Fixed effects estimation

Overview:

- When there is an observed fixed effect, an alternative to first differences is fixed effects estimation
- The average of a_i across t will be a_i , so if you subtract the mean, a_i will be differenced out just as when doing first differences
- This method is also identical to including a separate intercept for every individual (dummy var.)
- First Differences and Fixed Effects will be exactly the same when $T = 2$

Pooled data vs. Fixed effects

Fixed effects vs. dummy variable regression (LSDV)

- FE is equivalent to adding dummy variables for each cross-sectional observations >> get intercept for each $i = a_i$
- View the a_i as omitted variables (as dummy variables) that we control for
- If the intercept is reported in FE, it is interpreted as the average across i of the estimated a_i (the average of the individual-specific intercepts)
- But, we have $N + k$ parameters to estimate with only N observations >> not practical
- We can allow for 'time effect': Two-way FE model

Fixed effects estimation

- Consider a model with k explanatory variables:

$$y_{it} = \beta_1 x_{1it} + \dots + \beta_k x_{kit} + a_i + u_{it}, \quad t = 1, 2, \dots, T \quad (1)$$

- For each i , average the equation over time to get

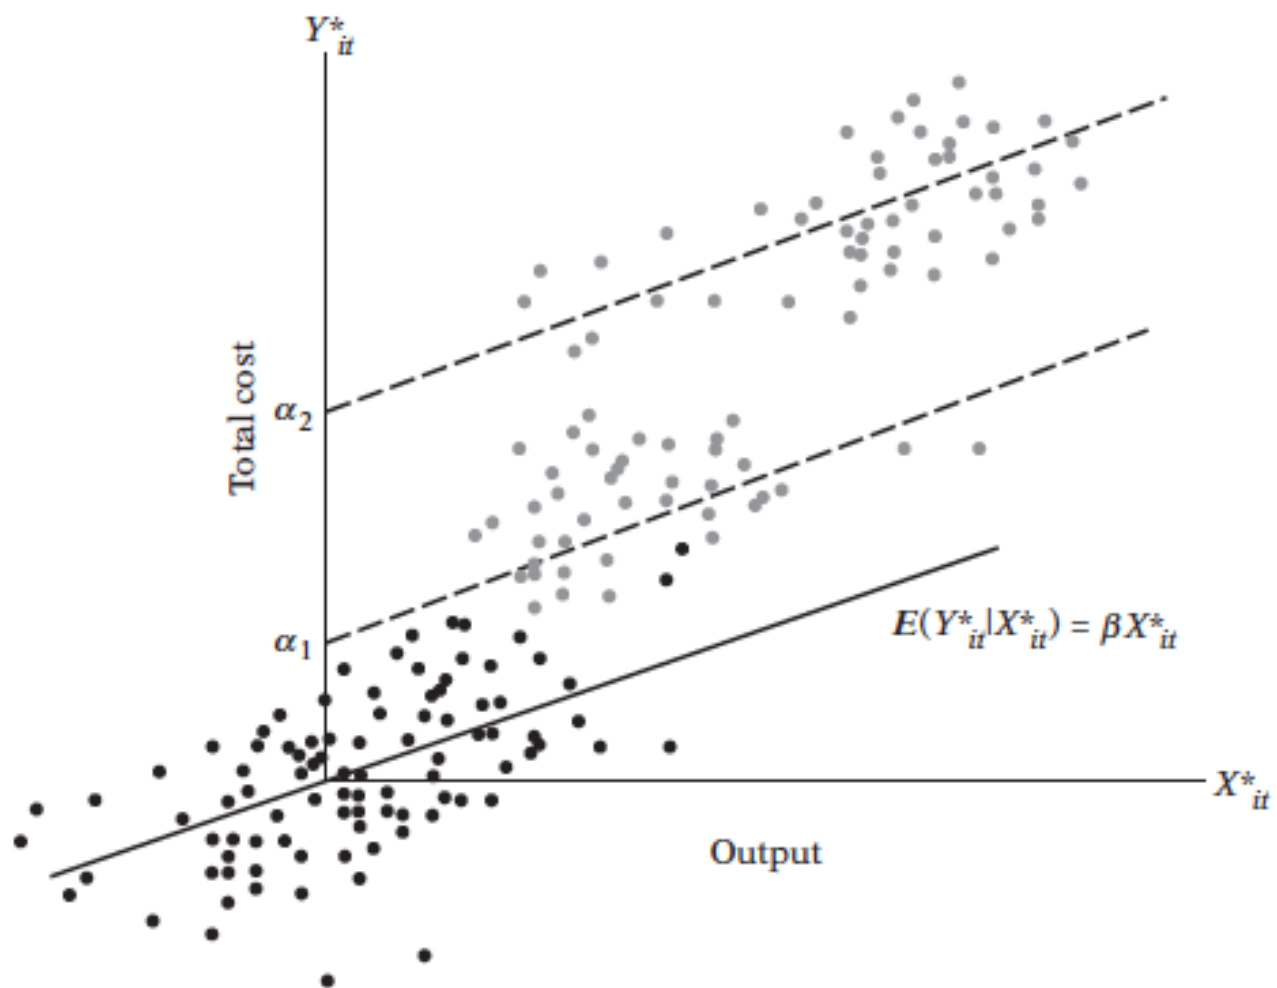

$$\bar{y}_i = \beta_1 \bar{x}_{1i} + \dots + \beta_k \bar{x}_{ki} + a_i + \bar{u}_i \quad (2)$$

- Subtract (2) from (1), for each t , we have

$$y_{it} - \bar{y}_i = \beta_1 (x_{1it} - \bar{x}_{1i}) + \dots + \beta_k (x_{kit} - \bar{x}_{ki}) + u_{it} - \bar{u}_i, \quad t = 1, 2, \dots, T$$

$$\ddot{y}_{it} = \beta_1 \ddot{x}_{1it} + \dots + \beta_k \ddot{x}_{kit} + \ddot{u}_{it}, \quad t = 1, 2, \dots, T \quad (3)$$

- $\ddot{y}_{it} = y_{it} - \bar{y}_i$ is time-demeaned data on y
- Fixed effects estimator or within estimator: pooled OLS estimator based on the time-demeaned variables

Fixed effects estimation

- Between estimator: apply OLS estimator on the cross-sectional data equation (2) with an intercept
 - It is biased when α_i is correlated with $\bar{x}_i$
 - If we think α_i is uncorrelated with x_{it} , it is better to use the random effects estimator
 - It ignores information on how the variables change over time
- Under strict exogeneity assumption (u_{it} is uncorrelated with each x_{jit} across all time periods), FE estimator is unbiased.
 - this rules out feedback from past u_{is} shock to current x_{it} , or we cannot have lagged dependent variables on RHS
- We also need u_{it} to be homoskedastic and serially uncorrelated (across t).

Fixed effects estimation

- Degree of freedom: for each cross-sectional observation i , we lose one df because of the time-demeaning.
 - Use $df = NT - N - k = N(T-1) - k$ when correcting s.e. and test
- R^2 (within transformation) from (3) is interpreted as the amount of time variation in the y_{it} that is explained by the time variation in the explanatory variables.
- We cannot include time-constant variables
 - but they can be interacted with time-varying variables, e.g., time dummy variables >> how each year differs from the base period
- We cannot estimate the effect of any variable whose change across time is constant, e.g., years of experience

Assumptions for Fixed Effects

- FE.1: For each i , the model is

$$y_{it} = \beta_1 x_{1it} + \dots + \beta_k x_{kit} + a_i + u_{it}, \quad t = 1, \dots, T$$

- FE.2: A random sample from the cross section
- FE.3: Each explanatory variable changes over time (for at least some i), and no perfect linear relationships exist among the explanatory variables
- FE.4: For each t , the expected value of the idiosyncratic error given the explanatory variables in all time periods and the unobserved effect is zero: $E(u_{it} | \mathbf{X}_i, a_i) = 0$, $\mathbf{X}_i$ contains x_{jit} , $t = 1, \dots, T$; $j = 1, \dots, k$
 - x_{jit} are strictly exogenous conditional on the unobserved effect.
 - FE estimator is also consistent with a fixed T and as $N \rightarrow \infty$

Assumptions for Fixed Effects

- FE.5: The variance of the errors, conditional on all explanatory variables, is constant (homoskedasticity)

$$\text{Var}(u_{it} | \mathbf{X}_i, a_i) = \text{Var}(u_{it}) = \sigma_u^2, \text{ for all } t = 2, \dots, T$$

- FE.6: For all $t \neq s$, the idiosyncratic errors are uncorrelated (serially uncorrelated)

$$\text{Cov}(u_{it}, u_{is} | \mathbf{X}_i, a_i) = 0, t \neq s$$

- FE.1-6: FE estimator β_j is the best linear unbiased estimator (conditional on the explanatory variables).
- FE.7: Conditional on $\mathbf{X}_i$ and a_i , $u_{it} \sim \text{Niid}(0, \sigma_u^2)$
 - FE estimator is normally distributed, and t and F stats have exact t and F distributions

Fixed effects (FE) vs. First Differences (FD)

- When $T = 2$, FE and FD are equivalent.
- Both FD and FE are unbiased (consistent) under FD.1-4 and FE.1-4, respectively. Look at the relative efficiency of the estimators.
- If u_{it} is a random walk ($u_{it} = u_{i,t-1} + \varepsilon_{it}$), then Δu_{it} is serially uncorrelated. FD will be more efficient than FE.
- Under 'classical assumptions': $u_{it} \sim iid(0, \sigma_u^2)$, FE will be more efficient.
- If $cov(u_{it}, \mathbf{X}_i) = 0$ but the strict exogeneity is violated (there is a lagged dependent variable), then FE likely has less bias than FD.

Random effects models

- Let the unobserved effects model is

$$y_{it} = \beta_0 + \beta_1 x_{1it} + \dots + \beta_k x_{kit} + a_i + u_{it} \quad (4)$$

- where an intercept is included so that we can make the assumption that $E(a_i) = 0$
- Here, we think a_i is uncorrelated with each x_j in all time period: $\text{Cov}(x_{jit}, a_i) = 0, t = 1, \dots, T; j = 1, \dots, k$
- Why don't just use a single cross section when β_j can be consistently estimated?
- Suppose we define the composite error as $v_{it} = a_i + u_{it}$.

$$y_{it} = \beta_0 + \beta_1 x_{1it} + \dots + \beta_k x_{kit} + v_{it} \quad (5)$$

- Because a_i is in the composite error in each time period, v_{it} are serially correlated across time.

Random effects models

- Under the random effects assumption, $t \neq s$

$$\text{corr}(v_{it}, v_{is}) = \frac{\sigma_a^2}{\sigma_a^2 + \sigma_u^2}$$

- The pooled OLS standard errors ignore this correlation. They will be incorrect, so as the test statistics.
- We can use GLS to solve the serial correlation problem.
 - need large N and relatively small T
- Random Effects (RE) estimator is a GLS estimator that take the above correlation into account.

Random effects models

- Define $\lambda = 1 - \left(\frac{\sigma_a^2}{T\sigma_a^2 + \sigma_u^2} \right)^{1/2}$
- Multiply λ by the individual average of the original equation and subtract from the original equation:

$$y_{it} - \lambda \bar{y}_i = \beta_0(1 - \lambda) + \beta_1(x_{1it} - \lambda \bar{x}_{1i}) + \dots + \beta_k(x_{kit} - \lambda \bar{x}_{ki}) + (v_{it} - \lambda \bar{v}_i) \quad (6)$$
- Then, using OLS on this transformed equation gives the random effects GLS estimator
- Now, $v_{it} - \lambda \bar{v}_i$ is serially uncorrelated.
- Since λ is unknown, we need to estimate it from estimated σ_a^2 and σ_u^2 :
 - Use pooled OLS to obtain estimates of the composite residual $\hat{v}_{it}$. Calculate σ_a^2 as $\text{cov}(\hat{v}_{it}, \hat{v}_{i,t-1})$, and $\hat{\sigma}_u^2 = \hat{\sigma}_v^2 - \hat{\sigma}_a^2$

Random effects models

- The transformation in eq.(6) allows for explanatory variables that are constant over time.
- Relationship between RE, pooled OLS and FE from eq.(6):
 - Pooled OLS: $\lambda = 0$ (or $\hat{\lambda}$ close to zero), when the unobserved effect, a_i , is relatively unimportant because it has small variance relative to σ_u^2
 - FE: $\lambda = 1$ (or $\hat{\lambda}$ close to unity), when σ_a^2 is large relative to σ_u^2
- Rewrite $v_{it} - \lambda \bar{v}_i$ as $(1 - \lambda)a_i + u_{it} - \lambda \bar{u}_i$. We can see that the errors in the transformed equation in RE weight the unobserved effect by $(1 - \lambda)$.

Assumptions for Random Effects

- FE.1 & FE.2
- RE.3: No perfect linear relationships exist among the explanatory variables
- RE.4: In addition to FE.4, the expected value of a_i given all explanatory variables is constant, $E(a_i | \mathbf{X}_i) = \beta_0$
 - to rule out correlation between the unobserved effect and the explanatory variables.
- RE.5: In addition to FE.5, the variance of a_i given all explanatory variables is constant, $\text{Var}(a_i | \mathbf{X}_i) = \sigma_a^2$
- FE.6: Serially uncorrelated
- Under these assumptions, RE estimators are asymptotically efficient: in large samples, RE will have smaller s.e. than pooled OLS; more efficient than FE for coefficients on time-varying explanatory variables

Random effects or Fixed effects?

- The FE estimator is always consistent, but inefficient under the null hypothesis that $\text{Cov}(x_{it}, a_i) = 0$. RE is both consistent and relatively efficient under that null hypothesis, but inconsistent under the alternative.
- Hausman test: the preferred model is random effects vs. the alternative the fixed effects

$$H = (\hat{\beta}^{FE} - \hat{\beta}^{RE})' [\text{var}(\hat{\beta}^{FE}) - \text{var}(\hat{\beta}^{RE})]^{-1} (\hat{\beta}^{FE} - \hat{\beta}^{RE}) \sim \chi_M^2$$

Comparing all models

FD	FE	RE	Pooled OLS
$\text{Cov}(x_{it}, a_i) \neq 0$	$\text{Cov}(x_{it}, a_i) \neq 0$	$\text{Cov}(x_{it}, a_i) = 0$	$\text{Cov}(x_{it}, a_i) = 0$
Time-invariant vars: drop	drop	allow	allow
Efficient estimators <u>FD vs. FE:</u> when u_{it} is a random walk	$u_{it} \sim iid(0, \sigma_u^2)$		
	<u>FE vs. RE:</u> Hausman test reject H_0	cannot reject H_0	
		<u>RE vs. Pooled OLS:</u> Breusch-Pagan test reject H_0	cannot reject H_0

Testing for the presence of an unobserved effect: The Breusch-Pagan test

- If the regressors are strictly exogenous and u_{it} is non-autocorrelated and homoskedastic, then both pooled OLS and RE will both be efficient if no unobserved effects ($\sigma^2_a=0$). If $\sigma^2_a > 0$, then RE is efficient.
- Lagrange multiplier test $\gg H_0: \sigma^2_a = 0$

$$LM = \frac{NT}{2(T-1)} \left[\frac{\sum_i \left(\sum_t \hat{v}_{it} \right)^2}{\sum_i \sum_t \hat{v}_{it}^2} - 1 \right]^2 \sim \chi_1^2$$

where $\hat{v}_{it}$ is the estimated pooled OLS residual

- `xttest0`: if failed to reject the null = no significance across units (no panel effect)

Applying Panel Data Methods to Other Data Structures

- FD, FE, and RE can be applied to data structures that do not involve time, e.g., demography, to control for unobserved family and background characteristics (family fixed effects)
- Cluster sample: cross-sectional data set, but each observation belongs to a well-defined cluster, e.g. each family is a cluster.
- Outcomes within a cluster are likely to be correlated, allowing for an unobserved cluster effect – use FE
- If the cluster effect is uncorrelated with all Xs – use RE
- If using pooled OLS and there is correlation within clusters, correct for s.e. – STATA option for `vce cluster()`
