - D$ is 5 minutes; there is a smaller effect when $D' - D$ is 1 minute.

The fMRI data is shown in Figure 23.26. It is not based on a region of interest analysis, but rather on a whole brain analysis in which the BOLD signal measure in each voxel is regressed on a number of variables such as the reward magnitude and time delay. The brain regions that were most activated when subjects chose the earlier option were classified as the β areas (top panel of Figure 23.26). These brain regions include the nucleus accumbens (NAcc), subgenual cingulate cortex (SGC), medial orbitofrontal cortex (mOFC), posterior cingulate cortex (PCC), and precuneus. As in McClure et al. (2004), these regions lie within the limbic system and the paralimbic

Figure 23.26 Activation in the β areas and the δ areas in the brain as rewards with varying delays are presented to the subjects.

Source: McClure, S. M., Ericson, K. M., Laibson, D. I., Loewenstein, G., and Cohen, J. D. (2007). "Time discounting for primary rewards." *Journal of Neuroscience* 27: 5796–804.

cortex. In contrast, the brain regions that are correlated with the larger-later choices, the δ areas (bottom panel of Figure 23.26), include regions associated with higher-level cognitive functions such as the posterior cingulate cortex (PCC), bilateral areas in the posterior parietal cortex (pPar), bilateral areas in the anterior insula (Ant Ins), and several regions in the dorsolateral prefrontal cortex (dlPFC) (Brodmann areas 9, 44, 46, and 10). Other areas that were activated included primary visual and motor cortex areas, possibly because subjects made choices by looking at a visual display. In comparing the results in McClure et al. (2004) and McClure et al. (2007), there is a greater match between the two in the δ -areas, but a lower match in the β -areas, suggesting that the β -areas might be context and task dependent.

Other studies have questioned the findings of McClure et al. (2004, 2007). Glimcher et al. (2007) do not find increased activation of the limbic and paralimbic systems in the case of immediate rewards. Kable and Glimcher (2007) find that the β -areas in McClure et al. (2007) are activated when the delayed reward, x' , changes, thus, they question if these areas are exclusively associated with immediate rewards. For some possible explanations for these contrary findings, see Loewenstein et al. (2008).

A second class of models that explains the choice between immediate and delayed rewards invokes conflict between two brain systems for control. Two main types of models in this class are the planner–doer model of Thaler and Shefrin (1981) and the dual-selves model of Fudenberg and Levine (2006); see Parts 3 and 6 for the details. Hare et al. (2009) confront subjects with 50 different kinds of foods and ask them to rate them on health and taste. This allows the identification of a reference food for each subject that is neutral on taste and health grounds. In a second task, subjects are asked to choose between each of the 49 food items and the reference food item; fMRI is used to monitor their brain activity as they make their choices. The subjects were then classified into two groups. Self-controllers (SC) use health and taste criteria to make choices while the non self-controllers (NSC) decided on the basis of taste alone.

The behavioral results show that the subjects in the SC group were more successful in avoiding liked-unhealthy foods relative to the NSC group. The SC group also chose liked-healthy foods more frequently than the NSC group. The dlPFC shows greater activity in the choices of SC subjects who avoid unhealthy foods and also shows greater activity when the reference food item is chosen over the tempting food items. Thus, the dlPFC appears to play the role of a patient long-run planner. This interpretation is supported in the results of Figner et al. (2010) who find that temporary disruption of the dlPFC by TMS induces greater impatience in subjects. Relative behavioral impulsivity in adolescents is also associated with slower development of the neural brain circuitry in the prefrontal cortex (Sowell et al., 2003; Casey et al. 2008). This provides some neural basis for why younger people might make more impatient choices, which has economic implications for them such as higher car insurance premiums.

23.7 The neuroeconomics of strategic interaction

In this section, we consider the neural evidence on strategic interaction. The direct cognitive evidence from eyetracking studies, typically using the MOUSELAB software, that supports level- k and cognitive hierarchy (CH) models is considered in Part 4 and is not repeated here (Crawford, 2008; Wang et al., 2010).

In Bhatt and Camerer (2005), subjects play eight, two-player, dominance solvable games with 2–4 strategies. Players engage in three tasks in random order. In the *choice task* (C), they choose their own strategy. In the *first order belief task* (B), they guess the strategy choice of the opponent. In the *second order belief task* (2B), they guess the opponent's first order beliefs about them. In the classical game theoretic equilibrium, choices, first order beliefs, and second order beliefs, should align, i.e., beliefs should be confirmed in equilibrium and choices should be optimal given beliefs. Bhatt and Camerer hypothesize that when subjects play according to equilibrium, neural activity in the three tasks C, B, and 2B should be similar. However, when the choices of subjects are not in equilibrium, say, because they follow level- k or CH reasoning (see Part 4), then dissimilar areas of the brain are likely to be activated. For instance, nonstrategic or level-0 players might not spend much time in forming beliefs. Consistent with these predictions, the authors find that in task C, when subjects were out of equilibrium, there is relatively greater activity in the mPFC and

dlPFC. In contrast, for equilibrium subjects, brain activity was confined largely to similar brain areas, except for a small area in the ventral striatum.

In game theory, it is critical to determine what *theory of the mind* players have about others, i.e., how players believe others feel, believe, and choose. One line of research seeks to identify such *mentalizing* on the part of players by comparing their behavior when they play against other humans, relative to playing against computer programs. The hypothesis is that humans may need to mentalize against other humans, but not computers; this is confirmed in several neuroeconomic studies (Gallagher et al., 2002; McCabe et al., 2001; Coricelli and Nagel, 2009).²³

In Coricelli and Nagel (2009), subjects play a *p*-beauty contest. They simultaneously choose a number in the interval $[0, 100]$ and the winning individual's guess is closest to p times the average guess of all individuals. For $p < 1$, in a Nash equilibrium, all subjects are predicted to choose 0. By contrast, a level- k individual chooses $p^k 50$, $k = 0, 1, 2, \dots$ (see Part 4 for details). For instance, when $p = \frac{2}{3}$, the optimal guess of a (i) level-0 individual is 50, (ii) level-1 individual is $\frac{2}{3} 50 = 33.3$, (iii) level-2 individual is $(\frac{2}{3})^2 50 = 22.2$, and so on. In the human condition, subjects were matched with other humans and in the computer condition, they were matched with computers who were pre-programmed to choose a number in the interval $[0, 100]$. Various values of p were used.

Figure 23.27 shows the results (the letter M in the figure is to be read as the probability p). The behavioral results are shown in panel A for a representative individual in each category—low level of reasoning (level-1 against a human opponent) and a high level of reasoning (level-2 against a human opponent) for varying values of p (data shown by filled-in dots). Although their behavior was different against human opponents, both types chose to behave like level-1 individuals against the computer opponent (data shown in triangles). The level-1 prediction is shown as the dotted line with triangles and the level-2 prediction as the dotted line with dots; in panel A, below $p = 1$, the dotted line with dots is below the dotted line with triangles, and above $p = 1$, the line with triangles cross over. The data for the two types of individuals for a particular value of $p = \frac{2}{3}$ is shown in the bottom figure in panel B. Overall, across all individuals, the majority of choices were consistent with level-1 to level-3 players and only 5% of the players were higher than level-3.

Panel B in Figure 23.27 shows the fMRI data. In the human versus computer contrast, enhanced activity was found in the mPFC, rostral anterior cingulate cortex (rACC), superior temporal sulcus (STS), posterior cingulate cortex, and bilateral temporoparietal junction (TPJ). However, the crucial finding came from comparing the data for low and high level reasoning subjects. In this case, in the contrast between the human and the computer treatments, activity in the mPFC was found in the high level reasoners but not in the low level reasoners. Two areas in the mPFC stood out. A more dorsal area with coordinates $(x, y, z) = (0, 48, 24)$ and a more ventral area with coordinates $(x, y, z) = (9, 48, -6)$. The area $(0, 48, 24)$ has been found to be important when humans take a third person perspective (Amodio and Frith, 2006; D'Argembeau et al., 2007) and the area $(9, 48, -6)$ has been found important in thinking about like-minded other people (Mitchell et al., 2005; Mitchell et al., 2006; Jenkins et al., 2008). While the *p*-beauty contest is a simultaneous move game, the mPFC has also been implicated in a theory of the mind when players make sequential choices (Hampton et al., 2008).

In contrast, the fMRI evidence indicates that the main brain area engaged in the decisions of low level reasoners appears to be the rACC that has been implicated in self-referential thinking in social cognitive tasks (Moran et al., 2006). Two areas of the brain showed increased activity, irrespective of the level of reasoning of the players; these are the TPJ and the superior temporal sulcus.

²³ One may conjecture that humans need to mentalize against computers too because humans wrote the software that determines the computer's choices. However, whether humans do so or not is an empirical question.

Figure 23.27 Results in the p-beauty contest game. Behavioral results (panel a) and fMRI results (panel b). M is to be read as the probability p .

Source: Coricelli, G. and Nagel, R. (2009). "Neural correlates of depth of strategic reasoning in medial prefrontal cortex." *Proceedings of the National Academy of Sciences* 106(23): 9163–8.

The TPJ has been implicated in a theory of the mind in other studies (Saxe and Wexler, 2005), while the superior temporal sulcus has been implicated in assigning intentions to the actions of others and establishing causality (Brunet et al., 2000; Castelli et al., 2000). However, several other empirical studies do not necessarily support the conclusions arrived at here. For instance, Kuo et al. (2009) show that in other contexts, the mPFC does not correlate with steps of reasoning in others. Similarly, the TPJ has been implicated in other studies in tasks that are unrelated to the theory of the mind (Decety and Lamm, 2007; Mitchell, 2008).

Bhatt et al. (2010) consider issues of deception or *management of social image* as with poker players who are engaged in bluffing. They use a two-player bargaining environment in which players must form first and second order beliefs about models of the mind. In the experiments, a buyer and a seller play 60 rounds of a bargaining game. At the beginning of each round, the buyer's private valuation, $v \in \{1, 2, \dots, 10\}$, is privately revealed to the buyer. The buyer then suggests a price to the seller, s , who is free to ignore the suggestion if he wishes to. Finally, the seller asks for a price, p . If $v \geq p$, then trade takes place with respective payoffs to the seller and

the buyer equal to p and $v - p$. Otherwise, no trade takes place and both parties receive 0. Since the interests of the two parties are completely non-aligned, the prediction of standard economic analysis is that the buyer will babble and the seller will pay no attention to the suggestions.

A regression of the suggested price, s , on the buyer's valuation, v , reveals three kinds of buyers. *Conservationists* play with their cards close to their chest and their suggestions do not reveal valuations; their behavior is closest to the standard game theoretic prediction. *Incrementalists* demonstrated a strong positive correlation between v and s ; this behavior is potentially efficiency enhancing if believed by the seller. Finally, *strategists* reveal a significant negative correlation between v and s . This behavior is consistent with buyers who are level-2 players who believe that the seller is level-1.²⁴

As compared to the other types, there is relatively greater activity in the dlPFC of strategists when they make their suggestions. Furthermore, when their realized value, v , is higher, strategists need to bluff the most (because v and s are strongly negative correlated); in this case they exhibit greater activity in the superior temporal sulcus (STS). In a later paper, Bhatt et al. (2012) show that the absolute gap between the actual price asked by the seller, p , and the buyer's suggested price, s , reflected the degree of suspicion that sellers have about the suggestions. There was relatively greater activation in the amygdala when more suspicious sellers choose prices.

23.8 Pharmacoeconomics: an application to social effects of oxytocin

There has been much interest in studying the economic effects of *neuromodulator systems*. In classical synaptic transmission, described in Section 23.2, information is transmitted from a single neuron to another neuron. In a different kind of information transmission, a small group of neurons can secrete neuromodulators in a wide and diffuse area of the brain, simultaneously influencing information transmission to many neurons; these effects can be long lasting. Examples of neuromodulators include neurotransmitters such as *dopamine*, *serotonin*, *norepinephrine*, as well as hormones such as *testosterone* and *oxytocin*. Crockett and Fehr (2014) provide an excellent and accessible survey on the economic effects of these neuromodulators. In this section, we confine ourselves to a brief outline of some of the social effects of oxytocin.

In their seminal study using a trust game experiment, Kosfeld et al. (2005) gave one group of subjects a single dose of intranasal oxytocin, while the other group received a placebo. Both players were initially endowed with 12 MUs. The trustor/investor could pass on any amount from the set $\{0, 4, 8, 12\}$ to the trustee; the experimenter tripled the amount before it was received by the trustee. The aim was to examine the effect of oxytocin on the behavior of trustors and trustees. In a second set of experiments, the risk experiments, trustees played against an inanimate random mechanism. This random mechanism replicated the trustees' decision in trust experiments, say, by randomly choosing from the distribution of back transfers in the trust game.

The transfers in the trust and risk experiments are shown, respectively, in panels a and b in Figure 23.28. Filled-in bars and blank bars represent, respectively, subjects who were given oxytocin and the placebo. In the trust experiments, subjects who are given oxytocin make, on average, 17% higher transfers relative to the placebo group. The maximum transfer of 12 MUs was made by 45% of the subjects in the oxytocin group and 6% in the placebo group. At the bottom end

²⁴ Level-1 sellers will look at the past history in judging current suggestions; if strategists behaved like conservationists, then a low suggestion will be interpreted as a bluff, hence, level-2 strategists will mix their suggestions.

Figure 23.28 Transfers in the trust experiments (panel a) and risk experiments (panel b). Filled-in bars represent subjects who were given oxytocin and the blank bars represent subjects who were given a placebo.

Source: Reprinted by permission from Macmillan Publishers Ltd. *Nature* 435: 673–6. Kosfeld, Michael, Markus Heinrichs, Paul J. Zak, Urs Fischbacher, and Ernst Fehr (2005). "Oxytocin increases trust in humans."

of transfers, 21% of the oxytocin group made transfers less than 8 MUs while 45% of the placebo group made similarly low transfers.

The authors then engage in an exemplary experimental design that further illuminates the role of oxytocin. Do the trustors transfer more in the oxytocin group because they perceive "lower risk in a social interaction" or just "lower risk"? The risk experiments that do not involve any social interaction are able to answer this question. In the risk experiments, there is no significant difference in the transfers made between the oxytocin and placebo groups. Thus, oxytocin appears to enhance trust only in social interactions. Could the results be caused by other factors such as moods and calmness differences? In order to test this, measures of moods and calmness were taken before and after the administration of oxytocin but no significant differences were found. Does oxytocin cause a general increase in prosocial behavior? In order to test this, one can examine the back transfers of trustees, which were not found to be statistically different among the oxytocin and the placebo groups. Thus, oxytocin does not lead to a general increase in prosocial behavior, but, specifically, an improvement in trusting behavior. Is the observed effect of oxytocin caused by a general increase in optimism? In order to test this, the beliefs of trustors about the back transfers of trustees in the oxytocin and placebo groups are elicited but no differences are found in these beliefs. Thus, the results are not driven by an increase in optimism.

Subsequent research has examined several social effects of oxytocin. In addition to trusting behavior, these include interpersonal relations, generosity, cooperation, perceptions of trustworthiness, attractiveness, approachability, attachment, and socio-emotional responses, such as envy and social aversion; the interested reader can look up the associated references in the meta-study

by Bartz et al. (2011). Bartz et al. (2011) also note that the overall social effects of oxytocin are small and heavily context dependent. Their solution is to advocate greater recognition of heterogeneous frames and contexts as well as individual-level heterogeneity. For instance, the prosocial effects of oxytocin are moderated, disappear, or reverse if one's opponents are portrayed as untrustworthy or are perceived to be outgroup members (Mikolajczak et al., 2010; Declerck et al., 2010; De Dreu et al., 2010).

Israel et al. (2014) examine the effect of oxytocin on the ability to detect deception, based on facial expression, body language, tone of voice, and other non-verbal clues. Two groups of subjects are shown clips of the game show "Friend or Foe" in which two individuals engage in a non-binding discussion prior to playing a prisoner's dilemma type of game; each player in the game has two strategies, friend (cooperate) or foe (defect). The clip is paused just before the outcome is revealed and subjects are asked to guess the outcome. One group is exposed to oxytocin and the second group is exposed to a placebo. Oxytocin subjects were more likely to be deceived as compared to placebo subjects, i.e., their accuracy in predicting deception was lower. However, oxytocin and placebo subjects made guesses of similar accuracy when predicting the cooperative behavior of others. Placebo subjects, but not oxytocin subjects, were able to predict the decisions of the contestants better than chance. Thus, oxytocin appears to reduce social vigilance that can reduce their payoffs.

APPENDIX ON GAME THEORY

A.1 Introduction

This appendix introduces the notation and some of the basics of game theory in an informal manner, with particular emphasis on some of the games that are considered in this book. It is not a substitute for a course in game theory, nor intended to teach formal game theory as such. The idea is to provide interdisciplinary readers and undergraduate economics students with a practical starter-guide that enables them to read this book. The material is provided in a relatively condensed form, without proofs, but with recourse to simple examples. Readers who are interested in a formal treatment of game theory can consult several excellent sources.¹

A.2 Normal form games

The set of players is $N = \{1, 2, \dots, n\}$. Each player $i \in N$ can play n_i *pure strategies*, thus, the pure strategy set of player i , $S_i = \{s_{i1}, s_{i2}, \dots, s_{ini}\}$. To minimize notation, we shall denote a generic element of the set S_i by s_i . Elements of S_i can be abstract entities, but for most of the applications we have $s_i \in \mathbb{R}$.² A *pure strategy profile* is given by $s = (s_1, s_2, \dots, s_n)$; this is an element of the set $S = \times_i S_i$. It is sometimes convenient to write the pure strategy profile as $s = (s_i, s_{-i})$ where s_{-i} is the pure strategy profile of all players other than player i .

The utility function of the i th player is given by the mapping $u_i : S \rightarrow \mathbb{R}$. We summarize the list of all payoff functions by $u = (u_1, u_2, \dots, u_n)$.³ An n -player *normal form* or *strategic form* game is denoted by $G(N, S, u)$. *Actions* and *strategies* coincide in one-shot simultaneous move games, as in the static prisoner's dilemma game. However, in sequential move games (see below) these two entities differ.

It is possible that players might wish to randomize between their pure strategy, much like a tennis player randomizing his service to the right and to the left of the opponent or a football player kicking a penalty to the right or to the left of a goalkeeper. This motivates the concept of a *mixed strategy*.

Player i 's *mixed strategy*, σ_i , is simply a probability distribution over the pure strategy set, S_i . We denote by $\sigma_i(s_i)$ the probability with which player i plays the pure strategy $s_i \in S_i$. Sometimes

¹ There is a range of excellent books on the subject. For instance, at a basic level, Gibbons (1992), Dixit and Skeath (2004), Osborne (2004), and Watson (2013) provide lucid treatments that are rich in applications. Fudenberg and Tirole (1991a) is a more advanced, but very concise and authoritative, book that would be suitable for those who prefer a more rigorous approach. A small sample of other advanced books that may be consulted is Maschler et al. (2013), Osborne and Rubinstein (1994), Myerson (1991), and Kreps (1990).

² When this may create potential ambiguity we denote the generic element of S_i by s_{ij} , $j = 1, 2, \dots, n_i$.

³ At this point, we impose no restrictions on the compactness of the strategy space or the continuity or shape (e.g., quasiconcavity) of the payoff functions. Such restrictions will, however, be needed when we consider sufficient conditions for the existence of an equilibrium below.

we may need to use the slightly more cumbersome notation $\sigma_i(s_{ij})$ for the probability with which player i plays the pure strategy $s_{ij} \in S_i$. Any pure strategy that is played with a non-zero probability under σ_i is said to belong to its *support*. In particular, a pure strategy $s_i \in S_i$ for player i , simply corresponds to a degenerate mixed strategy, $\sigma_i(s_i) = 1$. The set of all mixed strategies of player i is denoted by Σ_i . Formally,

$$\Sigma_i = \left\{ \sigma_i = (\sigma_i(s_{i1}), \sigma_i(s_{i2}), \dots, \sigma_i(s_{in_i})) : \sigma_i(s_{ij}) \geq 0 \forall j \text{ and } \sum_{j=1}^{n_i} \sigma_i(s_{ij}) = 1 \right\}. \quad (\text{A.1})$$

The mixed strategy profile of the game $\sigma = (\sigma_1, \sigma_2, \dots, \sigma_n)$ is an element of the set $\Sigma = \Sigma_1 \times \Sigma_2 \times \dots \times \Sigma_n$. It will sometimes be convenient to express the mixed strategy profile by $\sigma = (\sigma_i, \sigma_{-i})$ where σ_{-i} is the mixed strategy profile of all players other than player i . In actual practice, one only observes a particular pure strategy played by a player, so the observer must infer the underlying mixed strategy of the player. Whether players can do so is an empirical question. Part 4 considers these issues in some detail.

Suppose that each player's randomization over the pure strategies is independent of that of the other player. Hence, the joint probability of any strategy profile $s = (s_1, s_2, \dots, s_n) \in S$ is $\prod_{i=1}^n \sigma_i(s_i)$. Thus, assuming the expected utility property, the expected payoff of player i from the mixed strategy profile $\sigma = (\sigma_i, \sigma_{-i})$ is given by

$$\pi_i(\sigma_i, \sigma_{-i}) = \sum_{s \in S} \left[\prod_{i=1}^n \sigma_i(s_i) \right] u_i(s_i, s_{-i}). \quad (\text{A.2})$$

In (A.2), the own strategy, σ_i , or the strategy of others, σ_{-i} , can be possibly degenerate. This allows us to compute $\pi_i(s_i, \sigma_{-i})$, $\pi_i(\sigma_i, s_{-i})$ and $\pi_i(s_i, s_{-i}) \equiv u_i(s_i, s_{-i})$.

Definition A.1 (*Best response*): Suppose that players satisfy the expected utility property.

(a) Denote the mixed strategy profile of all players other than player i by σ_{-i} . Then σ_i^* is said to be a *best response* (sometimes called *best reply*) of player i if

$$\pi_i(\sigma_i^*, \sigma_{-i}) \geq \pi_i(s_i, \sigma_{-i}) \text{ for all } s_i \in S_i. \quad (\text{A.3})$$

Denote the set of all best responses to σ_{-i} by $BR_i(\sigma_{-i})$.

(b) (*Nash equilibrium*) A strategy profile $\sigma^* = (\sigma_1^*, \sigma_2^*, \dots, \sigma_n^*)$ is a *Nash equilibrium* if for all $i \in N$ we have $\sigma_i^* \in BR_i(\sigma_{-i}^*)$.

In Definition A.1, the best response and the Nash equilibrium need not be unique. Also note that in (A.3) we need to check only if there are any profitable “pure strategy deviations” of player i . Due to the linearity of the payoffs in (A.2), if (A.3) holds then so does $\pi_i(\sigma_i^*, \sigma_{-i}) \geq \pi_i(\sigma_i, \sigma_{-i})$ for all $\sigma_i \in \Sigma_i$ [The reader should check this.]

All pure strategies in the support of a mixed strategy must give identical expected payoffs. Suppose that two pure strategies in the support of a mixed strategy give different expected payoffs. Then the individual can improve the payoff by eliminating the pure strategy with the lower expected payoff. Thus, it follows that a *strict best response* in which the inequality in (A.3) is strict can only be in pure strategies. We now give the strict version of Definition A.1.

Definition A.2 (*Strict best response*): If $\pi_i(s_i^*, \sigma_{-i}) > \pi_i(s_i, \sigma_{-i})$ for all $s_i \neq s_i^*$ then the *best response* is *unique*, i.e., $BR_i(\sigma_{-i}) = \{s_i^*\}$.

Remark A.1 (Strict Nash equilibrium): The strategy profile $s^* = (s_1^*, s_2^*, \dots, s_n^*)$ is a strict Nash equilibrium if $BR_i(s_{-i}^*) = \{s_i^*\}$ for all $i \in N$.

There is no guarantee that a strict Nash equilibrium will exist (see, for instance, the matching pennies game below).

An alternative equilibrium concept can be given in terms of dominated strategies.

Definition A.3

(a) (Strict dominance): A pure strategy s_i is “strictly dominated” for player i if there exists some other mixed strategy $\sigma_i \in \Sigma_i$ such that

$$\pi_i(\sigma_i, s_{-i}) > \pi_i(s_i, s_{-i}) \text{ for all } s_{-i} \in S_{-i}. \quad (\text{A.4})$$

(b) (Weak dominance): If the inequality in (A.4) is weak but for at least one $s_{-i} \in S_{-i}$ it is strict then s_i is a “weakly dominated” strategy for player i .

Note that due to the linearity of the payoffs in (A.2), if (A.4) holds for all $s_{-i} \in S_{-i}$ then it also does hold for all $\sigma_{-i} \in \Sigma_{-i}$. The reason that we check for dominance of a pure strategy against a mixed strategy in (A.4) is given in the next example.

Example A.1 A pure strategy which is not dominated by any pure strategy can nevertheless be strictly dominated by a mixed strategy. As an example, consider the following payoff matrix.

	L	R
U	8, .	0, .
M	0, .	8, .
D	3, .	3, .

The row player (player 1) has three strategies, U, M, D and the column player (player 2) has two strategies, L, R. The payoffs of player 1 are shown in the payoff matrix while the payoffs of the column player are suppressed because they are not relevant to the argument. For player 1, none of the pure strategies is dominated by any other pure strategy. Now consider a mixed strategy for the row player in which U and M are each played with probability 1/2. The payoff from this mixed strategy, given any strategy of the opponent is $4 > 3$, hence, it dominates the pure strategy D.

It is obvious that any mixed strategy whose support contains a dominated pure strategy, is itself dominated by another possibly mixed strategy—one that eschews the play of the dominated strategy. The next example makes a more subtle point that even if a mixed strategy does not contain any dominated pure strategy in its support, it could still be dominated by another mixed strategy.

Example A.2 Suppose that we alter the normal form of the game in Example A.1 to the following (continuing to suppress the payoffs of player 2).

	L	R
U	8, .	−6, .
M	−6, .	8, .
D	2, .	2, .

None of the pure strategies of the row player is dominated. Consider a mixed strategy in which the row player plays U, M with equal probabilities. Irrespective of the strategy of the column player, the expected payoff from this mixed strategy is 1 which is dominated by the pure strategy D .

Suppose that we were to iteratively delete strictly dominated strategies of players. The simplest case occurs when one round of deletion of strictly dominated strategies leads to a unique strategy profile $s^* = (s_1^*, s_2^*, \dots, s_n^*)$. It follows that for all i , $\pi_i(s_i^*, s_{-i}^*) > \pi_i(s_i, s_{-i}^*)$ for all $s_i \neq s_i^*$ and $s_i \in S_i$. Thus, s^* is the unique Nash equilibrium of the game. One can analogously show that if one round of deletion of weakly dominated strategies leads to a unique surviving strategy profile, it too must be a Nash equilibrium. These results can be generalized significantly as shown in the next proposition; the reader can consult any standard game theory text for the proof.

Proposition A.1 *Suppose that the successive iterated deletion of strictly dominated strategies leads to a unique strategy profile $s^* = (s_1^*, s_2^*, \dots, s_n^*)$. Then s^* is the unique Nash equilibrium of the game. The result is invariant to the order of deletion of the strictly dominated strategies.⁴*

Proposition A.1 demonstrates the importance of the concept of iterated deletion of dominated strategies by showing its relationship with a Nash equilibrium. A few comments are in order. First, as one engages in more rounds of iterated deletion of dominated strategies, the degree of rationality that we impose on players grows too. Indeed, we need *common knowledge of rationality*⁵ and of the *structure of the game* for these results to hold. Second, not all games can be solved by iterated deletion of dominated strategies, yet they may have a Nash equilibrium, hence, the latter concept is less restrictive. Third, the concept of iterated deletion of dominated strategies bears an important relation to the concept of *rationalizability* introduced by Bernheim (1984) and Pearce (1984). The basic idea of rationalizability is to narrow down the set of strategies that rational players will play as best responses, given their beliefs. The beliefs themselves are not arbitrary. The assumption of common knowledge of rationality ensures that rational players believe that other rational players would also play a best response to some reasonable beliefs that they hold about them and so on; rationalizable strategies are those that survive this infinite regress. In two-player games, the set of rationalizable strategies and those that survive iterated strict dominance, coincide. However, for more general games, rationalizable strategies are a subset of the strategies that survive iterated deletion of strictly dominated strategies.

It is often said that a Nash equilibrium gives a *consistent prediction* of how the game will be played. The reason is that if each player can correctly guess the strategy of the others in a Nash equilibrium, then none of the players has any incentive to deviate from their own strategies in a Nash equilibrium. Whether players actually do so is an empirical question that is examined in Parts 4 and 5. The situation gets murkier if there are multiple Nash equilibria. How do players coordinate their beliefs on a particular Nash equilibrium in this case? Evidence on this issue is examined in Part 4.

⁴ This conclusion does not hold for the iterated deletion of weakly dominated strategies (IDWDS) where the order of deletion may be important. Further, not all Nash equilibria may survive IDWDS (the reader may wish to construct simple examples to show this).

⁵ In a two-player game with players A and B, there is common knowledge of an event X if the following infinite regress holds. Player A knows X. Player A knows that B knows X. Player A knows that B knows that A knows that B knows X and so on. A similar statement holds for player B. By contrast, *mutual knowledge of rationality* means that each player knows that he or she is rational and that other players are rational.

Although this is ultimately an empirical question that we address in the book, why should a purely deductive equilibrium concept such as a Nash equilibrium hold in static, simultaneous move games, or in novel situations with new players? In a strict Nash equilibrium with N players, say, $s^* = (s_1^*, s_2^*, \dots, s_n^*)$, we imagine player i asking questions such as these: “My opponents are playing their part of the Nash equilibrium, s_{-i}^* , can I do any better by deviating to one of my other pure strategies $s_i \in S_i$?” But why should someone be thinking along these lines when they do not know what strategies their opponents are choosing? Perhaps there is an obvious way to play the game where such a deductive approach may be useful. But what if there is no obvious way to play the game? There are two observations in this respect.

1. The concept of a Nash equilibrium (Definition A.1) does not place any restrictions on the beliefs of players about what others will do. Restrictions on beliefs that lead to a Nash equilibrium outcome are the subject matter of the *epistemic foundations of a Nash equilibrium*. The epistemic conditions for a Nash equilibrium turn out to be extremely demanding. Aumann and Brandenburger (1995) proved the following result. Suppose that we have mutual knowledge of the payoffs, mutual knowledge of rationality of players, common knowledge of the beliefs (or conjectures) each player has about the others, and common priors. Then the common conjectures about each player j by the other players agree and constitute a Nash equilibrium of the game. Polak (1999) showed that if mutual knowledge of the payoffs is strengthened to common knowledge of payoffs then the Aumann–Brandenburger conditions imply common knowledge of rationality. Recent research offers an unsettled view of the epistemic foundations; see for instance, Gintis (2009). For our purposes, it is important to note that if a Nash equilibrium is violated by the empirical evidence, then the epistemic conditions are also empirically refuted.
2. A commonly used defence of Nash equilibrium is that it is the outcome of a learning process that takes place over a “sufficiently long period of time”. In these learning processes, players could be responding to the average play of the opponent in the past, or the play of the opponent in the previous period (as in a *Cournot adjustment process*), or the past level of some aggregate variable. At a purely theoretical level, (i) convergence of play to a Nash equilibrium is not always guaranteed using these learning processes, and (ii) when convergence takes place, there is no guarantee that the underlying learning process is plausible; see, for instance, Fudenberg and Tirole (1991a, pp. 25–9).

Even when convergence does take place, a valid question to ask is: Does it take place in a “sensible amount of time” that is representative of actual real-world interactions?⁶ On an empirical level, when we use field data, can we be sure that the data is not contaminated by repeated game effects in what is essentially a static game? By contrast, such repeated game effects can be controlled within an experimental setting by ensuring that subjects are not repeatedly matched and do not communicate. These are some of the issues that must be addressed by learning-based justifications of a Nash equilibrium.

Rationalizability, on the other hand, does not make predictions based on any equilibrium concept. However, if the set of possible strategy profiles that are deemed to be reasonable under rationalizable strategies is too large then the predictive power of theory is weak.

⁶ My long time co-author, Ali al-Nowaihi, attended a conference at a leading university where the speaker claimed that, in his model, he was pleased to report that convergence to a Nash equilibrium occurs in 10^{83} periods. Ali asked him if he knew the number of particles in the observable universe (an estimate is 10^{80})? Clearly such justifications of a Nash equilibrium are not convincing.

Does a Nash equilibrium exist? In many examples that we consider, the pure strategy sets of players, S_i , are finite (this is not always the case, e.g., in Cournot games where output choices are continuous⁷). For such games, the existence of a Nash equilibrium, possibly in mixed strategies, is always guaranteed. The proofs require standard fixed point arguments so we omit them; see for instance Fudenberg and Tirole (1991a).

Theorem A.1 (Nash, 1950): Consider the normal form game $G(N, S, u)$ where N is a finite set. Suppose that, for all i , the strategy sets S_i are finite. Then there exists at least one Nash equilibrium in mixed strategies.

In some commonly used games, such as under Cournot competition, the strategy spaces of each player are chosen from some continuous interval, hence, S_i is not finite. Thus, Theorem A.1 is not applicable. Notice that Theorem A.1 only provides sufficient conditions, so while a Nash equilibrium might still exist when the finiteness of strategy spaces is violated, it is not guaranteed. Another theorem is often helpful in this case for finding a *pure strategy* Nash equilibrium.

Theorem A.2 Consider the normal form game $G(N, S, u)$ where N is a finite set. Suppose that for all i , the strategy sets S_i are non-empty, convex, and compact subsets of some Euclidean space. If for all i , π_i is continuous in $s = (s_1, s_2, \dots, s_n)$ and quasi-concave in own strategy, s_i , then a pure strategy Nash equilibrium exists.⁸

Example A.3 (Mixed strategy Nash equilibrium in the battle of the sexes game).

	O	T
O	2, 1	0, 0
T	0, 0	1, 2

A couple can either go to the Opera (strategy O) or the Theater (strategy T). They only like going out together so the payoff from going separately to the two events is zero for both. The husband (row player) prefers the Opera while the wife (column player) prefers the Theater. There are two pure strategy Nash equilibria, (O, O) and (T, T). There is also one mixed strategy equilibrium, which can be found as follows. Denote the mixed strategies of the husband and wife respectively by σ_H and σ_W . The husband's mixed strategy σ_H involves the play of O, T with respective probabilities $p, 1 - p$ while under σ_W the strategies O, T are played with respective probabilities $q, 1 - q$. We wish to find the best response of each player, given the mixed strategy of the other. The husband's payoffs from the two pure strategies are:

$$\pi_H(O, \sigma_W) = 2q; \quad \pi_H(T, \sigma_W) = 1 - q \quad (\text{A.5})$$

Recall that if two pure strategies belong to the support of a mixed strategy, they should generate identical expected payoffs (otherwise the one that generates a lower payoff can be eliminated to improve payoffs). The two payoffs in (A.5) are equal when $2q = 1 - q \Leftrightarrow q = 1/3$. For the husband, when $q > 1/3$, the strategy Opera dominates and when $q < 1/3$, the strategy

⁷ In a Cournot game, two firms simultaneously choose their quantity levels. The sum of these quantities determines the market supply and the market demand curve is downward sloping. The two firms may or may not have identical costs.

⁸ For proofs see Debreu (1952) and Glicksberg (1952). A proof is also sketched in Fudenberg and Tirole (1991a).

Figure A.1 Best response functions for the battle of sexes game.

Theater dominates. However, when $q = 1/3$ then the husband is indifferent between the two. Denote the best response of the husband, given the wife's strategy by $\sigma_H^* \in BR^H(\sigma_W)$. Since $p + 1 - p = 1$, let us summarize σ_H as a choice of p alone (analogously for the wife, by q alone). The optimal value of $p = p^*(q)$ for any q is, thus, summarized by:

$$p^*(q) = \begin{cases} 1 & \text{if } q > 1/3 \\ [0, 1] & \text{if } q = 1/3. \\ 0 & \text{if } q < 1/3 \end{cases} \quad (\text{A.6})$$

Proceeding analogously, one can derive the best reply of the wife:

$$q^*(p) = \begin{cases} 1 & \text{if } p > 2/3 \\ [0, 1] & \text{if } p = 2/3. \\ 0 & \text{if } p < 2/3 \end{cases} \quad (\text{A.7})$$

The two best reply functions are shown in Figure A.1. On the vertical axis we have $p^*(q)$, the probability with which the husband plays O, as a function of the probability, q , with which the wife plays O. $p^*(q)$, the husband's best response, as described in (A.6), can then be drawn as the bold continuous step function. On the horizontal axis we have $q^*(p)$, the optimal probability with which the wife plays O as a function of p , the husband's probability of playing O. The best response of the wife, $q^*(p)$, is shown as the bold, dotted step function. The two best response functions intersect at the two pure strategy Nash equilibria, (0, 0) and (1, 1). They also intersect at the unique interior point (2/3, 1/3), which is the (unique) Nash equilibrium in mixed strategies.

A.3 A basic taxonomy of some normal form games

Consider the following game with two players and two actions for each player. The row player chooses from the actions U, D and the column player chooses from the actions L, R . The payoffs corresponding to each strategy profile are shown in the following payoff matrix.

	L	R
U	a_{11}, b_{11}	a_{12}, b_{12}
D	a_{21}, b_{21}	a_{22}, b_{22}

1. If (U, L) and (D, R) are Nash equilibria, then we have a *coordination game*. In such games, (U, L) is said to *payoff dominate* (D, R) if $a_{11} \geq a_{22}$ and $b_{11} \geq b_{22}$ with at least one of these inequalities being strict. This enables us to Pareto rank the two equilibria: (U, L) is Pareto superior to (D, R) . Under these conditions, if we observe that (U, L) is not played, then we have a *coordination failure*. These definitions go through for any finite game.
2. Consider a coordination game in which (U, L) and (D, R) are strict Nash equilibria (i.e., $a_{11} > a_{21}$, $b_{11} > b_{12}$, $a_{22} > a_{12}$, $b_{22} > b_{21}$), but in addition, we have $a_{12} < a_{21}$ and $b_{21} < b_{12}$ then we have a *stag-hunt game*. For instance,

	L	R
U	2, 2	0, 1
D	1, 0	1, 1

Payoff maximizing players want the equilibrium (U, L) to be played. However, there might be uncertainty about the strategy of the opponent. For instance, if the row player plays U and the column player plays R , the row player gets the lowest possible payoff. Hence, this game is sometimes also known as an *assurance game*; each player would like to be assured that the other will play their part of the *payoff dominant equilibrium*, (U, L) . In the absence of such assurance, players might wish to play a *secure option*. The *maximin outcome* or the *secure option* (see formal definition below) arises when the outcome is (D, R) . In this case, each player is guaranteed a minimum payoff of 1, irrespective of the action of the opponent.

3. Suppose that (U, L) and (D, R) are Nash equilibria. If $a_{11} > a_{22}$ and $b_{11} < b_{22}$ then this is known as a *battle of sexes game* (BoS) that we used to illustrate the computation of mixed strategy equilibrium, above. The row player would like the Nash equilibrium (U, L) to be played while the column player prefers the Nash equilibrium (D, R) to be played.

A.4 Two-person zero-sum games

A fair deal of the testing of the *mixed strategy Nash equilibrium* (MSE) has been carried out in finite, two-player zero-sum games. In such games, for any pair of strategies of the two players, (s_1, s_2) , the sum of the payoffs of the two players is zero, i.e., $\pi_1(s_1, s_2) + \pi_2(s_1, s_2) = 0$. The *minimax outcome* in such games can be explained as follows. Suppose that the mixed strategies of the two players are σ_1, σ_2 and the payoff functions of the players are $\pi_1(\sigma_1, \sigma_2)$, $\pi_2(\sigma_1, \sigma_2)$. The *minimax value* to player 1 is then defined as

$$v_1 = \min_{\sigma_2} \left(\max_{\sigma_1} \pi_1(\sigma_1, \sigma_2) \right).$$

Essentially first fix the strategy of player 2 and maximize the payoff of player 1 with a choice of his strategy, σ_1 . Then minimize the result with a choice of the strategy of player 2, σ_2 . Clearly, player 1 can never be held to a payoff lower than this.

The *maximin value* to player 1 can be similarly calculated in two steps as follows.

$$V_1 = \max_{\sigma_1} \left(\min_{\sigma_2} \pi_1(\sigma_1, \sigma_2) \right).$$

von Neumann (1928) showed that for zero-sum games, $v_1 = V_1$. Analogously for player 2, $v_2 = V_2$. Let the mixed strategy Nash equilibrium for the game be denoted by (σ_1^*, σ_2^*) . For finite, zero-sum games, the minimax, maximin, and MSE outcomes coincide and $v_1 = V_1 = \pi_1(\sigma_1^*, \sigma_2^*)$ and $v_2 = V_2 = \pi_2(\sigma_1^*, \sigma_2^*)$. Thus, support for or rejection of minimax in these games is respectively support for or rejection of MSE.

A.5 Selection criteria among Nash equilibria: payoff dominance and risk dominance

In the presence of multiple Nash equilibria, one needs to invoke extra refinements to predict which equilibrium might be chosen. An important refinement of Nash equilibrium, based on purely deductive reasoning, is Harsanyi and Selten's *payoff dominance* and *risk dominance criteria*. Consider the two-player coordination game given by:

1\2	L	R
L	a_{11}, b_{11}	a_{12}, b_{12}
R	a_{21}, b_{21}	a_{22}, b_{22}

We assume that (L, L) and (R, R) are strict Nash equilibria (i.e., $a_{11} > a_{21}; b_{11} > b_{12}; a_{22} > a_{12}; b_{22} > b_{21}$). Further, both players get a higher payoff under one of the two Nash equilibria so that one equilibrium *payoff dominates* the other. For instance, (R, R) *payoff dominates* (L, L) if $a_{22} \geq a_{11}$ and $b_{22} \geq b_{11}$ with at least one of these two inequalities being strict. Can one make an argument in favor of (L, L) , on the grounds that it is less risky in some sense? The risk dominance criteria explores this question.

Suppose that player 1 (the row player) believes that player 2 (the column player) plays R with probability q and L with probability $1 - q$. Player 2 believes that player 1 plays R with probability p and L with probability $1 - p$. If $q = 1$ then player 1 should play R because (R, R) is a Nash equilibrium. For $q = 0$, player 1 should play L because (L, L) is a Nash equilibrium. This motivates the next definition.

Definition A.4 Let $\underline{q}$ be the minimum probability of play of R by player 2 such that it is optimal for player 1 to play R . Analogously let $\underline{p}$ be the minimum probability of play of R by player 1 such that it is optimal for player 2 to play R .

Definition A.5 (*Risk factor and risk dominance*): The risk factor of the equilibrium (R, R) is defined as $\min \{ \underline{q}, \underline{p} \}$. Similarly the risk factor of the equilibrium (L, L) is defined as $\min \{ 1 - \underline{q}, 1 - \underline{p} \}$. A risk dominant equilibrium is one whose risk factor is lowest.

Using Definition A.5, (L, L) is the risk dominant equilibrium if

$$\min \{ \underline{q}, \underline{p} \} \geq \min \{ 1 - \underline{q}, 1 - \underline{p} \}. \quad (\text{A.8})$$

Consider the equilibrium (R, R) first. It is optimal for the row player to play R if

$$a_{21}(1 - q) + a_{22}q \geq a_{11}(1 - q) + a_{12}q,$$

hence,

$$\underline{q} = \frac{a_{21} - a_{11}}{a_{21} + a_{12} - a_{11} - a_{22}}. \quad (\text{A.9})$$

Analogously, we can find that

$$\underline{p} = \frac{b_{12} - b_{11}}{b_{12} + b_{21} - b_{11} - b_{22}}. \quad (\text{A.10})$$

Using (A.8), (A.9), (A.10), (L, L) is the risk dominant equilibrium if

$$(a_{11} - a_{21})(b_{11} - b_{12}) \geq (a_{22} - a_{12})(b_{22} - b_{21}). \quad (\text{A.11})$$

Expression (A.11) gives a quick way of finding the risk dominant equilibrium. Each player is less likely to deviate if the equilibrium payoff is relatively greater as compared to deviating to an alternative strategy. The risk dominant equilibrium maximizes the product of the gain from unilateral deviation. There is a particularly simple criteria to check for risk dominance in symmetric 2×2 games such as the following.

	L	R
L	a, a	c, d
R	d, c	b, b

Using (A.11) (L, L) is risk dominant relative to (R, R) if

$$(a - d)(a - d) \geq (b - c)(b - c) \Leftrightarrow a - d \geq b - c. \quad (\text{A.12})$$

Consider the following symmetric coordination game from Fudenberg and Levine (1998).

	L	R
L	$2, 2$	$-a, 0$
R	$0, -a$	$1, 1$

In this game, there are two pure strategy Nash equilibria, (L, L) and (R, R) . The reader may wish to find the conditions under which (L, L) is a risk dominant equilibrium relative to (R, R) .

Figure A.2 Two examples of extensive form games.

A.6 Extensive form games

In an *extensive form game*, players move in sequence, having observed the history of the game so far. Consider two examples of extensive form games in Figure A.2 in panels A and B used in the experimental tests of, respectively, Beard and Beil (1994) and Schotter et al. (1994). The empirical evidence for these games is considered in Part 4.

1. The game in Figure A.2-A is a 2-player *dynamic game of perfect information*. Player 1 moves first, choosing among two possible strategies L, R. If player 1 plays R, then player 2 gets an opportunity to choose one among two possible strategies, l, r. The payoffs are shown at the bottom of the game. When making a move, each player is perfectly certain which decision node he is at.
2. The game in Figure A.2-B is a *dynamic game of imperfect information*. Player 1 can play T and end the game or he can play L and hand over the choice of moves to player 2. Player 2 can then play T and end the game or play L, in which case both players play a simultaneous move battle of sexes game, BoS (see Section A.3 above), in which each player chooses among one of two possible strategies, M, B. The dotted line indicates that when player 2 chooses his action, M or B, he does not, in the simultaneous move BoS game, know the action chosen by player 1; this is the sense in which information is imperfect.

Consider a slightly more formal structure of extensive form games. There is a finite number of players, $i = 1, 2, \dots, n$ who typically move in sequence although at some stage of the game, a subset of the players may move simultaneously. There is a finite set of (decision) nodes $T = \{t_1, t_2, \dots, t_K\}$. For instance, in the extensive form in Figure A.2-B, there are five nodes at which players decide on their choice of actions. A binary relation $<$ is defined on T that takes the form of a *strict precedence relation*. Thus, $t_i < t_j$ means that the node t_i precedes the node t_j . Since this relation is strict, it is asymmetric so we cannot have $t_i < t_i$ but the relation is transitive, i.e., $t_i < t_j$ and $t_j < t_k$ imply $t_i < t_k$. It may help to think of several generations of a family as the motivation for this structure.

It will be useful, for exposition purposes, to classify the nodes into the following distinct categories. By $P(t)$ we denote the set of *predecessors* of node t and by $S(t)$ the set of *successors* of node t . Formally,

$$P(t) = \{t_j \in T : t_j \prec t\} \text{ and } S(t) = \{t_j \in T : t \prec t_j\}.$$

There is an *initial node* in each panel of Figure A.2 corresponding to the move by player 1 which is not preceded by any node. We call this the set of initial nodes $I = \{t \in T : P(t) = \phi\}$, where ϕ denotes the empty set. In this book we typically assume that the set I is a singleton set. Also in each panel of Figure A.2, there are a set of *final nodes* immediately followed by the payoffs but no successor nodes. We call these the *terminal nodes* $Z = \{t \in T : S(t) = \phi\}$. Other than at the terminal nodes, some player makes a decision at every other node. Thus, we call $D = T \setminus Z$ the set of decision nodes.

Drawing the analogy with successive generations of humans, any human has a unique parent. Analogously, any node other than the set of initial nodes, $t \in T \setminus I$, has an immediate unique predecessor node, $\rho(t)$, so $\rho(t) \prec t$. Thus, if $t_k \prec t$ and $t_k \neq \rho(t)$ then it must be that $t_k \prec \rho(t)$ [The reader should try to show this.]. This is an important implication because it means that starting from any node $t \in T$, by tracing the immediate predecessor of each node $(t, \rho(t), \rho(\rho(t)), \dots)$ we will eventually reach one of the initial nodes. Analogously, starting from an initial node, there is a unique path to any node t . In particular, there can be no cycles, and so we get a tree structure or an *arborescence*.

At any decision node $d \in D$, a subset of the players, or a special player, *nature*, listed as player $n + 1$, can make a move. We say that player $i(d) \subseteq \{1, 2, \dots, n, n + 1\}$ moves at the decision node $d \in D$. The set of actions available at a decision node $d \in D$ is denoted by $A(d)$.

A critical component in the description of extensive form games is the specification of *information sets*. All decision nodes $d \in D$ are partitioned into information sets. Denote by H the set of all possible information sets. A typical element of H is denoted by h . Two nodes, d_1, d_2 belong to the same information set h if the following three conditions are satisfied. (i) Each of the nodes does not belong to the set of predecessors of the other ($d_1 \notin P(d_2)$ and $d_2 \notin P(d_1)$). (ii) The player who moves at the two nodes is identical ($i(d_1) = i(d_2)$) and this player does not know with certainty, which of the two nodes he or she is at. (iii) The set of actions at the two nodes are identical ($A(d_1) = A(d_2)$).

Extensive form games in which each information set $h \in H$ is a singleton are known as *dynamic games of perfect information*. An example is the game in Figure A.2-A as are many other games examined in this book such as the *centipede games* which provide important empirical insights on refinements of Nash equilibrium. By contrast, when there is at least one $h \in H$ that is not a singleton then we have a *dynamic game of imperfect information*, as in Figure A.2-B. In Figure A.2-B when players play the BoS game, the two nodes at which player 2 may move and play M or B are in the same information set (check that this satisfies the conditions of an information set).

The final component, the payoff function, u_i , gives the payoff of each of the players $i \in N$ at each of the terminal nodes in T .

Dynamic games of perfect information can be solved by *backward induction*, which can be explained as follows. Assume that there is common knowledge of the game, of the payoff structure, and of the rationality of players. Begin at the bottom of the tree with all nodes whose successors are terminal nodes. The player with the move at any of these nodes chooses an action that maximizes his payoff. Fold back the game tree, replacing each of these nodes with the payoffs achieved in the previous calculation and call this the new terminal node. Now start with the predecessor of all these terminal nodes and repeat the previous step, folding back the game tree again. Continue to do so until one reaches an initial node of the tree. Backward induction can eliminate strategies that are weakly dominated, hence, it can also remove Nash equilibria that are based on such strategies.

Let us illustrate the method of backward induction for the dynamic game of perfect information in Figure A.2-A. There are two Nash equilibria (R,r) and (L,l) (check that the strategy of each player is a best response to the strategy of the other player). However, the equilibrium (L,l) relies on a *non-credible threat* by player 2 to play l if he gets the move (because the payoff of player 2 from the action r is higher). The backward induction equilibrium eliminates precisely these sorts of non-credible threats. Using the method outlined above, the reader can check that the equilibrium backward induction outcome for the extensive form game in Figure A.2-A is uniquely given by (R,r).

For dynamic games of imperfect information, we need to define the concept of a *proper subgame*. Formally, a proper subgame is (i) a node t that belongs to an information set that is a singleton ($h(t) = \{t\}$) and, (2) all successors $S(t)$ of node t such that for any $t_j \in S(t)$, the information set containing t_j , $h(t_j)$, is a *proper subset* of $S(t)$ (i.e., $h(t_j) \subseteq S(t)$). Consider Figure A.2-B. The third node at which the two players play a simultaneous move BoS game is an example of a proper subgame. The definition of a proper subgame allows us to consider the game starting at the decision node t as a game in its own right, which motivates the next definition. We do not define strategies in extensive form games formally, but the reader can think of such strategies as complete contingent plans of action that specify the action which a player will take at each possible node, when called upon to make a move.

Definition A.6 (*Subgame perfect Nash equilibrium*): A Nash equilibrium of an extensive form game is “subgame perfect” if the restriction of strategies to any subgame, constitute a Nash equilibrium for that subgame.⁹

As an illustration of a subgame perfect equilibrium, apply Definition A.6 to the extensive form game in Figure A.2-B. The game starting at the third node when player 1 has the move and both players play a simultaneous move BoS game is a proper subgame (check that it satisfies the definition of a proper subgame). In the BoS game, there are two equilibria in pure strategies: (M, M) and (B, B). There is also a mixed strategy equilibrium in which player 1 plays M with probability 2/3 and player 2 plays M with probability 1/3 for an expected payoff to each player of 2. The mixed strategy (expected payoff of 2) is dominated by the two pure strategy equilibria (which give a payoff of either 6 or 3), hence, we rule it out by a dominance argument.

We now need to roll back the game tree for each of the two cases that arise with a play of (M, M) and (B, B). Thus, replace the third node respectively with payoffs of (6, 3) and (3, 6). In both cases when the tree is rolled back to the move of player 2, he finds it optimal to play L. In the first case (where (M, M) is the outcome in the BoS game) player 1 plays L at the first node so that in the subgame perfect outcome, the payoffs are (6, 3). In the second case (where (B, B) is the outcome in the BoS game) player 1 finds it optimal to play T, so the payoffs in the subgame perfect outcome are (4, 4).

In some cases, we may need a refinement of subgame perfection in order to pin down beliefs at *out of equilibrium actions*. The relevant refinement has two main components.

1. For each information set $h \in H$, a specification of a mixed strategy that will be played at all nodes in that information set. Denote by σ the resulting strategy profile for the entire extensive form game when one pools this information for each possible information set.
2. For each information set $h \in H$, a specification of the beliefs about the node in h where the player makes a move. Thus, for any information set $h \in H$ and for any node $t \in h$, we may denote the belief of player $i(h)$ who moves at this information set by $\mu(t) \geq 0$ such

⁹ If an extensive form game has no proper subgames, then a Nash equilibrium of the game is also subgame perfect.

that $\sum_{t \in h} \mu(t) = 1$. Denote the set of such beliefs for the entire game, considered across all possible information sets, by μ .

Definition A.7 (*Perfect Bayesian equilibrium (PBE)*; Fudenberg and Tirole, 1991b): A perfect Bayesian equilibrium (PBE) is a pair of strategy vector and belief vector for the entire game, (σ, μ) , such that the following conditions hold.

- (i) (*Sequential rationality*): At any information set $h \in H$ the action of player $i(h)$ who moves at this information set maximizes his payoff given (i) his belief at each node in this information set, $\mu(t)$, $t \in h$, and (ii) the subsequent strategies of the players as listed in σ .
- (ii) (*Bayes' rule applied along the path of play*): Consider the set of information sets that are reached with positive probability, conditional on the actions, σ . On these information sets, we require a mutual consistency of beliefs with actions in the sense that beliefs are computed from the strategies given in Bayes' rule.

One problem with the definition of a PBE in Definition A.7 is that it is silent about beliefs at those information sets that are *off the path of play*, i.e., never reached with strictly positive probability, given the equilibrium strategies; see Definition A.9 below. The reason is that Bayes' rule does not allow us to specify any probabilities at such nodes (see the discussion following Definition A.9); technically the denominator in Bayes' rule becomes zero, hence, the ratio is undefined. In order to ensure that all information sets are reached with a positive probability, a *sequential equilibrium* focuses on sequences of strictly mixed strategies $\{\sigma_n\}$ in which all actions are played with some probability such that $\lim_{n \rightarrow \infty} \sigma_n = \sigma$.¹⁰ The corresponding beliefs are found by Bayes' rule, which are now defined at each node, and given by $\{\mu_n\}$ such that $\lim_{n \rightarrow \infty} \mu_n = \mu$. A sequential equilibrium is found by $\lim_{n \rightarrow \infty} (\sigma_n, \mu_n) = (\sigma, \mu)$ and it is subgame perfect. However, in the limiting case, Bayes' rule cannot be applied to information sets that are off the path of play. In applications, the PBE is often simpler to apply as compared to a sequential equilibrium. Further refinements, such as the Cho–Kreps intuitive criteria (see signaling games below) are needed to put more restrictions on such beliefs.

To see some of these equilibrium concepts in action, consider the two games in Figure A.3 that are due to Kreps (1990).

Consider first the game in Figure A.3-A. The game begins with a move by player 1, who plays either A or D. If player 2 gets the move, he can either end the game by playing action a or can play

Figure A.3 An illustration of sequential rationality with two examples.

¹⁰ The sequential equilibrium concept was introduced by Kreps and Wilson (1982). The basic idea is very similar to the notion of a *trembling hand perfect equilibrium* due to Selten (1975).

action b to give the move to player 3. If given the move, player 3 does not know whether he is at the left or the right hand side node, thus both nodes belong to the same information set, hence, they are connected with a dotted line. Player 3, the only player whose information set is not a singleton, can play either L or R. Subgame perfection cannot refine the set of Nash equilibria here because there are no proper subgames.

One Nash equilibrium of the game is (D, a, L). The reader can check that the action of each player is optimal given the actions of the other players. In the equilibrium (D, a, L), the action a of player 2 is *off the path of play* so we may wonder if it is reasonable? Given that player 3 is supposed to play L, player 2 if given the move should never play a; instead, he should play b to get a payoff of 5 instead of 3. But then the profile (D, b, L) is no longer an equilibrium because player 1 would wish to deviate to A (however, in that case (A, b, L) is no longer an equilibrium because player 3 would wish to deviate to R).

Let us now use sequential rationality to show that the choice of a by player 2 in the equilibrium (D, a, L) is unreasonable. Since the information sets of players 1 and 2 are singletons, they must place probability equal to one of being at their respective nodes if given a chance to move. However, there are two nodes in player 3's information set. Suppose that player 3 assigns a probability of 1 to being at the left node. First note that the action profile for this game is mutually consistent with the beliefs of players (Definition A.7(ii)). Given the prior play of the game in the strategy profile (D, a, L), Bayes' rule recommends player 3 to assign probability 1 of being at the left hand side node. Given that the subsequent path of play specifies that player 3 will play L, player 2 should play b not a. Thus, the play of a by player 2 is not sequentially rational.

Consider the strategy profile (A, b, L) and the belief of player 3 that he is at the left node in his information set with probability 0.95. It is easily checked that the actions of the players are sequentially rational but the condition in Definition A.7(ii) is violated. Given the path of play leading up to the choice by player 3, consistent with Bayes' rule, player 3 should assign probability 1 of being at the right node in the information set. Thus, a PBE can be used to rule out nonsensical equilibria such as (A, b, L).

Let us now consider the game in Figure A.3-B. The extensive form features of this game should by now be apparent to the reader. In order to apply the definition of a PBE, we need to specify the strategy at each information set and the beliefs of players where the information sets are not singletons. Player 2's information set is not a singleton. Suppose that we wish to check for the sequential rationality of the strategy profile (L, d, D). The strategies of players 2 and 3, in this case, are off the path of play, hence, we cannot use Bayes' rule to pin down the precise beliefs that player 2 holds at any of the nodes in his information set. Rather, any beliefs will do (see below). So let us suppose that player 2 assigns a probability of 0.5 of being at any of his nodes. The payoff to player 2 from playing u is $0.5(8) + 0.5(1) = 4.5$ and the payoff from playing d is $0.5(4) + 0.5(2) = 3.0$. Clearly the play of d by player 2 in the strategy profile (L, d, D) is not sequentially rational.

A.7 Games of incomplete information

In the games analyzed so far, there is complete information in the sense that each player knows the *types* of other players. Incomplete information arises when players are not sure of the types of other players. For instance, in a Cournot oligopoly, a firm's type could be its privately known cost; each type then corresponds to a different level of privately known cost.

The set of types of any of the finite number of players $i \in N$ is given by $T_i = \{t_{i1}, t_{i2}, \dots, t_{i\tau_i}\}$; τ_i is the number of possible types of player i , which can potentially be an infinite number, although

for most applications we assume a finite number of types. We take types to differ in their payoff functions. For instance, in a Cournot oligopoly, the different types of the same firm may have different marginal costs. The Cartesian product of types of all players is given by the set $T = T_1 \times T_2 \times \dots \times T_n$. The prior probability of type $t_i \in T_i$ is given by $p(t_i)$, which is common knowledge among all players. The prior probability of a particular vector of types $(t_1, t_2, \dots, t_n)$ is given by $p(t_1, t_2, \dots, t_n)$ and it is also common knowledge. For any player i , the set of types of all other players belongs to the set $T_{-i} = \times_{j \neq i} T_j$; a typical member of T_{-i} is denoted by $t_{-i} = (t_1, \dots, t_{i-1}, t_{i+1}, \dots, t_n)$. The set of actions of any player $i \in N$ is given by S_i and the same action set S_i is available to all types of the player.

Each player has incomplete information about the exact type of the opponents, although he/she is aware of the prior probability, p , of the vector of types of the other players. In this sense, this is a *game of incomplete information* with common priors.¹¹ Following Harsanyi, we assume that nature moves first and draws some vector of types $\mathbf{t} = (t_1, t_2, \dots, t_n) \in T$. To each player $i \in N$, nature privately reveals the corresponding type t_i that was drawn but does not give this information to any other player. This *changes a game of incomplete information into a game of imperfect information*.

A.7.1 Finite Bayesian games of incomplete information

In static games of incomplete information, the players choose their actions simultaneously. The types of the players may be correlated, hence, the probability assigned by player i that the type vector of other players is t_{-i} is given by Bayes' rule

$$\mu(t_{-i} | t_i) = \frac{p(t_{-i}, t_i)}{p(t_i)} = \frac{p(t_{-i}, t_i)}{\sum_{t_{-i} \in T_{-i}} p(t_{-i}, t_i)}.$$

When types are independent, then $\mu(t_{-i} | t_i)$ does not depend on t_i and $\mu(t_{-i} | t_i) = \mu(t_{-i} | t'_i)$ for all $t_i, t'_i \in T_i$.

A finite Bayesian game is denoted by $G(N, S, \pi, T, \mu)$ in which the number of players is finite and their strategy sets are also finite. In normal form games, S_i simply gives the set of actions available to player i , but in extensive form games, the elements of S_i specify what the player does at each information set. The strategy profiles of all players other than player i are given by $S_{-i} = \times_{j \neq i} S_j$. μ , which is common to all players, gives the set of probability distributions over T . The payoff of player i , $\pi_i : S \times T \rightarrow \mathbb{R}$, thus, the payoffs depend on the actions of all the players as well as the types. We shall denote by $\pi_i(s_i, s_{-i}; t_i, t_{-i})$ the payoff of a type t_i of player i from the pure strategy profile (s_i, s_{-i}) when the types of the other players are given by t_{-i} . Denote the vector of payoffs of all players by $\pi = (\pi_1, \pi_2, \dots, \pi_n)$.

A mixed strategy for player i , σ_i , specifies the probability with which each of the pure strategies in the set S_i is played by each of the possible types of the player in the set T_i . Thus, $\sigma_i : T_i \rightarrow \Sigma_i$ and $\sigma_i(s_i | t_i)$ is the probability with which type t_i of player i plays strategy s_i . The mixed strategy profile of all players other than player i is denoted by $\sigma_{-i} : T_{-i} \rightarrow \times_{j \neq i} \Delta S_j$, where ΔS_j denotes probability distributions over the set S_j . We denote the probability that some realization of the types of other players $t_{-i} \in T_{-i}$ play some pure strategy profile $s_{-i} \in S_{-i}$ by $\sigma_{-i}(s_{-i} | t_{-i})$.

¹¹ The common prior assumption is a strong one. Gintis (2009) argues that traditional game theory provides weak justification for this assumption. He proposes a correlating device, such as social norms, which may induce a set of common priors.

A *Bayesian Nash equilibrium* (BNE) of the game $G(N, S, \pi, T, \mu)$ specifies an optimal strategy for each type of each player conditional on the beliefs. The reason is that since players only know their own types but not the types of other players, each player needs to take into account the strategy of each of the possible types of the other players.

Definition A.8 (*Bayesian Nash equilibrium*): Consider the static Bayesian game $\{N, S, \pi, T, \mu\}$. The strategy vector (σ_i, σ_{-i}) is a Bayesian Nash equilibrium if for all $i \in N$, all types $t_i \in T_i$ and all actions s_i^* such that $\sigma_i(s_i^* | t_i) > 0$ we have

$$s_i^* \in \arg \max_{s_i \in S_i} \sum_{t_{-i} \in T_{-i}} \mu(t_{-i}, t_i) \sum_{s_{-i} \in S_{-i}} \sigma_{-i}(s_{-i} | t_{-i}) \pi_i(s_i, s_{-i}; t_i, t_{-i}). \quad (\text{A.13})$$

The Nash equilibrium is a special case of a BNE when each player has a single type that is public information, thus, the BNE imposes relatively more stringent rationality requirements. For instance, the evidence in Chapter 19 on judgment heuristics shows that players typically do not use Bayes' rule. This per se is not fatal to the concept of a BNE; one may replace μ by non-Bayesian beliefs in (A.13). However, there are other reasons why a BNE might not be able to explain the evidence. For instance, it is linear in beliefs, and does not have reference dependence and loss aversion. By contrast, the evidence reviewed in Part 1 on behavioral decision theory suggests that non-linear probability weighting, reference dependence, and loss aversion, are important features of human behavior.

A.7.2 Signaling games

We motivate signaling games by considering the game used in the experiments of Brandts and Holt (1992) in Figure A.4; for the experimental results on this game, see Chapter 12.

Signaling games are two-player games with a *sender* (Player 1) and a *receiver* (Player 2). The sender knows his own type but the receiver does not, hence, this is a game of incomplete information. The set of possible types of the sender is $T = \{t_1, t_2, \dots, t_n\}$. The receiver has prior beliefs about the types in T ; the prior probability of type $t_i \in T_i$ is given by $p(t_i)$. As in static games of incomplete information, we use the device of an external player, nature, who chooses the type of the sender and reveals it only to the sender. The sender can then send a set of signals $S_1 = \{s_1, s_2, \dots, s_m\}$. The receiver observes the signal (but not the type of the sender) and then chooses from a set of actions $S_2 = \{a_1, a_2, \dots, a_q\}$. Generic elements of S_1 and S_2 are denoted respectively by s and a .

Figure A.4 The signaling game in Brandts and Holt (1992).

Source: With permission from the American Economic Association.

In the signaling game in Figure A.4, the sender has two types $T = \{L, H\}$ and the initial move by nature is represented by the hollow circle in the middle of each figure. The initial beliefs of the receiver are that Type L is chosen with probability $1/3$ (game proceeds to the top of the figure) and type H with probability $2/3$ (game proceeds to the lower end of the figure). The sender can send two possible signals $S_1 = \{A, B\}$. The receiver can take two possible actions $S_2 = \{C, D\}$. Since the receiver does not know the type of the sender, having observed any signal, say, A, the receiver does not know if play has proceeded to the upper right hand node or the lower right hand node. This imperfect information is captured by the two information sets of the receiver that are connected by dotted lines. The payoffs are shown at the terminal nodes.

Signals and actions can be in pure or in mixed strategies. We denote by $\sigma_1(s, t)$ the mixed strategy of the sender. It is to be interpreted as the probability with which a sender of type t sends signal s . Each type is required to send at least one signal, so for all $t \in T$ we have $\sum_{s \in S_1} \sigma_1(s, t) = 1$. We denote by $\sigma_2(a, s)$ the mixed strategy of the receiver; it is the conditional probability with which the receiver plays action a after observing the signal, s . We assume that on observing any signal, receivers do take some action, i.e., for all $s \in S_1$ we have $\sum_{a \in S_2} \sigma_2(a, s) = 1$.

Payoffs accrue at the end of the game, at the terminal nodes, once the receiver has taken his action. The payoff of the sender is given by $\pi_1(t, s, a)$; it depends on his type, signal, and the action subsequently taken by the receiver. The payoff of the receiver is given by $\pi_2(t, s, a)$.

On receiving a signal, the receiver updates his prior beliefs about the possible types of the sender by using Bayes' rule to form the appropriate posterior. $\mu(t | s)$ is the posterior probability that an observed signal s originates from type t of the sender. In conformity with Bayes' rule, it is given by

$$\mu(t | s) = \frac{p(t)\sigma_1(s, t)}{\sum_{t' \in T} p(t')\sigma_1(s, t')}, \quad (\text{A.14})$$

where the numerator gives the probability that the signal s comes from type t and the denominator gives the a-priori probability that the signal is s .

Definition A.9 (“On the path of play” and “off the path of play”): A signal s is said to be along the path of play if the denominator in (A.14) is strictly positive, i.e., non-zero. Conversely if the denominator is zero then the signal s is off the path of play; such a signal is not sent by any of the types.

Since division by zero is undefined, we cannot use Bayes' rule to pin down posterior beliefs for off the path of play signals. In this case, any assignment of probabilities to off the path play can be made (this may not hold when we consider refinements of a perfect Bayesian equilibrium; see definition below).

Definition A.10 (Perfect Bayesian equilibrium (PBE) in signaling games): A perfect Bayesian equilibrium (PBE) in a signaling game is the triple $(\sigma_1, \sigma_2, \mu)$ that satisfies the following.

- (a) If any signal is played by the sender with strictly positive probability then it must be a maximizing choice for the sender. Thus, if $\sigma_1(s^*, t) > 0$ then

$$s^* = \arg \max_{s \in S_1} \sum \sigma_2(a, s) \pi_1(t, s, a). \quad (\text{A.15})$$

- (b) On receiving a signal s , if any action a is played with strictly positive probability by the receiver then it must maximize the receiver's expected utility. Thus, if $\sigma_2(a^*, s) > 0$ when signal s is observed, then

$$a^* = \arg \max \sum_{t \in T} \mu(t | s) \pi_2(t, s, a). \quad (\text{A.16})$$

- (c) The posterior beliefs in (A.16) are constructed by using Bayes' rule as given in (A.14) for signals that are "on the path of play."
 (d) For signals that are "off the path of play," some beliefs must be assigned such that (A.16) holds.

From (A.15), (A.16), the reader can immediately see that sequential rationality is built into the definition of an equilibrium. The sender plays optimally given the subsequent equilibrium action of the receiver and the receiver plays optimally given the equilibrium signal sent by the sender. Furthermore, in computing the optimal action, the receiver uses Bayes' rule along the path of play—thus, actions and beliefs must be mutually consistent. However, and as noted earlier, the equilibrium may impose beliefs on signals that are off the path of play, which may not be reasonable; this leads to a refinement of the equilibrium that we consider below. The rationality requirements in a PBE of a signaling game are even higher than those of a BNE and these mainly come about from an imposition of sequential rationality that was missing in a BNE.

Three kinds of equilibria are of typical interest in signaling games. In a *separating equilibrium*, all types of the sender send distinct signals, hence, immediately revealing their types to the receiver. The receiver then assigns a posterior probability of 1 to the corresponding type of a sender after observing a particular signal, which is consistent with Bayes' rule. In a *pooling equilibrium*, all types of the sender send identical signals, hence, as required by the Bayes' rule, the posterior beliefs of the receiver are identical to the prior beliefs. In a *hybrid equilibrium*, the situation is intermediate between a separating and a pooling equilibrium. For instance, one of the types may choose to separate (in strategy), while the other plays a mixed strategy—choosing to separate with some probability and to pool with the complementary probability. The posterior beliefs of the receiver then reflect this probability mixture appropriately.

A drawback of the PBE concept in Definition A.10(d) is that it does not require out of equilibrium beliefs to be reasonable enough. One natural restriction is suggested by Cho and Kreps (1987). Suppose that for some type of the sender $t \in T$ there is a signal s that strictly dominates another signal s' in the following sense

$$\min_{a \in S_2} \pi_1(t, s, a) > \max_{a \in S_2} \pi_1(t, s', a), \quad (\text{A.17})$$

i.e., the maximum payoff that the sender gets from sending the signal s' (irrespective of the actions of the receiver) is lower than the minimum payoff from signal s . The *simple dominance* criteria then requires that on observing the signal s' , even if it is out of equilibrium, the receiver should assign probability zero that it was sent by a sender of type t .

A second refinement, due to Cho and Kreps (1987), is *equilibrium dominance*. Suppose that the equilibrium signal of a type t sender is s^* and the equilibrium action of the receiver is a^* . Then signal s' is *equilibrium dominated* for the type t sender if

$$\pi_1(t, s^*, a^*) > \max_{a \in S_2} \pi_1(t, s', a). \quad (\text{A.18})$$

Equilibrium dominance in (A.18) provides an important restriction on out of equilibrium beliefs, which we state next.

Definition A.11 (*Intuitive criterion; Cho and Kreps, 1987*): Suppose that the signal s' is off the equilibrium path (as defined above). In any equilibrium, if (A.18) holds then the receiver should assign a posterior probability of zero that the sender of type t will send the signal s' . This is known as the intuitive criterion or the equilibrium dominance criterion.

We do not pursue further refinements of games with incomplete information, partly because the empirical support for such refinements is quite weak; see Chapter 12 on behavioral game theory.

Let us now apply these ideas to determine the equilibrium outcomes in the signaling game in Figure A.4. The game has only two equilibria and these are both pooling equilibria (we leave it as an exercise to the reader to show that there are no separating equilibria). The equilibrium responses are shown by the bold lines in Figure A.4. (1) In the left panel, in equilibrium, both types of senders play B. The receiver responds to B by playing C and to the non-equilibrium signal A by playing D. (2) In the right panel, both types of senders send the signal A and the receiver plays C in response to the equilibrium signal A and D in response to the non-equilibrium signal B.

In each pooling equilibrium, the posterior beliefs of the receiver are identical to prior beliefs. Bayes' rule permits us to place any restrictions on the out of equilibrium beliefs. One set of out of equilibrium beliefs that can support these two pooling equilibria (see Definition A.10(d)) is the following. Whenever the receiver observes an out of equilibrium signal by the sender, it is assumed that the sender is of type L. The reader can check that the stated equilibrium actions and beliefs constitute a PBE of the signaling game (check all components of Definition A.10).

To see if these equilibria are reasonable, consider the pooling equilibrium in the right panel. The out of equilibrium beliefs require that if the receiver observes signal B, he should assume that it is sent by a type L sender. We can use the Cho–Kreps (1987) *equilibrium dominance* criteria, described above, to rule out this pooling equilibrium. In the right panel, type H of the sender gets an equilibrium payoff of 120, while type L gets an equilibrium payoff of 140. If instead, type L decided to send an out of equilibrium signal, B, then the highest payoff that he could get is always lower than 140. Hence, type L will never want to send an out of equilibrium signal. However, the out of equilibrium signal is not equilibrium dominated for type H because type H can get a maximum of $140 > 120$. Thus, the out of equilibrium beliefs of player 2 are not intuitive or reasonable. Player 2 should have beliefs such that an out of equilibrium signal of B could only come from type H. In that case, the optimal response of the receiver to signal B is to play C. But then B rather than A is optimal for type H, breaking down the pooling equilibrium in which both types of senders send signal A. This is the reason why the right panel is labeled as the unintuitive equilibrium. There is no problem with the pooling equilibrium in the LHS panel. It survives equilibrium dominance (the reader should check this¹²).

In signaling games, a signal s is dominated for type t of a player, if there is another signal s' , such that the lowest possible payoff of type t from the signal s' is greater than the highest possible payoff from signal s ; we may term this as *simple dominance*. Equilibrium dominance is stronger than *simple dominance*. The concept of simple dominance cannot be used to eliminate the *unintuitive equilibrium* in the right panel of Figure A.4. This is because, for type L, neither of the two actions A or B dominates the other in the sense of (A.17). Refinements of PBE that are stronger than equilibrium dominance such as *divinity* and *strategic stability* can also be used to rule out the unintuitive equilibrium on the RHS. Hence, experimental tests that show subjects do not play the equilibrium in the right panel are also consistent with these other refinements.

¹² The reader should also check that there are no separating equilibria.

A.8 Correlated equilibrium

Consider an n -player *strategic form* game, $G(N, S, u)$, where probability distributions over S_i are denoted by Σ_i , given in (A.1), and probability distributions over S are denoted by Σ . Choose a particular member of Σ , say, q . Then for any $s \in S$, $q(s)$ is the probability of the strategy profile s , which implies $\sum_{s \in S} q(s) = 1$.

Definition A.12 (*Correlated equilibrium; Aumann, 1974*): A probability distribution $q \in \Sigma$ is a *correlated equilibrium* if $\forall i$ and $\forall s_i \in S_i$, with $q(s_i) > 0$:

$$\sum_{s_{-i} \in S_{-i}} q(s_{-i} | s_i) \pi_i(s'_i, s_{-i}) \leq \sum_{s_{-i} \in S_{-i}} q(s_{-i} | s_i) \pi_i(s_i, s_{-i}), \text{ for all } s'_i \in S_i.$$

Definition A.12 can be motivated as follows.

1. Suppose that all players know that an element $s \in S$ will be drawn using the probability distribution q .
2. Once $s = (s_1, \dots, s_n)$ is drawn, then player $i \in N$ is told of his pure strategy, $s_i \in S_i$, but not about the remaining strategy profile, $s_{-i} \in S_{-i}$.
3. q is a correlated equilibrium if all players $i \in N$ wish to follow their recommended strategy s_i and not change to some other $s'_i \in S_i$, when they know that the strategies are drawn with respect to the underlying distribution, q .

We now define the more general notion of *coarse correlated equilibrium*. To understand the intuition, let us now change the three steps above as follows:

1. Suppose that all players know that an element $s \in S$ will be drawn using the probability distribution q .
2. Any player $i \in N$ can opt out at this stage and play any $s'_i \in S_i$.
3. Suppose that the set of players who do not wish to opt out is $N' \subseteq N$. A strategy profile $s = (s_1, \dots, s_n)$ is drawn according to q . All players in N' are now committed to playing their part in the profile s (so player $i \in N'$ must play $s_i \in S_i$).
4. q is a coarse correlated equilibrium if no players prefer to opt out in stage 2, i.e., $N' = N$.

Definition A.13 (*Coarse correlated equilibrium; Moulin and Vial, 1978*): A probability distribution $q \in \Sigma$ is a *coarse correlated equilibrium* if $\forall i$ and $\forall s'_i \in S_i$,

$$\sum_{s_{-i} \in S_{-i}} q_{-i}(s_{-i}) \pi_i(s'_i, s_{-i}) \leq \sum_{s \in S} q(s) \pi_i(s). \quad (\text{A.19})$$

The LHS of (A.19) is the expected payoff of player i if he opts out in stage 2 and the RHS is his payoff if he chooses to opt in. If q is a correlated equilibrium then it is also a coarse correlated equilibrium. In the special case of a product distribution, i.e., when $q(s) = \prod_{i=1}^n q_i(s_i)$, the following three concepts coincide: correlated equilibrium, coarse correlated equilibrium, and Nash equilibrium.

SUBJECT INDEX

- Abreu–Matsushima mechanism 714, 734, 735–7
- absolute magnitude effect, exponential discounted utility model 598
- acquisition utility 1454–5, 1474, 1476–7
- action-sample learning 1136, 1137, 1138
- adaptive learning 827, 1094
- addiction
 - animal experiments 1649
 - cue-conditioned behavior 1236, 1237, 1240, 1241–2
 - present-biased preferences 646, 647
 - projection bias 1257
 - visceral influences 1230
- additive discount functions 634–5
- advertising 1401, 1402, 1423
- affect heuristic 45–6, 1344, 1366, 1367–9
 - experts 1449
 - neuroeconomics 1665
 - stake size effect 178
- ffective response of experts 56
- age factors
 - educational incentives 560
 - investor skills 1501
 - lying 461
 - neuroeconomics of time preferences 1689
 - overconfidence 1528
 - patience 664
- agent-based computational economics (ACE) 25, 872–3
- aggregate monotonicity condition, evolutionary game theory 1091
- agrarian contracts, social networks applied to 1184–5
- all causes model 14–15
- Allais paradox 18, 26, 95–7
 - as common consequence violation 98
 - dual selves model with costly commitment 1303
 - hyperbolic discounting 627
 - probability weighting functions 116
 - prospect theory 28
 - rank dependent utility theory 124, 129
 - regret theory 182
 - salience and context in decision theory 185, 186
- allocative efficiency, competitive equilibrium experiments 871, 872, 874
- α -maximin expected utility (α -MEU) model 293, 298, 299, 309
- alternating offers bargaining game 801
- altruism 341–2, 343, 398–9
 - axiomatic foundations 450, 451
 - centipede games 733
 - dictator game 352, 353, 354, 356
 - evolution 385
 - evolutionary game theory 1039–40, 1073–84
 - cultural evolution, formal model of 1068–73
 - gene-culture coevolution 1066–7
 - fairness and stochastic dominance 414–15
 - Fehr–Schmidt model 417
 - genuine 345, 354
 - incentives 531, 533–40, 552–3, 554, 555
 - interdependent preferences models 447–9
 - neuroeconomics 1647, 1677–8, 1683
 - parochial 1233, 1647, 1677–8
 - public goods games 377
 - reciprocal 342, 1039–40, 1076–8
 - reluctant 345, 353, 354
 - social identity 469, 471
 - trust game 368
 - white lies 455, 461
- ambiguity 79, 284–6
- aversion 293, 298
 - empirical evidence 298–301
 - support theory 304

 - group size, gradual growth in 778–9
- weak WARP axiom 1623
- wealth factors, and patience 664
- weighted fictitious play 1111–13, 1127–8
- weighting function for uncertainty 305
- welfare
 - behavioral welfare economics 1577–83
 - comparison 1298
 - evolutionary stable strategies 1046
 - fairness and general equilibrium 400–1, 426–31
 - improvement 1615

- welfare (*cont.*)
 - payments, long-term dependence on 689
 - present-biased preferences 675
 - social identity 473
- well-being
 - externalities 429–30
 - see also* happiness economics
- Westermarck effect 1067
- white lies
 - altruistic 455, 461
 - evidence on 455
 - Pareto 455, 461
- white matter 1651
- willingness to accept (WTA) 81, 217
 - defined 220
 - mental accounting 1472–3
 - neuroeconomics 1665
 - risky (RWTA) 222, 223, 224
 - third generation prospect theory 153
 - and willingness to pay, discrepancy between 213
 - see also* endowment effect; exchange asymmetries
- willingness to pay (WTP) 81, 217
 - defined 220
 - neuroeconomics 1665, 1666
 - risky (RWTP) 223, 224
 - third generation prospect theory 153
 - and willingness to accept, discrepancy between 213
 - see also* endowment effect; exchange asymmetries
- willpower
 - asymmetric information about 1308
 - confidence, motivation, and self-esteem 1311
 - dual selves model with costly commitment 1299, 1300, 1302, 1303
 - limited attention 1437
 - and personal rules 1321
 - two-modules view of the brain 1291, 1293–4, 1295, 1296, 1297, 1298
 - ultimatum game 355
- win–stay, lose–shift strategy, evolutionary game theory 1077
- windfalls, and mental accounting 1460, 1461, 1463
- winner's curse 881, 991–2
 - cursed equilibrium 995–7, 1000–1
 - empirical evidence 993–5
 - level-*k* explanation 998–1002
 - managers 1528
- wishful thinking 988
- Yerkes–Dodson law 543
